protection for times greater than 4 microseconds. By his comparison, the rod gap will flash over at a lower voltage for times greater than 4 microseconds. This, of course, means more unnecessary outages and it is not quite clear why the protection should be any better as long as the gap will flash over in any event before the voltage rises to a dangerous level. We consider an ideal protective curve one that parallels that which it is to protect. Relative to the statement that more data are needed at times less than one microsecond, we wish to point out that the curves published are intended for operating data, so that the gap may be adjusted to define a minimum flashover level. The high overvoltages are not plotted in these curves because we do not rely on indirect comparison where small deviations due to personal analysis result in uncertainty regarding the actual performance. We have cases on record, and have observed in other data, where identically the same time for flashover of a gap was recorded by a cathode ray oscillograph at voltages differing by 100 per cent in the short-time range. A graph of such data is a matter of personal judgment and it is difficult to plot a line to represent such phenomena as accurate performance. Too frequently conclusions are drawn by making indirect comparisons and stressing exactness where precision is not justified. We believe the ultimate criterion of protection is to be found by a comparison where it is possible to determine relative performance directly. Therefore, we do not attempt to show that we differ by some questionable margin from other data through the medium of comparing curves which should preferably be shown as a band.

That the parallel test method adequately illustrates the advantage of the control gap is illustrated in figure 8. This figure, with the control-gap equivalent added, is reproduced from the August 1934, *G. E. Review*, "Lightning Protection of Power Transformers Connected to Overhead Circuits," by K. B. McEachron. This curve, particularly at minimum flashover and at the high overvoltages, is substantiated by Mr. F. J. Vogel ("Adequate Impulse Tests," *Electric Journal*, January 1935). From this curve, according to Mr. McEachron, a transformer is adequately protected at the high overvoltages by a rod gap spaced 55 per cent of the spacing which would protect the transformer at minimum flashover (100 per cent). The dashed curve superimposed on this figure illustrates that the control gap is approximately 10 per cent better throughout its entire range than Messrs. McEachron and Vogel show is necessary to protect power transformers. Although Mr. McEachron's curve applies only to positive polarity, Mr. Vogel illustrates that on negative polarity the same general percentages obtain, particularly at the minimum flashover and at the high overvoltages.

The question relative to spheres having a "flat" volt-time characteristic is answered by inspection of our figure 9 *E*. This applies to any type of test and particularly to front of wave testing. Such characteristics are shown to have a rising voltage curve in the short time range. Frequently, the curve is plotted as a straight horizontal line from minimum flashover at about 2 microseconds to infinity. It is not possible to obtain long time lags in sphere gap flashovers. Some curves lead us to believe that at the minimum flashover, any time is obtainable. Actually there is no test point obtainable in the "flat" region. The curve ceases to exist once it becomes flat. Long time lags are associated with corona formation and for sphere-gap curves to be plotted illustrating that long times to flashover are obtainable under any condition (with spacing within their normal operating range) is a misnomer.

We concur that it is not easy to maintain electrical stability in multigaps under all weather conditions. In the control gap, this has been accomplished by using insulators having a capacitance approaching the range of coupling condensers, which are known to give satisfactory performance. By his question of unbalance due to melting ice, Mr. McEachron is undoubtedly concerned only with operating characteristics since we are not normally concerned with lightning storms in freezing weather.

We appreciate Mr. McEachron suggesting an explanation of variations in time to flashover at minimum voltage. This further justifies our contention that such characteristics should be plotted as a band rather than a line. The oscillograms illustrated were chosen at random during the tests and are not at all unusual. Inspection of our figure 9 *A* and *B* illustrates that while the oscillograms show times of the order mentioned, the adjacent volt-time curves show that minimum flashover is reached in about 16 microseconds. At minimum, the range in time to flashover for gaps which are dependent upon corona formation is more than 100 per cent. Successive flashovers showing 10 to 25 microseconds for gaps of the order shown are common, without a measurable difference in voltage. This band becomes narrow rapidly with increasing overvoltages, but is still measurable on front-of-wave tests. The inadequacy of drawing conclusions by representing such a characteristic as a line is apparent.

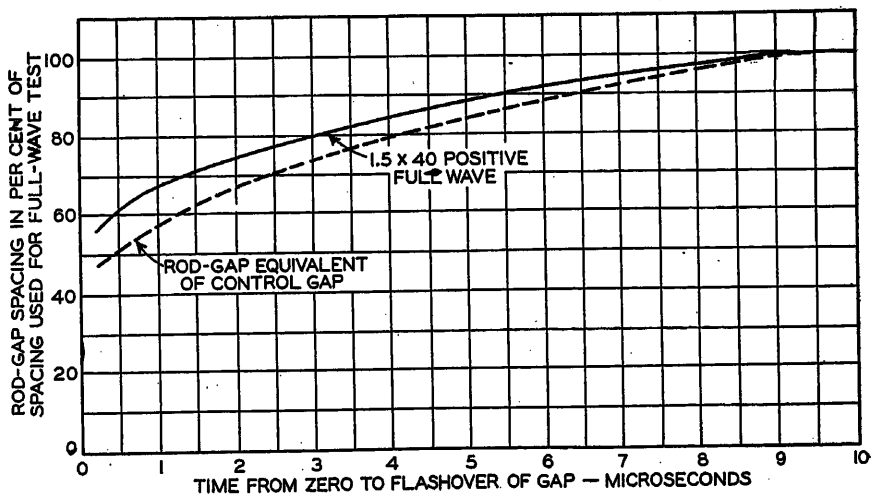

**Figure 8. Rod-gap spacings to give a constant factor of safety in power transformers (based on approximate major insulation strength) from "Lightning Protection of Power Transformers Connected to Overhead Circuits," by K. B. McEachron, "General Electric Review," August 1934**

The previous discussion has undoubtedly answered Mr. McEachron's question regarding the use of the control gap as back-up protection, since the control gap characteristic closely parallels that of insulation. A higher insulation level could be accompanied by a corresponding control-gap spacing. Where the control gap is used in conjunction with arresters, it is expected that the arrester will perform first and relieve part of the surge. The control gap should flash over only when potentials beyond the scope of the arresters are reached and therefore a somewhat closer margin might be adopted.

Mr. Montsinger points out that sphere gaps have a time lag when flashover is of the order of one microsecond or less. Mr. Montsinger has shown (*Electrical World*, November 21, 1936) that his approximate equivalent of transformer insulation has a time lag when flashover is of the order of 3 microseconds or less. He therefore shows that a sphere-gap characteristic is considerably faster than that of major insulation. The control gap has a characteristic very similar to that which Mr. Montsinger has shown to represent such insulation. His illustration of a sphere-gap curve merging with insulation at high overvoltages is of interest, since this characteristic is contrary to the general trend of flashovers. We are also interested in Mr. Montsinger's statement concerning a no-time-lag gap.

Such a characteristic is undoubtedly possible in a multigap so unbalanced that successive rather than simultaneous flashovers determine the minimum breakdown. We think his suggestion that a sphere gap be used for transformer testing is excellent, although its characteristic, as he shows, is faster than transformer insulation. The sphere gap lends itself readily to laboratory tests, is easily adjustible, and complete calibrations are available, but it is not suitable for protection in service. The control gap on the other hand is not as desirable for laboratory testing but lends itself readily to station protection.

## Of Institute and Related Activities

# Milwaukee, Wis., Is Host to 53d Annual Summer Convention

IN 1906 the Institute held its 23d annual summer convention in Milwaukee, Wis. Just 31 years and 3 weeks later, Milwaukee again played host to the Institute, this time for its 53d annual summer convention (none was held in 1917). Several unusual features marked the program of the 1937 convention held June 21–25, with headquarters at the Schroeder Hotel.

All these features are covered in this issue of ELECTRICAL ENGINEERING, which brings to all members of the Institute not only a comprehensive news digest covering the high lights of the convention activities outlined in programs previously published, but also the full text of the 2 principal special addresses delivered by men prominent in the engineering profession, and several other special presentations of interest and value to the membership at large.

### Annual Business Meeting

With some 250 or more persons in attendance, and with K. L. Hansen, general chairman of the 1937 summer convention committee, presiding, the opening session convened Monday morning, June 21, in the Crystal Ball Room of the Schroeder Hotel. Chairman Hansen outlined briefly the several unusual features on the program and then introduced as honorary chairman and "an outstanding Milwaukee personality . . . for many years associated with electrical developments on a large scale," General Otto H. Falk. General Falk in his brief but generous message of warm welcome mentioned the fact that the last AIEE summer convention held in Milwaukee was in 1906.

On behalf of the summer convention committee Chairman Hansen paid special tribute to General Falk and to "Milwaukee industries that have contributed so generously to make this convention a success . . . contributed by permitting their men to use their time for convention purposes, financial contributions, hospitality, inspection trips, and in other ways." At this point the gavel was turned over to President MacCutcheon who presided for the annual business meeting.

#### REPORTS OF THE BOARD OF DIRECTORS AND THE COMMITTEE OF TELLERS

On behalf of the Institute, President MacCutcheon responded to General Falk's message of welcome. The president's address, "The Engineer of Tomorrow," is reproduced in this issue (pages 941–3).

The customary digest of the annual report of the board of directors for the fiscal year ending April 30, 1937, was presented by National Secretary H. H. Henline. Mr. Henline pointed out that the report, published in full in the July issue of ELECTRICAL ENGINEERING, is made up of a large number of brief reports covering all major phases of Institute activities, and many activities in which the Institute co-operates jointly with other organizations. In this report is a wealth of information of interest and value to every Institute member. One of the features of the year's activity has been the prodigious amount of time, effort, and energy spent by President A. M. MacCutcheon in visiting some 46 Institute Sections and 20 educational institutions and

**President A. M. MacCutcheon (left) exchanging greetings with General Otto H. Falk, honorary chairman of the general summer convention committee**

Student Branches in 29 states, the District of Columbia, and Canada; in attending the 2 national conventions and 2 District meetings, and several District student conferences held during the year; and in effectively stimulating the activities of many Institute committees.

Concerning general activities Mr. Henline reported that the 2 national conventions and 2 District meetings held during the year were well attended. He stated also that during the year new records had been set in Section activities, with a total of 621 meetings reported including numerous group meetings for special discussions, and in Student Branch activities, with 1,363 Branch meetings reported. With the organization of Student Branches at Columbia University, New York, and at Tulane University, New Orleans, La., there are now 119 Branches functioning.

Further with reference to Section activities, Secretary Henline reported that the organization of the East Tennessee Section brought the total number of Sections now functioning up to 62, with the formation of several others in prospect. During the past year a total of 23 Sections sponsored special activities, 20 holding meetings of special types in addition to their regular meetings, and 3 others conducting educational courses. The survey and reallocation of Section territory was reported as having been completed by the special committee that has been working on it since 1935, and approved by the board of directors to become effective as of August 1, 1937. In general principle, the plan so modifies and enlarges the territory assigned to Sections as to place within Section territory all members residing in continental United States with the exception of approximately 300 residing in scattered and sparsely settled areas neither contiguous nor tributary to Section territory. For convenience and accuracy, county boundaries now are used in specifying Section territory. All District officers and the officers of all Sections involved in territorial changes have been given full information concerning the changes, and membership lists for each Section as of August 1, 1937, will be prepared on the new basis.

In commenting upon the report of the membership committee, National Secretary Henline called attention to the following figures:

| Item | May 1, 1936 | May 1, 1937 |
|---|---|---|
| Total membership | 14,600 | 15,308 |
| Applications from Enrolled Students | 631 | 710 |
| Other applications | 946 | 1,040 |
| Enrolled Students | 4,049 | 4,503 |

Further details concerning Section and Branch activities for the year 1936–37 are given in the comprehensive annual report published in the June 1937 issue of ELECTRICAL ENGINEERING, beginning on page 762. Other items have been published during the year.

The report of the committee of tellers was published in the July issue of ELECTRICAL ENGINEERING, page 913, along with a report covering the election of honorary members.

#### TREASURER'S REPORT

An independent and personal verification of Institute accounts as covered in the auditor's statement published as a part of the report of the board of directors, was reported by National Treasurer W. I. Slichter, professor of electrical engineering, Columbia University, New York, N. Y. He reported that further returns had been made to the reserve capital fund in compensation for withdrawals required for

Institute activities during 1932–33–34, at the same time accommodating increased appropriation to the publication committee and to certain other committees for the further extension and development of Institute services to its members. He urgently recommended continuance of a conservative financial policy in order that future possible economic disturbances of a general nature should not injure nor unduly curtail Institute activities.

PRIZE AWARDS

Chairman H. S. Osborne of the AIEE committee on award of Institute prizes presented formally the committee's report, and President MacCutcheon made the presentations to the recipients present, Mr. P. S. Millar and Professor H. E. Edgerton. Complete text of the report may be found on page 756 of ELECTRICAL ENGINEERING for June 1937.

## Lamme Medal for 1936 Presented to Doctor Frank Conrad

"For his pioneering and basic developments in the fields of electric metering and protective systems" Doctor Frank Conrad (A '02) assistant chief engineer, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa., received during the annual summer convention business session at Milwaukee, Wis., the ninth in the series of AIEE Lamme Gold Medals. This was the second major award made by the Institute to Doctor Conrad, the earlier award having been that of the Edison Medal for 1930.

One of 3 bequests provided in the will of Benjamin Garver Lamme (deceased July 8, 1924), the AIEE Lamme Medal was established for the encouragement and recognition of "meritorious achievement in the development of electrical apparatus or machinery." The other bequests were made to The Ohio State University, Columbus, and to the Society for the Promotion of Engineering Education (this year's awards are announced elsewhere in this issue).

LAMME CAREER OUTLINED BY PRESIDENT-ELECT HARRISON

As a background for the presentation of the Medal to Doctor Conrad, President-Elect W. H. Harrison presented the following outline of the life of Lamme as indicative of the circumstances that led to the founding of the Medal:

"Fortunately, Mr. Lamme recorded his life history, a fascinating story, from his boyhood on the farm, country schooling, natural bent for mechanical things, devotion to elementary mathematics, engineering course at The Ohio State University, and affiliation with the Westinghouse Electric and Manufacturing Company that began in 1889 in a testing department and ended with his death in 1924 as its chief engineer.

"His achievement as the guiding genius and inspirational force of the engineering work of that great organization, and in particular his contributions to the advancement of the science of electrical-machine design, hardly need to be reviewed at any Institute gathering. Monuments to the brilliance of his mind, to his industry, to his courage, to his imagination, are to be found literally wherever electric energy is generated and applied.

"Beginning early in his career he gave generously of his time and knowledge to affairs of the Institute, participating in its deliberations and particularly in its technical discussions. He served in many capacities, perhaps the most noted being his service on behalf of the Institute on the Naval Consulting Board of the United States from 1915 to 1919. He was honored by the AIEE in 1919 by the award of the Edison Medal, the most distinguished award the Institute can bestow. From his Alma Mater, Ohio State University, he was the first to receive the Joseph Sullivant Medal in recognition of the value of his work to the world. Pioneering in a field when so little was known of the science of electricity, even as to its fundamentals, and full well realizing the necessity for training and education, he gave freely to these activities. It was like the man to establish in his will a medal for the advancement of a profession he cherished and to which he contributed so much. This significant and highly prized medal will continue to serve as an inspiration to the engineers of the future."

MEDALIST INTRODUCED BY A. M. DUDLEY

With enthusiasm for the human qualities of the medalist as well as for his versatile technical genius, A. M. Dudley (A'08, F '13) marine electrical engineer, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa., outlined the more outstanding features of Doctor Conrad's career:

"To do justice in a casual quarter of an hour to the lifetime accomplishment of a busy man is unthinkable, and to mention a few of the high spots of what he has done is to create the thought that perhaps one has omitted many of the best . . . .

"In 1890 at the very tender age of 16 years, without benefit of even a complete grade-school education, Frank Conrad went to work in the Garrison Alley Shops of the Westinghouse Electric and Manufacturing Company as a bench hand. His biography gives us an intriguing picture of a clever mischievous boy filled with an insatiable curiosity about scientific measuring instruments and about electricity. As the result of some suggestions that he made about the work which he was doing with his hands, he was selected to go to the testing floor as a laboratory assistant. While there he worked on meters and laid the groundwork of that work for which he is being cited today. He also worked on arc lamps.

"In 1904, when I first knew him, he had been designated general engineer, as a free lance under the direction of the vice-president of engineering to work on any or all engineering problems to which he might be assigned. He followed that period with work on circuit interruption on the New Haven Railroad electrification. A little later he worked on starting, lighting, and

**North Eastern District Meeting**
Pittsfield, Mass., Spring 1938

**Summer Convention**
Washington, D. C., June 20–24, 1938

ignition for automobiles. During the War he rendered signal service to our government in the matter of radio communication. At present he is a Lieutenant Commander in the Naval Reserve. . . . He is a sage counselor of youth; young men come to him and enjoy working with him . . . . In 1921, he was appointed assistant chief engineer, a title which still serves to designate the man to whom you can carry any kind of questions you may have.

"He followed that with some work on rectifiers, radio broadcasting, short wave radio, and . . . on voting machines.

"Four times have medals come to him . . . : In 1925 the Morris Leibmann prize of the Institute of Radio Engineers; in 1933 the John Scott Medal of the City of Philadelphia; in 1930 the AIEE Edison Medal; in 1936 the AIEE Lamme Medal . . . In 1928 the University of Pittsburgh conferred upon him the degree of doctor of science. He is a Fellow in the Institute of Radio Engineers, and a Fellow of the AIEE.

"What has he done, briefly, to deserve all this acclaim? First, unquestionably comes radio broadcasting, and perhaps more important, we would have to mention short-wave radio development . . . . Following these there is a long list of distinguished design accomplishments along many lines, including the arc lamps, meters, automotive equipment, and radio that has been mentioned; in all he has something like 250 patents to his credit, and most of these have been manufactured, or are still being manufactured in some form.

"Known to only a few is Doctor Conrad's interest in biology and physiology; in conjunction with one of the doctors in Columbia Hospital in Wilkinsburg, Pa., he developed a method for draining fluid from an infected lung in pneumonia cases, which method has been highly successful and probably will be used much more. It is characteristic that in connection with that work he had developed by one of the big rubber companies a special form of rubber tubing which has a passage through the middle to conduct ingoing liquid and corrugations around the outside to conduct outgoing fluid for use in cases of irrigation or removal of fluid.

"Frank Conrad and his work stand to me for the spirit of service . . . for the aristocracy of intellect as shown in the power of his scientific curiosity and his creative imagination . . . for the flowering of this great democracy in which we live."

### Doctor Conrad Responds

In responding to Mr. Dudley's address, Doctor Conrad stated that his pleasure in receiving the Lamme Medal is "enhanced by the fact that the Lamme Medal was provided by the generosity of a man who to an extent was responsible for the part I was enabled to take in the development of electrical measuring instruments." In recounting some of the problems incident to the development of the a-c system, Doctor Conrad said: "It became imperative that means be provided for observing all aspects of this new industrial service, and through fortune it happened that I was privileged to play a part in the subsequent development of a-c instruments . . . . Aside from the Siemens' dynamometer and the Kelvin balance, which were adapted to the laboratory but not to the station switchboard, there were some types of measuring instruments in existence at the time that did give some approximation of correct readings on alternating current although they had been designed for d-c use. Attempts were made to adapt these instruments to a-c operation by calibrating them, especially for the particular a-c circuit in which they were to be used.

"Our crude cut-and-try methods of development soon taught us that it was necessary to subdivide or laminate any iron used in the magnetic field. Also if the coils were wound on metal spools, these spools had to be slotted in some manner to avoid a closed circuit around the magnetic core. In a few years a line of instruments was made available in which the voltmeters and the wattmeters had moving coils and the ammeters had moving iron armatures; these were comparable in accuracy to those of the present, although they were unwieldy and expensive . . . . Some years later the general principle of utilizing the current induced in the moving element, employed by Shallenberger in his pioneer current meter, was incorporated in new designs of compact switchboard instruments. This type of instrument constituted an intermediate step in instrument design and made possible the use of a scale length which extended around almost the entire circle.

"As often is true, fashions in instrument design now have swung back to those early days, and at present the induction type of instrument, excepting the watt-hour meter, has been almost supplanted by types corresponding to the first moving-iron-core and moving-coil instruments. Great advances made in the improvement of magnetic materials and complete understanding of the principles involved, now permit the production of instruments of many sizes and types, completely satisfactory as to accuracy and dependability."

## Other Convention Features

### Technical Sessions

Two special sessions featured this year's formal program. One was an all-morning session devoted partly to a special address "The Engineer in a Changing World" by Ralph E. Flanders, past president of the American Society of Mechanical Engineers, and partly to a general discussion of the subject "How can the Institute programs be made of greatest value to the membership?" which was introduced by 7 discussions prepared by prominent Institute members. The second special session was an evening general meeting addressed by Director-Elect Vannevar Bush on the subject "The Engineer and His Relation to Government." These 2 special addresses and the 6 discussions mentioned are published in full elsewhere in this issue as part of the convention report.

S. B. Crary, Jr. (left) of Schenectady, N. Y., winner of the Mershon tennis trophy, being congratulated by W. J. Morrill of Fort Wayne, Ind., runner-up

The 10 regular technical sessions accommodated the presentation and discussion of some 39 formal technical papers and 4 technical presentations of a special character. In addition, and for the benefit of the specialists particularly interested, 2 conference meetings were included in the schedule: one on field problems, and one on electrical apparatus for 3-phase arc furnaces. These 2 technical conferences provided the opportunity for informal discussion of several topics of specialized interest.

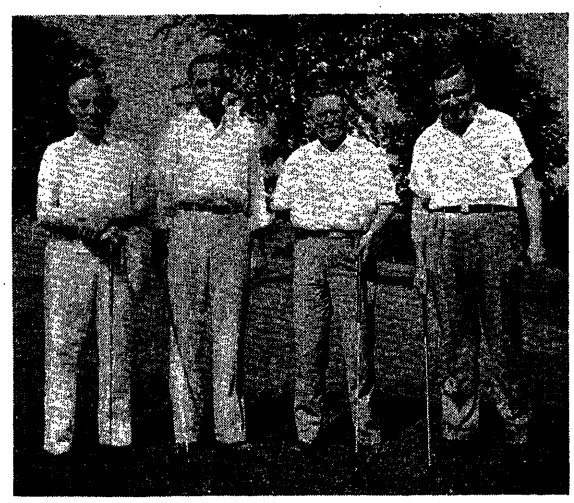
### Attendance

With its total registered attendance of 1,067, Milwaukee sets an attendance record for summer conventions that has not been exceeded since the summer convention held in Detroit in 1927. In one of the accompanying tabulations is given an analysis of the attendance at the current summer convention; in another table are given comparative registrations over a period of years.

### Entertainment

A generous and well organized program of entertainment, and special inspection trips involving attractive entertainment features, was provided by the Milwaukee committee for both men and women. The entertainment program opened Monday evening, with some 400 men in attendance at a stag buffet supper and smoker held at the Milwaukee Athletic Club, and with the women entertained at a buffet supper in the banquet room of the Schroeder Hotel. On Wednesday evening, some 470 men, women, and children, enjoyed a 2-hour boat trip on Lake Michigan. In spite of record hot weather, more than 400 were reported present at the president's reception and dinner-dance held Thursday evening at the Schroeder Hotel. The entertainment program was terminated by a "farewell gathering" for dinner Friday evening at the Bluemound Country Club.

Provisions for the reception and entertainment of the women were thoughtfully arranged and effectively carried out. Features arranged especially for the women included special inspection trips Monday and Tuesday, a tea Tuesday afternoon, a luncheon and card party at the Wisconsin Club Wednesday, "Country Club Day" Thursday at the Tripoli Country Club, and Friday open for activities of individual choice.



### Golf

Major golf events, of course, were the competitions for the Mershon and the Lee trophies and the District team contest.

The Mershon trophy is open for national competition among Institute members on the basis of match play under handicap. The 16 who qualified during the first day's play (low net score) were A. H. Sweetnam, Boston, Mass.; T. O. Rudd, New York, N. Y.; R. M. Darrin, Buffalo, N. Y.; R. A. Wheeler, Milwaukee, Wis.; H. T. McPhail, Denver, Colo.; G. V. Smith, Mansfield, Ohio; H. P. Kuehni, Schenectady, N. Y.; G. A. Kositzky, Cleveland, Ohio; Lee Cook, Dallas, Texas; W. O. Helwig, Milwaukee, Wis.; R. H. Fair, Omaha, Neb.; J. H. Irwin, Chicago, Ill.; R. G. Lorraine, Schenectady, N. Y.; H. O. Anderson, New Haven, Conn.; C. H. Teskey, Cleveland, Ohio; G. R. Canning, Cleveland, Ohio. Out of this field emerged:

Winner—C. H. Teskey (A'32)
Runner-up—G. A. Kositzky (M'22, F'29)

Mr. Teskey will be the second to have his name engraved on the present trophy, which is the third cup donated by Past President Ralph Mershon, the first having been won in 1931 by L. F. Deming of Philadelphia, Pa., after having withstood competitions since 1912; the second having been won in 1935 during the summer convention at Ithaca, N. Y., by L. R. Keiffer of Cleveland, Ohio, after having been in competition for only 4 years. The regulations governing the present trophy are that it shall remain on permanent exhibit at AIEE headquarters in New York bearing engraved upon it the name of the winner of each successive year's competition.

**A group of summer convention golfers (left to right): President A. M. MacCutcheon of Cleveland, Ohio, Chairman Lee Cook of the Dallas Section, Chairman E. D. Freeman of the Oklahoma City Section, and W. O. Helwig, chairman of the convention registration and housing committee**

The Lee trophy, presented in 1932 by the late Past-President W. S. Lee is awarded each year to the player having the lowest net score for 36 holes, and must be won twice by the same player for permanent possession. The results of the 36-hole medal play at Milwaukee were:

Winner—G. A. Kositzky (M'22, F'29) of Cleveland, Ohio

Runner-up—G. R. Canning (A'32) of Cleveland, Ohio

Mr. Canning narrowly missed winning permanent possession of the trophy. With the newest addition, the names now appearing on the Lee trophy are:

1932—C. H. Teskey, Cleveland, Ohio
1933—G. R. Canning, Cleveland, Ohio
1934—F. M. Craft, Atlanta, Ga.
1935—A. H. Sweetnam, Boston, Mass.
1936—H. S. Warren, Los Angeles, Calif.
1937—G. A. Kositzky, Cleveland, Ohio

District team competition, on the basis of 36-hole medal play was won by a team representing the Great Lakes District with a total of 667 gross for the 36 holes: G. F. Crowell (A'20, M'36), Milwaukee; J. H. Irwin (A'20), Chicago; E. L. McClure (A'37), Milwaukee; R. A. Wheeler (A'21), Milwaukee.

Each of the several day's play was featured by various special prizes. The winners of these special awards were too numerous to record here.

The golfing events for men were played at the Tripoli Country Club Monday and Tuesday afternoons, June 21 and 22, at the Ozaukee Country Club Wednesday and Thursday afternoons, June 23 and 24, and at the Bluemound Golf and Country Club Friday, June 25. The dinner dance held Friday evening at the Bluemound Country Club was intended to be the grand finale for the convention, at which prizes for golf and tennis competitions would be awarded. Early departures from the convention, however, restricted the attendance at this final affair.

## Membership—

Mr. Institute Member:

Please concentrate for just one minute on this thought: What man among your associates would receive most benefit from membership in the Institute?

Think over the list of men who are headed toward higher responsibilities, who would be broadened by the contacts with more experienced men in their profession, and who would profit by the discussions at the Section meetings.

Which one stands out? That man needs the Institute and the Institute needs and will welcome his membership. Why not speak to him right now?

A. B. Cooper

Vice-Chairman, District No. 10
National Membership Committee

### Tennis

The annual tennis tournament was held on the clay courts of the Milwaukee University School beginning Monday afternoon, June 21, and comprised both singles and doubles for men. The principal formal competition, of course, was for the Mershon trophy. Out of a field of 8 entrants in the singles tournament, W. J. Morrill (A'25, M'35) of Fort Wayne, Ind., and S. B. Crary, Jr. (A'31) of Schenectady, N. Y., emerged into the semifinals. Mr. Crary won the final match, and the privilege of being the third to have his name engraved on the present Mershon trophy which was donated in 1935 by Past-President Ralph Mershon to replace an earlier trophy that was permanently won in 1934 by E. F. Lopez (A'16, M'18) of Mexico City. The names now appearing on the current Mershon trophy are:

1935—Allen O. White, Washington, D. C.

1936—E. F. Lopez, Mexico City, D. F., Mex.

1937—S. B. Crary, Jr., Schenectady, N. Y.

Stipulations governing the present trophy are that it shall remain on permanent exhibit at Institute headquarters with the names of successive winners engraved upon it.

# Annual Conference of Officers, Delegates, and Members Held at Milwaukee, Wis.

SPONSORED jointly by the Sections committee and the committee on Student Branches, the annual conference of officers, delegates, and members of the Institute assembled for 2 busy sessions Monday and Tuesday afternoons, June 21 and 22, 1937, at the Hotel Schroeder in Milwaukee, Wis., as one of the regular activities of the summer convention. In attendance at the sessions were delegates from 57 of the Institute's 62 sections, 6 of the 10 District secretaries, counselor delegates from all 9 of the Districts in which committees on student activities have been organized, and many other local and national officers of the Institute and members actively interested in the conduct of Institute affairs. A complete list of the authorized representatives present is given in the accompanying tabulations. W. H. Timbie, chairman of the Sections committee, presided.

Topics discussed were essentially as outlined in a program mailed to delegates and others in advance of the meeting:

### Monday Afternoon, June 21

1. Opening remarks—President A. M. MacCutcheon.
2. Presentation of summary of past actions of delegates' meetings (1931 to date).
3. Presentation of summary of Section "self analysis" questionnaires.
4. Situation regarding registration of engineers.
   (*a*) In the East—representative from New York Section.
   (*b*) In the Midwest—representative from Chicago Section.
   (*c*) In the West—representative from Los Angeles Section.
   (*d*) General comments on Sections activities and present attitude of AIEE board of directors regarding registration—President MacCutcheon.
5. General discussion on above subjects.

### Tuesday Afternoon, June 22

6. Publication policy.
   (*a*) Report from publication committee—I. M. Stein, chairman.
   (*b*) Report from technical program committee—R. N. Conwell, chairman, of a special subcommittee of the technical program committee.
   (*c*) Mechanics and economics of past, present, and proposed schemes—G. Ross Henninger, editor.
   (*d*) General discussion.
7. Miscellaneous subjects.

Section and Branch activities were covered in some detail in a report published in the June 1937 issue of ELECTRICAL ENGINEERING, beginning on page 762. Inasmuch as this information thus already had been circulated to the entire membership, no pamphlet copies of the report were prepared for use at the conference, and nothing remains to be reported here.

### President MacCutcheon Opens Session

In brief opening remarks made at the request of Chairman Timbie, President MacCutcheon described the Institute as being "really only an organization of Sections," and sought to emphasize the responsibility of each Section delegate to these summer conferences. In speaking of the necessity for constantly planning for the future, President MacCutcheon spoke strongly of the value to the board of directors of well considered recommendations emanating from these annual conferences. He pointed out that all past recommendations of the conferences had received the attention of the board of directors and that many of them had been adopted as recommended.

In a manner supplementing the remarks of President MacCutcheon, Doctor H. H. Race, Schenectady, N. Y., of the Sections committee made available to members and delegates present a mimeographed record of all actions taken by the annual conferences since 1931, together with brief information as to subsequent action taken and disposition made of each recommendation. This report had been compiled by the Sections committee for the meeting partly as a matter of record and partly to avoid spending unnecessary time during the conference session in the discussion of matters already disposed of.

### Section Self-Analysis

Desirous of assisting in local Section activities, the AIEE Sections committee sent a questionnaire to each Section, March 23, 1937, suggesting that the questionnaire be used as a form around which to build a self-analysis of local activities. Four main considerations to which attention was called in the questionnaire were as follows:

1. Aim or objective of Section.
2. Activities carried on by the Section to accomplish the objective.
3. Results obtained by the activities during the last 5 years.
4. Changes or additions suggested in the activities by your Section.

Chairman Timbie reported that although the time allowed was short, some 25 returns out of the possible 62 had been received in time to report to the convention, and that others were expected later. Reporting for the Sections committee at the request of Chairman Timbie, Clifford M. Foust, chairman of the Schenectady Section, summarized the information given in the 18 responses that had been received by May 28:

I. *Aim or Objective of Section.* Some 60 total aims or objectives were recognized in 18 analyses returned, although cases of similarity reduced the number of definite and differing aims to about 25. The aim or objective set forth in the AIEE Constitution, article I, section 2, was specifically recognized by a considerable number of Sections:

> Its objects shall be the advancement of the theory and practice of electrical engineering and of the allied arts and sciences and the maintenance of a high professional standing among its members.

In addition the generally accepted objectives of practically all Sections may be briefly stated as follows:

> To provide opportunities for workers in the field to become acquainted, to exchange ideas, to keep up to date technically, and to advance the profession to higher standards.

Further items mentioned include the following:

1. To stimulate interest in national activities of the AIEE.
2. To stimulate contributions to ELECTRICAL ENGINEERING.
3. To inform the public of progress in electrical engineering.
4. To provide a place and an opportunity to present and discuss papers.
5. To assist the student and to retain his membership in AIEE.
6. To retain among the membership those of high professional reputation.
7. To promote individual, organizational, and civic interest.
8. To discuss topics of economic interest.
9. To co-operate with other engineering societies in promoting education and other purposes.
10. To supply where required an organization for the promotion of civic interests such as a popular lecture course.
11. To create opportunities of advancement for young engineers.

It is recognized that many of these stated objectives are means, not ends, and may be regarded as but secondary aims. However, these secondary aims are frequently the guides to the daily conduct of affairs, and must therefore be in accord with the primary aims or objectives as given in the Constitution and previously quoted.

II. *Activities Carried on by the Sections To Accomplish the Objective.* The principle

activities reported under this heading include:

1. Technical lecture meetings.
2. Combined business-social meetings.
3. Prize papers or paper competitions.
4. Combined Section and Student Branch meetings.
5. Technical discussion groups.
6. Young member discussion groups.
7. Co-operation with other engineering societies.

Some of the special activities reported to have been especially helpful to particular Sections include:

1. Popular non-technical meetings.
2. Inspection trips.
3. News letters.
4. Weekly luncheons.
5. Technical courses (particularly electronics).
6. Educational services to schools.

III. *Results Obtained From Activities as Carried on During the Last 5 Years.* Practically all Sections express confidence that substantial progress is being made toward the desired objectives summarized under item I through the program as outlined under item II.

IV. *Changes or Additions Suggested in Activities of Individual Sections.* This critical portion of the self-analysis lends itself less readily to summarizing than the preceding 3 sections, where an extensive degree of overlapping of aims, activities, and results permitted a fairly representative summary to be prepared. Under this section, however, no such overlapping prevails; each Section has its attention fixed for the moment on one or more changes that seem valuable to it. The following enumerates most of these prospective changes and attempts some classification:

**Those pertaining to organization**

1. More definite plans for active participation of young members.
2. More democratic elections.
3. Admit "local" members.
4. Make activities for members only.
5. Closer co-operation with Student Branches.
6. Establish a local advisory board.

## Table I. Record of Attendance of Section Delegates and Student Branch Counselors at Milwaukee Conference

| Section | Delegate Name and Affiliation |
|---|---|
| Akron | A. A. Austin (A'04, F'24) manufacturing engineer, Barberton, Ohio; Section chairman 1937–38 |
| Atlanta | J. M. Flanders (A'23, M'28) assistant superintendent, Georgia Power Company; Section secretary 1936–38 |
| Baltimore | R. L. Thomas (A'19, M'29) general superintendent, Pennsylvania Water and Power Company; Section chairman 1936–37 |
| Boston | C. L. Dawes (A'12, F'24) associate professor of electrical engineering, Harvard University; Section chairman 1936–37 |
| Central Indiana | L. F. Rick (A'20, M'37) assistant professor of electrical engineering, Purdue University |
| Chicago | N. C. Pearcy (A'24, M'30) electrical engineer, Public Utility Engineering and Service Corporation; Section chairman 1937–38 |
| Cincinnati | L. R. Culver (A'22, F'35) associate professor of electrical engineering, University of Cincinnati; Section chairman 1937–38 |
| Cleveland | F. E. Harrell (A'20, M'35) assistant chief engineer, Reliance Electric and Engineering Company; Section chairman 1937–38 |
| Columbus | E. E. Kimberly (A'16) associate professor of electrical engineering, Ohio State University; Section chairman 1936–37 |
| Connecticut | J. A. French (M'22) research engineer, Connecticut Light and Power Company; Section chairman 1937–38 |
| Dallas | I. R. Cook (A'25, M'35) supervisor of distribution, Texas Power and Light Company; Section chairman 1936–37 |
| Denver | H. P. McPhail (A'19, M'27) assistant chief electrical engineer, United States Bureau of Reclamation; Section chairman 1936–37 |
| Detroit Ann Arbor | D. H. Baker (A'09) transmission and protection engineer, Michigan Bell Telephone Company; Section chairman 1937–38 |
| East Tennessee | C. Hutchinson (A'30) electrical engineer, Tennessee Public Service Company; Section chairman 1936–37 |
| Erie | J. W. Teker (A'31) engineer, General Electric Company; Section chairman 1936–37 |
| Florida | W. Austin Smith (A'33) consulting engineer; Section chairman 1936–37 |
| Fort Wayne | D. H. Hanson (A'31) electrical engineer, General Electric Company; Section chairman 1936–37 |
| Houston | V. H. Clements (A'30) sales engineer, Westinghouse Electric & Manufacturing Company; Section chairman 1937–38 |
| Iowa | F. H. McClain (M'29) associate professor of electrical engineering, Iowa State College; Section chairman 1936–37 |
| Ithaca | K. P. Chamberlain (A'20) assistant professor of electrical engineering, Cornell University; Section chairman 1936–37 |
| Kansas City | A. L. Maillard (M'23) Kansas City Power and Light Company; Section chairman 1936–37 |
| Lehigh Valley | R. F. DeTurk (A'24, M'30) transmission and distribution superintendent, Metropolitan Edison Company; Section chairman 1937–38 |
| Los Angeles | J. C. Gaylord (A'11, M'26) hydro engineer, Southern California Edison Company Ltd.; Section chairman 1936–37 |
| Louisville | Stanley Warth (A'28, M'36) division transmission engineer, Southern Bell Telephone and Telegraph Company; Section chairman 1936–37 |
| Lynn | R. M. Pfalzgraff (A'29) assistant engineer, General Electric Company; Section chairman 1937–38 |
| Madison | E. D. Ayres (A'26, M'31) associate professor of electrical economics, University of Wisconsin; Section chairman 1937–38 |
| Memphis | F. G. Cartwright (A'30) relay tester, Memphis Power and Light Company; Section chairman 1936–37 |
| Minnesota | A. Nelson (A'28) sales engineer, Westinghouse Electric & Manufacturing Company; Section chairman 1937–38 |
| Montana | W. A. Boyer (A'26) electrical engineer, Anaconda Copper Mining Company; Section chairman 1936–37 |
| Nebraska | O. E. Edison (A'17, M'20) associate professor of electrical engineering, University of Nebraska; member, committee on Student Branches 1936–37 |
| New Orleans | F. G. Frost (M'22) general superintendent, electrical department, New Orleans Public Service, Inc.; Section chairman 1937–38 |
| New York | A. G. Oehler (A'18, F'26) editor, Simmons-Boardman Publishing Company; Section chairman 1936–37 |
| Niagara Frontier | R. M. Darrin (A'28, M'34) in charge of sales to central station customers, Buffalo District, General Electric Company; Section chairman 1937–38 |
| North Carolina | F. L. Moser (A'25, M'31) superintendent of maintenance, Duke Power Company; Section chairman 1932–33 |
| Oklahoma City | E. D. Freeman (A'32, M'35) superintendent, electrical department, Oklahoma Gas and Electric Company; Section chairman 1936–37 |
| Philadelphia | O. C. Traver (A'10, M'20) assistant designing engineer, General Electric Company; Section chairman 1936–37 |
| Pittsburgh | J. R. MacGregor (A'23, M'29) chief engineer, Bell Telephone Company of Pennsylvania; Section chairman 1936–37 |
| Pittsfield | A. Boyajian (A'18, F'26) technical engineer, General Electric Company; Section chairman 1937–38 |
| Portland | C. C. Boozier (A'23) sales engineer, Westinghouse Electric & Manufacturing Company; Section secretary 1936–37 |
| Rochester | E. H. Branson (A'15, M'35) director of engineering, research laboratory, General Railway Signal Company; Section chairman 1936–37 |
| St. Louis | L. O. Campbell (A'20, M'29) assistant to engineer, General Electric Company; Section secretary 1934–35 |
| San Antonio | N. B. Gussett (M'37) San Antonio Public Service Company |
| San Francisco | R. O. Brosemer (A'31) engineering department, General Electric Company; Section chairman 1937–38 |
| Schenectady | C. M. Foust (A'22, M'31) General Electric Company; Section chairman 1936–37 |
| Seattle | C. H. Hoge (A'19, M'29) assistant engineer, Puget Sound Power and Light Company |
| Sharon | T. H. Frankenberry (A'27, M'29) design transformer engineer, Westinghouse Electric & Manufacturing Company |
| Spokane | M. P. Hatch (A'33) assistant engineer, Washington Water Power Company; Section chairman 1937–38 |
| Springfield | C. G. Veinott (A'28, M'34) design engineer, Westinghouse Electric & Manufacturing Company; Section chairman 1936–37 |
| Syracuse | C. W. Henderson (A'20) professor of electrical engineering, Syracuse University; Student Branch counselor |
| Toledo | G. J. Clark (A'31) salesman, industrial division, General Electric Company |
| Toronto | M. J. McHenry (A'11, M'20) manager, Toronto district, Canadian General Electric Company; Section chairman 1936–36 |
| Urbana | H. J. Reich ('32) associate professor of electrical engineering, University of Illinois; Section chairman 1936–37 |
| Utah | C. A. Wolfrom (A'10) division manager, Utah Power and Light Company; Section chairman 1937–38 |
| Vancouver | F. L. Code (A'27) instructor, Vancouver Technical School |
| Virginia | J. E. Jackson (A'26) district manager, Appalachian Electric Power Company; Section chairman 1936–37 |
| Washington | J. F. Meyer (A'08, M'13) principal physicist, National Bureau of Standards; Section chairman 1937–38 |
| Worcester | V. Siegfried (A'32) instructor in electrical engineering, Worcester Polytechnic Institute; Section chairman 1937–38 |
| Chairman, Sections committee | W. H. Timbie (A'10, F'24) professor of electrical engineering, Massachusetts Institute of Technology, Cambridge |

(1) (2) (3) (4)

**(1) President-Elect W. H. Harrison (left) of New York, N. Y., interests Vice Chairman E. E. George of the East Tennessee Section, and Mrs. George. (2) Chairman H. S. Osborne (left) of the technical program committee, New York, N. Y., and Past-President J. B. Whitehead of Baltimore, Md., discussing a point of mutual interest. (3) Past-President H. P. Charlesworth, of New York, N. Y. (4) M. G. Malti (left) of Ithaca, N. Y., and Past Vice-President W. H. Timbie (right) of Cambridge, Mass., having an interesting discussion with a third party**

7. Better meeting place required.
8. Eliminate "local" members.
9. Representation on national committees.
10. Better co-operation with local engineering council.
11. Study and co-operate with ECPD on professional standing.
12. Refer applicants for admission to AIEE membership to local committee.
13. Appoint more young members to definite activities.
14. Increase number of contacts with engineers.
15. Elect chairmen of committees instead of appointing.
16. Give prizes for best membership work.

**Those pertaining to meetings**

1. Organize technical classes.
2. Study groups in public speaking, economics, business administration.
3. Hold meetings at other points in the Sections.
4. More inspection trips.
5. Discuss social and economic problems.
6. Take part in a monthly program with other societies.
7. Decrease number of meetings.

**Those relating to papers**

1. Exchange of papers in the District.
2. More national papers.
3. Begin a prize-paper contest.
4. Organize a committee to stimulate national papers.

In general these proposed changes are under consideration as means toward a more successful realization of avowed aims and objectives. Most of them have been tried in other Sections and frequently found valuable, while others have not been tried or have been unsuccessful experiments. However, local conditions, as has frequently been pointed out, call for local and particular treatment, and it is therefore desirable that each Section work out activities best fitted to its circumstances.

*General Results of Self-Analysis.* The 18 Section reports covered in the preceding digest are sufficient in number and of such quality as to justify the following definite conclusions concerning the analysis:

1. Each Section making an analysis has benefited by a better understanding of its own problems.
2. Through the availability of this summary, each Section can compare its own program with those of other Sections.
3. As a result of analyzing these returns, the Sections committee is in a better position to advise individual Sections concerning local problems.

Section officers are urged to communicate directly with the chairman of the Sections committee concerning any particular detail of this survey, or concerning any Section operating problem in which there may be a special interest.

## Registration of Engineers Discussed at Length

The current situation regarding the registration of engineers was the subject of practically a full afternoon's discussion. As indicated in the conference program, the general discussion was preceded by 4 informal reports: The eastern viewpoint was reflected by Chairman A. G. Oehler of the New York Section; the middlewest viewpoint was reflected by N. C. Pearcy of the Chicago Section; west-coast opinion was represented by Chairman J. C. Gaylord of the Los Angeles Section; President A. M. MacCutcheon traced briefly the evolution of the subject as it has been considered by the board of directors from time to time, and spoke at some length concerning the views that he had gathered incident to his recent contacts with a majority of the Institute's Sections.

Out of the ensuing discussion and variety of opinion concerning the various questions raised, the following general conclusions seemed to emerge as representing the consensus of opinion: (*a*) that inasmuch as laws providing for the registration of engineers have been adopted in some form or other by a majority of the States, efforts should be put forth to secure more nearly uniform legislation; (*b*) that ambiguities in existing laws should be clarified, and provisions made for the proper recognition of the different professional classes of engineers.

After extensive discussion of these and other phases of the problem, and after a generous exchange of experiences and recommendations from various Section representatives and other interested members, the entire question including a verbatim transcript of the meeting was turned over to a special national committee appointed by President MacCutcheon for the purpose of studying further into the question and for making such recommendations concerning national policy as might seem desirable.

## Publication Policy Considered at Length

In opening the Tuesday-afternoon conference session Chairman Timbie stated that the subject of publications was one of the 2 subjects for which a place on the conference program had been requested by a large number of Section representatives. He emphasized again that the principal objective of the discussions as scheduled was to provide an opportunity for the governing committees to learn "just exactly what the individual member wants," in this case "in the way of a publication policy."

## I. M. Stein Reviews Publication Policy

Chairman I. M. Stein of the publication committee read the following report:

"During the past year your publication committee has been studying our publication policy with the idea of recommending revisions which would provide an improved publication service to our membership.

"It will be recalled that a change was made in our publication policy in 1933 in order to effect economies which were necessary in view of our drastically reduced income. The arrangement adopted at that time has accomplished its primary purpose very well, namely, a substantial reduction in expenditures, and this without making any great reduction in the publication service rendered.

"Naturally it is desirable to retain all of those economies which do not materially interfere with the maintenance of a good publication service. On the other hand, there are some defects which should be remedied as soon as we can afford to do so. The arrangement adopted in 1933 reduced publication expenditures to what appears to be the practical minimum and, hence, any important modification is almost certain to result in some increase in cost, that is, unless, in providing some new desirable feature, some other feature which has been considered desirable in the past is withdrawn.

"However, in view of the improvement in general conditions, it is likely that we can afford a modest increase in publication expenditures in order to render better service.

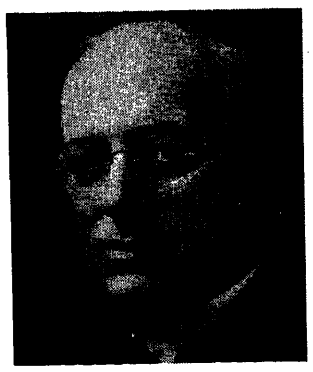
"Among the improvements which many of our members seem to desire are the following:

1. An increased number of high-grade general interest articles in ELECTRICAL ENGINEERING.

(*Continued on page 1050*)

**Table II. Record of Attendance of District Student Branch Counselor-Delegates**

| District | Delegate Name and Affiliation |
|---|---|
| 1 | E. M. Strong ('26) assistant professor of electrical engineering, Cornell University, Ithaca, N. Y. |
| 2 | E. O. Lange (A'19) associate professor of electrical engineering, Drexel Institute, Philadelphia, Pa. |
| 3 | H. N. Walker (A'27, M'34) assistant professor of electrical engineering, New York University, New York City |
| 4 | S. W. Anderson (A'16, F'31) professor of electrical engineering, Virginia Military Institute, Lexington |
| 5 | S. S. Attwood (A'21, M'28) associate professor of electrical engineering, University of Michigan, Ann Arbor |
| 6 | G. H. Sechrist (A'20) chairman, electrical engineering department, University of Wyoming, Laramie |
| 7 | Chester Russell (A'29, M'34) acting head, department of electrical engineering, University of New Mexico, Albuquerque |
| 8 | E. F. Peterson (A'30) professor of electrical engineering, University of Santa Clara, Santa Clara, Calif. |
| 9 | J. A. Thaler (A'03, F'13) professor of electrical engineering, Montana State College, Bozeman |



Chairman, committee on Student Branches—F. Ellis Johnson (A'13, F'31) dean of college of engineering, University of Missouri, Columbia

(1) Chairman I. Melville Stein of the publication committee, Philadelphia, Pa., and President A. M. MacCutcheon enjoying a good joke. (2) Past Chairman P. S. Biegler (left) of the Los Angeles Section. (3) Past Chairman F. R. Innes (right) of the Chicago Section. (4) Chairman J. C. Gaylord (left) of the Los Angeles Section interests E. L. Bettannier of Pasadena, Calif., and E. R. Hedrick of Los Angeles. (5) N. R. Stansel (left) of Schenectady, N. Y., past chairman of the committee on electrochemistry and electrometallurgy, conversing with M. R. Winkler of Chicago, Ill.

2. The restoration of some procedure for making available preprints of technical-program papers.

"Although the point has not been raised by many individual members, there is one important defect in the present publication policy which is quite evident to the publication committee and has been stressed by some outstanding Institute members who have clearly in mind the broad general interests of the Institute. This point has to do with the character of our annual bound volume called the TRANSACTIONS. With the adoption of the 1933 publication policy, the term TRANSACTIONS lost all real significance, as that volume then became nothing more than the annual bound volume of ELECTRICAL ENGINEERING. It seems clear that the broad general interests of the Institute would be served best if the earlier character of TRANSACTIONS were restored by publishing in TRANSACTIONS only those technical papers which mark a real advance in the electrical-engineering art. Probably this requirement could be met practically by publishing in TRANSACTIONS only those papers which have been approved by the technical program committee and which are otherwise acceptable to the publication committee.

"In keeping with these thoughts, the publication committee, at its meeting in January 1937, considered certain modifications in our publication policy. Several of these were approved by the committee and were presented to the board of directors, where they were also approved. Among these was one which is of general interest to our membership and had to do with providing a larger number of high-grade general-interest articles in ELECTRICAL ENGINEERING. The board of directors approved an increase in our publication budget in order to accomplish this, and those members who read ELECTRICAL ENGINEERING regularly have probably noticed an increased amount of such material, some dealing with economic and social subjects.

"The matters of providing preprints and of restoring the character of TRANSACTIONS were not included in recommendations to the board of directors, as it was felt that these features should have further discussion in the technical program committee and at this conference. The technical program committee referred these matters to a special subcommittee, which has made a real study of the matter and has arrived at tentative conclusions, some of which will be presented by the next speaker.

"The study made by this subcommittee has brought into the picture one feature not included in the publication committee's previous study, namely, the desirability of reducing the time between the submission of a paper to the technical program committee and its presentation at a meeting. This point will be discussed more fully by the next speaker and is mentioned here only because it ties in very closely with the matter of providing preprints. Specifically, the subcommittee's tentative recommendation is that the requirement of prepublication in ELECTRICAL ENGINEERING should be withdrawn and that the author's manuscript should be reproduced by the offset printing process so as to provide quite promptly at least a sufficient number of preliminary preprints to facilitate discussion at meetings. The subcommitee's tentative conclusions are in agreement with the publication committee's conclusions that the former character of TRANSACTIONS should be restored and that the contents of ELECTRICAL ENGINEERING should reflect the wishes of our membership in the matter of providing a large number of general-interest articles.

"It is apparent that there would be considerable opposition to making radical changes in our publication policy and procedures, and fortunately it would seem possible to provide the additional desirable features without making radical changes and with only a modest increase in publication expense. This might be accomplished about as follows:

1. Remove the requirement for the prepublication of technical-program papers in ELECTRICAL ENGINEERING and provide preliminary preprint copies of the author's manuscript by means of the offset printing process.
2. After technical-program papers have been presented, submit them to critical review and revision by the appropriate technical committees at the same time the discussion is reviewed, and then publish the paper and its associated discussion in a segregated section of ELECTRICAL ENGINEERING, the segregated section having appropriate page numbers to permit making an overrun for binding in TRANSACTIONS. The additional material in ELECTRICAL ENGINEERING, if bound at all, would be bound in a separate volume, carrying the title ELECTRICAL ENGINEERING.
3. Continue to provide a substantial number of general interest articles of a technical, economic, and social nature in each issue of ELECTRICAL ENGINEERING.

"It is not the intention of the publication committee to present at this time very definite recommendations, nor are we expecting this conference to pass any formal resolution with regard to publication policy, although, of course, this conference is at liberty to take any action that it pleases. According to our by-laws, it is the function of the publication committee to formulate a publication policy and submit it to the board of directors for approval. In formulating a publication policy, your publication committee desires to have the benefit of your advice and criticism and that is the purpose of presenting the matter here. It is hoped that you will discuss the matter freely and fully, stating just as informally as you like any dissatisfaction which you may have with the present publication policy and such changes as you may wish to have incorporated in this publication policy."

### PUBLICATION RECOMMENDATIONS FROM TECHNICAL PROGRAM COMMITTEE

Reporting for a special subcommittee appointed by the technical program committee, Director W. B. Kouwenhoven of Baltimore, Md., presented the following abstracts of recommendations endorsed by the technical program committee:

"The technical program committee, at its January 25 meeting, authorized the appointment of a special subcommittee to review our policy in regard to the handling of Institute technical papers and to report back to them any changes that were thought advisable." [Subcommittee: chairman, R. N. Conwell, past-chairman, technical program committee; J. W. Barker, past-chairman committee on production and application of light; and W. B. Kouwenhoven, director and past vice-president.]

"The problem of Institute programs and their proper handling involves not only the technical papers but also ELECTRICAL ENGINEERING, our publication, and TRANSACTIONS. As we see it, there are 4 or possibly 5 requirements that ought to be met. They are:

1. A minimum of elapsed time should pass between the preparation and presentation of a paper.
2. We should provide preprints of technical papers.
3. The TRANSACTIONS should carry high-quality contributions.
4. Development of ELECTRICAL ENGINEERING into a general-interest magazine or, as Mr. Stein put it, provision for making ELECTRICAL ENGINEERING a "balanced publication," containing a substantial number of general-interest articles in each issue.

"This subcommittee has held several meetings, and at the April 2 meeting of the technical program committee it presented a preliminary report making a few suggestions and asking for discussion. There was a gratifying response to our request, and, as a result of this discussion and further work, we submitted on June 8, to the technical program committee, a progress report suggesting 7 changes in our methods of handling technical papers and publications. In making these suggestions we had in mind 3 things:

1. To provide preprints for use at meetings.
2. Taking from ELECTRICAL ENGINEERING the necessity of publishing all technical papers submitted.
3. Making the TRANSACTIONS the principal place in which technical papers would be found.

Those suggestions are as follows:

1. The author prepares his manuscript in the

**Table III. Record of Attendance of District Secretaries**

| District | Name and Affiliation |
|---|---|
| 1 | R. G. Lorraine (A'29, M'36) central station dept., General Electric Co. |
| 2 | H. A. Dambly (A'24, M'30) asst.engr., special investigation and test div., Philadelphia Elec. Co. |
| 5 | A. G. Dewars (A'17, M'27) system planning engr., Northern States Pwr. Co. |
| 7 | L. C. Starbird (A'32, M'35) transmission and protection engr., Southwestern Bell Tel. Co. |
| 8 | Fred Garrison (A'22, M'29) commercial engr., General Elec. Co. |
| 9 | S. E. Caldwell (A'29) engr., Pacific Pwr. & Lt. Co |

form in which he wishes to present it and sends it to headquarters.

2. Manuscripts to be printed directly from the original immediately upon arrival, about 20 or 25 copies run off and the plates retained.

3. The editor of ELECTRICAL ENGINEERING receives his copy. The secretary of the technical program committee distributes the balance of the copies to the proper technical committee for review.

4. Review, grade, and recommend for or against presentation. They do no editing for the present, but retain their copies and notes.

5. If recommended for presentation, sufficient preprints are run off for distribution at the meeting. The editor of ELECTRICAL ENGINEERING may at this point elect to run all or part of the paper as a general interest article, if it suits his purpose.

6. Paper is presented and discussed.

7. Paper and discussion then edited by the proper technical committee, and recommended for inclusion in the TRANSACTIONS or discarded.

"These changes, if carried out, will tend to make ELECTRICAL ENGINEERING a general interest magazine. In the main, technical papers will appear in the TRANSACTIONS only. They will, however, be available in preprint form.

"We are hoping that at this meeting of the Section delegates and those others present, there will be considerable discussion of these proposals. Perhaps it may be that our membership is satisfied with the present arrangement; perhaps you desire changes. Not only do we want the changes and suggestions that you have here, but others that occur to you later. We would appreciate it very much if you would write Mr. H. S. Osborne (chairman of the technical program committee) and send him any suggestions that you may have."

### OTHER PHASES OF PROBLEM DISCUSSED

In discussing various questions raised with respect to publication procedures and related economics, Editor G. Ross Henninger pointed out that the so-called unified publication plan that has been followed for the past 3 years involved a minimum of cost for the amount of material published, and that any modification or broadening of any of the several phases of the Institute's publication service would require a commensurate increase in publication appropriation. Various phases of the publication problem were discussed at length by many interested delegates present.

To provide a means for expressing the opinion of members and delegates present in such a way as to guide the publication committee in formulating its policy modification, a hand vote was taken on the following questions, with the results as noted:

1. "Is our present publication policy generally satisfactory?" Yes, 16; No, 38.

2. "Shall the present general policy be continued, but provisions made for the printing of more material by using the present 'easy reading' type for only the summary of each paper, and smaller type for descriptive and technical portions?" Yes, 24; No, 36.

3. "Should ELECTRICAL ENGINEERING be 'popularized,' that is, have more general interest articles?" Yes, unanimous.

4. "Should preprints of technical papers be supplied at conventions, followed by publication in TRANSACTIONS?" Yes, 48; No, 5.

5. "Should the material of TRANSACTIONS be completely divorced from that of ELECTRICAL ENGINEERING resulting in effect in 2 separate periodicals, one of a general nature, and one technical?" Yes, 25; No, 40.

6. "Should TRANSACTIONS be split into sections according to subject matter so that each member can subscribe for individual sections?" Yes, 1; No, practically unanimous.

No formal action was taken by the group, it being the expressed opinion of Chairman Stein of the publication committee that the spoken character of the discussion had given to the several members of his committee present sufficient insight into the problem to enable the committee to proceed in due course with its disposition.

Vice-President C. F. Harding of Lafayette, Ind., and Mrs. K. L. Hansen of Milwaukee

For an hour or so prior to the closing of the conference, there was an active discussion of, and exchange of information and operating experiences concerning various operating problems confronting the Sections, such as the type of rooms provided for Section meetings and the cost thereof, and policies and procedures prevailing with respect to local members.

## Counsellor-Delegate Session

Under the leadership of Chairman F. Ellis Johnson of the committee on Student Branches, a large group particularly interested in that phase of Institute work spent all of Monday afternoon plus a dinner session Wednesday evening, in discussing various matters pertaining to Branch activity, and in exchanging experiences. These discussions concerned membership activities of the Branches, style and organization of programs, procedure in the election of officers, degree of stimulation of student participation in the preparation of technical papers, ways of developing leadership, the promotion of professional contact for student engineers, the relationship between the faculty and the Student Branches, and various suggestions concerning ways in which the Institute might aid in the development of Branch activity. No formal actions were taken nor resolutions adopted.

## Training for Marketing Industrial Products

A course of training in marketing technical products is being pursued by a group of young technical graduates employed by the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., under the leadership of Bernard Lester (A'06, M'13) assistant industrial sales manager of the company and lecturer at the University of Pittsburgh. The group, which consists of 25 men selected by their department heads, is taking the course as part of the University of Pittsburgh-Westinghouse graduate study program; this was described in the paper "The Pitt-Westinghouse Graduate Program" by H. E. Dyche and R. E. Hellmund in ELECTRICAL ENGINEERING, volume 53, January 1934, pages 103–08.

The days of the breezy, smart, slap-stick salesman have gone, according to Mr. Lester. Engineering selling today is a serious matter and although personality in the individual can add much to his success, the man who will attain a sound and continued success is the one who knows the technique of the product to be sold, the character of the market to be met, and above all, who is able to interest himself in his customer's problems and their solution. By study and application of principles the course aims to develop such men.

**Primer of Electric Service Costs.** A 94-page book comprising a discussion of utility problems from the standpoint primarily of utility costs has been written by Roy Page (A'11, M'21) vice-president and general manager of the Nebraska Power Company, Omaha, and published by Harper and Brothers, New York, N. Y. The book is intended primarily for educational use by public-utility employees, but according to the publisher also supplies material for all who are interested in public utility economics from any point of view. The author has been associated with the Nebraska Power Company for nearly 20 years, and formerly was employed by the Southern Pacific Company and the Pacific Telephone and Telegraph Company.

# Technical Conferences Held During Summer Convention at Milwaukee

A TYPE of meeting introduced at the 1935 summer convention at Ithaca, N. Y., and one that has proved most popular and effective, is the informal "technical conference." These conferences have been developed primarily to serve the younger members of the Institute and the technical specialists. Definitely on the program schedule at Milwaukee were 2 such technical conferences, one on field problems, and one on electrical apparatus for 3-phase arc furnaces. In addition, several technical subcommittee and other discussion-group sessions developed spontaneously during the course of convention week; these included meetings of:

1. Transformer subcommittee.
2. Joint subcommittee on insulation strength of electrical equipment.
3. Sectional committee on transformers.
4. Subcommittee on sphere-gap calibration and impulse-voltage measurements.

Available reports are given in the following paragraphs.

## Field Problems

By Ernst Weber, Chairman

The program of this meeting, which was attended by more than 50 people, was arranged as follows:

1. INTRODUCTION: The Field Concept in Physics and Engineering.
2. TOPICS:
   *a*. Graphical Field Plotting—Special Applications to Magnetic Fields.
   *b*. Analytical Solutions of Fields—Special Applications to Heat Problems.
   *c*. Conformal Representation—Special Applications to Electric Fields.
   *d*. Experimental Methods of Field Exploration—Special Applications to Hydrodynamics.

The introduction (by Chairman Weber) showed the evolution of the field concept from Newton to Maxwell in a historical survey. From the electromagnetic field the concept of continuous action then penetrated all other branches of applied physics; tables were shown to illustrate the common basis of mathematical treatment in all instances where the field concepts can be applied, such as electricity, gravitation, electron statics, magnetics, heat, electroconduction, and hydrodynamics.

To illustrate the most advanced experimental means for field exploration, films were shown by courtesy of the Institute of Aeronautical Sciences (RCA Building, New York, N. Y.) depicting experimental research in the laboratories of England and Germany. Various methods of making visible the flow of air past objects such as plates, wing profiles, and various attachments illustrated vividly the *lines of flow*.

A. L. Oklund (Marquette University, Milwaukee) described the adaptation of the electrolytic trough to obtain certain 3-dimensional field distributions important in designs of magnets. Sterling Beckwith (Allis-Chalmers, Milwaukee) delivered a discussion prepared by O. K. Marti (also Allis-Chalmers) describing the field distribution in rectifiers during the initiation of the arc.

Graphical methods to obtain field distribution were outlined by Doctor H. Poritsky (General Electric). Application of rotational symmetrical field plotting to the design of magnet poles, and for obtaining the stressed distribution in shafts under torsional forces was explained and illustrated. Professor H. B. Palmer (University of Colorado, Boulder) exhibited a motion-picture prepared under his direction, which gave the electric and magnetic field distribution about a 3-phase transmission line arranged in an equilateral triangle. This pictorial demonstration was received with great enthusiasm.

The treatment of 2-dimensional fields by conformal mapping was outlined by Chairman Weber. After a brief review of the theory of complex functions, the application of conformal representation to electron-tube problems was shown. The power of the method of transforming the boundary by means of complex functions was illustrated by an edge-correction problem, by profiling of airplane wings, and by problems in electron "guns." An application of the Schwartz-Christoffel theorem for the transformation of polygonal boundaries was given by Professor Palmer, who described the field about a capacitor.

Professor M. G. Malti (Cornell University, Ithaca, N. Y.) emphasized the difficulty of depicting the field in more complex arrangements, but Doctor Poritsky explained that at least approximate solutions always can be given by a proper combination of graphical and analytical methods. Professor Edward Bennett (University of Wisconsin, Madison) stressed the value of field methods in connection with research on antenna fields conducted under his supervision. Professor C. L. Dawes (Massachusetts Institute of Technology, Cambridge) emphasized the value of conformal representation in teaching electrostatics where time and labor can be saved to a considerable extent.

Informal group discussions continued after the conference session was formally closed.

## Electrical Apparatus for 3-Phase Arc Furnaces

By N. R. Stansel, Chairman

The first technical conference on electrical apparatus for 3-phase arc furnaces, sponsored by the AIEE committee on electrochemistry and electrometallurgy, was considered by all present to be highly successful, and by its result proved conclusively the value of such an informal conference as a means of disseminating information of use and interest to the engineers concerned, and of provoking a lively discussion on the subject under consideration. More than 100 persons attended.

As arranged by the chairman of the conference, N. R. Stansel (General Electric, Schenectady, N. Y.) the program provided for several brief and informal talks by engineers familiar with various aspects of arc-furnace equipment in which the user was particularly interested. Preceding these discussions, an illustrated talk was given by Samuel Arnold III (American Bridge Company, Pittsburgh, Pa.) concerning modern electrical equipment for arc furnaces.

The kilovolt-amperes required for arc furnaces in accordance with their dimensions and tonnage ratings was discussed by Frank Brooke (Swindell-Dressler Corporation, Pittsburgh, Pa.) and provoked some general comment.

Growth of the multivoltage arrangement for secondary voltages was outlined briefly by C. C. Levy (Westinghouse, East Pittsburgh, Pa.).

A lively discussion was aroused by F. V. Andreae (Ohio Ferro Alloys Corporation, Philo) by his comments on reactance, particularly with regard to the methods of specifying reactance in furnace circuits, and the effects of reactance.

In discussing regulations, F. E. Ackley (General Electric, Schenectady, N. Y.) emphasized some fundamental points in regulation with respect to maximum power inputs to a furnace, that are not always understood by furnace operators. He also described a newly developed electrode regulator.

Remarks concerning electrical protection for furnace circuits made by E. L. McClure (Milwaukee Electric Railway and Light Company) stressed the desirability of using service breakers for short-circuit protection independent of the furnace breaker itself, so as to avoid the problem of having an expensive circuit breaker especially designed for frequent operations.

A résumé of interesting analytical work done by the Detroit Edison Company to determine the size of sub-stations required to feed a given furnace load under prescribed conditions of maximum voltage variation, and what could be done when these prescribed conditions could not be met, was given in an illustrated discussion by L. W. Clark of that company.

**ASTM Awards Dudley Medal.** The American Society for Testing Materials has awarded the Dudley Medal for 1937 to W. H. Swanger, chief of the section of mechanical metallurgy and assistant chief of the division of metallurgy, and G. F. Wohlgemuth, associate metallurgist, of the National Bureau of Standards. The medal, which commemorates the name of the first ASTM president (1902–09), is awarded for the paper presented at the preceding annual meeting that is of outstanding merit and constitutes an original contribution on research in engineering materials. The winning paper, "Failure of Heat-Treated Steel Wire in Cables of the Mt. Hope, R. I., Suspension Bridge," describes the extensive work undertaken at the National Bureau of Standards to determine the causes of the failure.

# Last Call for the Pacific Coast Convention

THE Spokane Section extends a cordial invitation to members of the AIEE and their guests to attend the Pacific Coast convention in that city, August 31–September 3, 1937. As announced in the July issue, convention headquarters will be in the Davenport Hotel. A technical program has been arranged with papers on a wide variety of subjects, which will be presented by well-known Institute members. Social and recreational activities include a reception and dance, banquet, and golf; and a special program has been arranged for women guests. Inspection trips will be provided to points of interest.

The excellent possibilities for recreation and relaxation afforded by Spokane and nearby territory should induce many members and their families and guests to spend a few extra days in the city or at nearby lakes and resorts. There will be ample opportunity to use fishing tackle and golf clubs.

### Program

The tentative program published in ELECTRICAL ENGINEERING for July, page 911, is now the final program, with the following changes: The subject "Lighting the San Francisco-Oakland Bay Bridge" will be given as an address by C. R. Davis, and will not be published in advance. The sports committee has found it impossible to hold the golf competition on Wednesday afternoon, as originally planned. Therefore, the golf and banquet will be held on Thursday afternoon and evening, respectively, and the session on electrical machinery and the conference on electric house heating have been transferred to Wednesday afternoon and evening, respectively.

### Recreation

The golf tournament will be held on one of the several beautiful courses in Spokane. Arrangements may be made for members and guests to play at other times when desired.

Competition for the John B. Fisken Cup will be medal play on handicap in foursomes and will be open to members of the Districts 8 and 9 only. This perpetual trophy cup was donated by the electric utilities of the District 9 some 25 years ago, and competition for it has been very keen each year. Competition for a number of other golf prizes will be open to members and guests.

Excellent facilities for tennis playing are available within the city. Swimming, boating, and fishing may be enjoyed at any one of the many lakes and streams within a short distance of Spokane.

### Entertainment

On the first evening of the convention a reception and informal dance will be held in the headquarters hotel. This will provide opportunity for all to meet other delegates and officers, renew old friendships, and make other contacts.

The convention banquet and presentation of golf prizes will be on the third evening of the program. A number of interesting activities have been arranged for the women.

### Women's Program

The women's program committee, Mrs. L. R. Gamble, chairman, has arranged a number of parties in addition to the reception and dance and the banquet. These parties include a scenic trip through the home and civic gardens of Spokane, followed by an afternoon tea, putting and approaching contests for a number of prizes, a musical tea, and a luncheon and bridge tournament.

The many fine home gardens in Spokane will be an added attraction. The inspection trips also will hold the interest of many of the women guests.

### Inspection Trips

Probably of interest to the greatest number of members will be the inspection trip to the Grand Coulee Dam area. Construction work on the dam is going ahead rapidly and it is probable that at the time of the convention the entire foundation will be in place. At the present time the Columbia River has been diverted from the original channel and is flowing over some of the foundation blocks. The trip will include the model engineers' town, the contractor's electrically heated construction camp at Mason City and a ride through the several boom towns adjacent to the workings.

The inspection trip to the Coeur-d'Alene Mining District is of great scenic value, the road following the shore of Lake Coeur d'Alene to Wolf Lodge Bay and along the route of the Captain John Mullan military road through Fourth of July Canyon. In this area are found such great silver and lead producers as the Bunker Hill and Sullivan, the Hecla, the Morning, and the Sunshine mines. In Government Gulch is located one of the world's largest electrolytic zinc plants for the treatment of zinc ores. This plant is now being enlarged.

Special arrangements may be made for additional trips to nearby points of interest including the following: Long Lake and Little Falls hydroelectric plants of the Washington Water Power Company; Up-River hydroelectric plant of the City of Spokane equipped with Kaplan automatic adjustable-blade turbines; Clearwater electrified lumber mill at Lewiston; Inland Empire paper mill in Spokane; KHQ radio tower, tallest unguyed tower (828 feet) in the United States; and Comstock Park and Swimming Pool, Spokane.

### Joint Session With Radio Engineers

The Pacific Coast meeting of the Institute of Radio Engineers will be held in Spokane, September 1 and 2, concurrently with the AIEE convention and in the same hotel. Although the meetings of the IRE and the AIEE will be conducted separately, members of either organization will be welcome at the technical sessions of the other group. As previously announced, a joint session is planned for presentation of papers of interest to members of both institutes.

In addition, the inspection of Spokane's 4 broadcasting stations arranged by the IRE will be interesting to AIEE members who have not previously witnessed a broadcast.

### Hotels and Registration

All members who have received the advance registration card and who plan to attend the convention are urged to co-operate by immediately filling in and mailing the card, if they have not already done so. There is no registration fee for members or their immediate families or Enrolled Students. Nonmembers will be charged a registration fee of $2.

This card contains space for requesting hotel reservations. It is extremely important that this part of the card be filled out, because all available accommodations are expected to be taken during the convention. First and second choice should be given. Members who have not received an advance registration card and who plan to attend the convention should write promptly to D. H. Olney, chairman of the registration committee, care of Washington Water Power Company, Spokane, Wash., indicating the number of reservations desired, first and second choice, and the rate.

Rates in some of the leading Spokane hotels are:

| Hotel | Room for 1 | Room for 2 |
|---|---|---|
| Davenport (Headquarters) | $2.50–$4.00 | $4.00–$15.00 |
| Spokane | $2.00–$4.00 | $3.00– $5.00 |
| Desert | $2.50–$4.00 | $3.00– $5.00 |
| Coeur d'Alene | $2.00–$4.00 | $3.00– $5.00 |

Members should register upon arrival at the Davenport Hotel, official headquarters; registration will begin at 9:00 a.m., August 31.

### Student Activities

Besides the regular student conferences, the program includes 2 student technical sessions. Students will be welcome at all convention activities, including technical sessions, entertainment, and inspection trips. It is the hope of the Spokane Section that there will be full participation on the part of student delegates.

Special arrangements are being made for student housing facilities whereby students may have accommodations for $1.00 per night. Splendid auto camps are available for those who wish to use them. In sending in advance registration cards students should note the type and approximate price of accommodations required so that arrangements can be made in advance. They should also indicate whether transportation is desired for either or both of the major inspection trips.

# Divergent Views Expressed at Sessions on Institute Activities

DISCUSSIONS embracing widely divergent views featured the 2 general sessions on "Institute activities" held during the AIEE 1937 summer convention under auspices of the special committee on Institute activities appointed early in the year by President MacCutcheon. The first session was held on Wednesday morning, June 23, immediately following the presentation of the address "The Engineer in a Changing World" by Doctor Ralph E. Flanders (published elsewhere in this issue). The second session was held Thursday afternoon, June 24. These sessions were organized under the general chairmanship of H. S. Osborne, chairman of the committee; Director L. W. W. Morrow, and Past-President D. C. Jackson, respectively, presided at the 2 sessions.

At the first session, prepared discussions were presented by the following: Past-President A. W. Berresford (read by Past Vice-President G. G. Post); L. A. Doggett, past chairman of the committees on education and Student Branches; J. L. Hamilton, chairman of the committee on electrical machinery; F. R. Innes, past chairman of the Chicago Section; Vice-President Mark Eldredge; and Past-President J. B. Whitehead. During the second session, various interested members presented informal discussions from the floor. For the benefit of Institute members who did not attend the convention, full texts of the prepared discussions are published here.

## Institute Programs

By A. W. Berresford

My understanding of the purpose of this session is to obtain opinion as to the direction and degree in which Institute programs (and in "programs" I include activities) may profitably be extended.

In any such consideration one's thought reverts almost instinctively to social and economic problems. The years since 1929 have stressed them in degree unprecedented in the history of the Institute and many of them involve elements with which the engineer is familiar. Under these conditions nothing is more natural than that question should arise as to whether advantage would accrue to the Institute as a national body, and to its members as individuals, if consideration of and action on these public questions were accepted as an appropriate function.

Briefly stated, the objects of the Institute are the advancement of the theory and practice of electrical engineering and the maintenance of a high professional standing among its members. That it has achieved a notable accomplishment in its more than 50 years of life, and largely through adherence to these constitutional provisions, will, I believe, be generally conceded. To depart from them calls therefore for serious consideration. On the other hand, if actual advantage to the membership resides in such departure, or if the opportunity for the rendering of a real public service is presented, there should be no hesitancy. It may possibly be that some of the proposals of which I have heard could, by interpretation, be included within the present language of the Constitution, but this seems immaterial. The decision to undertake new activities is the important factor, not the question of whether or not the Constitution must be changed to permit.

It seems to me that there can be no doubt of the desirability of planned and intelligently directed discussion of these matters of public concern by the Institute membership. If no more were accomplished than the inevitably resultant self-education in the pertinent conditions, and the application of engineer thinking thereto, there would be ample warrant for the time and effort expended. If in addition the solutions evolved were of such nature and importance as to influence the thinking of other parties in interest, a definite public service would be rendered.

In my belief, however, if there is to be such practical accomplishment, the activity must begin and, at least for some years, be prosecuted locally. Only in localities can there be first-hand individual contact with the problems involved and really intelligent evaluation of all the elements which affect the ultimate decision. Moreover, an incentive to continuing interest and effective action will be needed, and this is better generated and maintained when individual welfare is directly affected than when the problems partake more of the abstract.

Such organization has had definite influence in public affairs in many places in matters involving engineering, and there is no reason for assuming other than equal influence in social and economic problems; granting only an equal intelligence, understanding, and application.

A notable instance is present, curiously enough, in the city in which we are convening. The Engineers' Society of Milwaukee, in which all of the local sections of the Founder Societies are affiliated, has for many years considered each public proposal which carried engineering content and has formulated and expressed its opinion thereon. The value of that opinion has come to such recognition that in many instances—if not in every one—the city authorities have requested it and have acted only after its receipt. In many cases it has been determinative.

Here then is one way in which both the members and the public can be advantaged by engineer consideration of these questions. If such an effort were instituted in as many as possible of the political divisions and subdivisions of the country, can there be doubt of a rapidly widening public appreciation of the engineer and of growing national prestige and recognition?

On the other hand, frankly, I doubt the possibility of directly exercising a national influence save through the foregoing procedure. The obstacles lie, not in the successful evolution of solutions, but in the securing of their adoption by the other parties in interest. Usually these are composed of people who are comparatively unskilled in the specific subject, and to whom it is of relative rather than primary importance. This would not be the case if the engineer were politically significant. But he is not. He casts perhaps 200 thousand votes out of a total of 40 to 45 million.

Unless the proposal or solution he offers is so novel and forthright as to acquire immediately "head-line" prominence (and the improbability of this is evident) the engineer alone can do little toward forwarding enactment.

It is a political axiom that the public seldom weighs the facts—that it responds only to an appeal to the emotions or the pocketbook. It is my own belief that action is finally based not on the quality of thinking, but on the quantity. Only through allying himself with others can the engineer obtain the necessary quantity, and he will succeed in so doing only in the degree that self interest is evidently absent. He will be welcomed as a consultant and adviser, but will attain prominent participation only if his individual personal qualifications indicate it.

These qualifications will, necessarily and rightly, be exterior to his purely engineering attainment. They will involve political vision, administrative experience and diplomacy in operation much more than they will the technical aspects. The economist may be necessary to the solution and the engineer valuable in making it effective and practical, but its acceptance will demand the methods and experience of the politician.

Even more will these conditions apply in any effort to locate an engineer in prominent relation for the reason that he is an engineer, and that the functions to be performed are basically engineering. Again the demand will be for general qualification rather than specifically technical ones.

If I am right in the foregoing, does there lie any advantage to either the Institute or its membership in including in its national program activities which promise so little of success through its own efforts? How much of real effect in a national, social, or economic situation would be a statement of Institute opinion unless pressed by political activity and through political alliances? And if these are employed may not the resultant disadvantages quite outweigh the gains? In such a relation the Institute must anticipate being classed with those organizations which exist for material ends and may well be obliged to sacrifice some portion at least of its present nonprofit status with its accompanying advantages. Decision should be reached neither hastily nor lightly.

## Institute Activities

By J. L. Hamilton

I think it will be generally agreed that during the last 50 years the Institute has served its purpose and has done a splendid job. This period has been one of technological development, and the Institute has fostered that line of work to a remarkable degree. A discussion yesterday showed that we have not reached 100-per cent perfection; we never will, but by and large a very good job has been done.

We seem now to be living in a new world, a world that is moving more rapidly than

any of us has seen or observed before, and we naturally are wondering what we are to do about it and what part we should take as engineers. We seem to have reached the inquiry stage as to what is going on and how we are going to fit into this developing picture. First, in any problem there is the will to do and the need of doing, and second, is the ability to carry out that will. It would seem that we have reached the stage where there is a will to do something about it, and that is most encouraging.

President MacCutcheon, you will recall, on Monday morning outlined his work of the year, and particularly his visits to all the sections of the country, and he brought to us a summary of the messages which he received from the crossroads, if you please. I consider that message of special significance to us in connection with the subject we are discussing here now.

In the East a few weeks ago I heard a very profound discussion by profound thinkers, or at least as profound as we have in the country. It was on the success that the New Deal has had; and, whether we are New Dealers or not is beside the point, the New Dealers do know what is going on at the crossroads, not only at *some* of the crossroads but at *all* of the crossroads, and they have the ability to interpret and put into words what is being discussed at the crossroads.

To my mind the important thing before this Institute is the matter of procedure. Do we want a planned economy in the Institute? Do we want our present committees, as efficient as they may be, and our board of directors to shoulder all the problems? Is it fair? Do we not want to get the crossroads working and get this information correlated?

I recently heard a very splendid executive on business reorganization and rejuvenation make this rather interesting statement. He said: "If you want to know how to sell more goods, the chances are you cannot pull it out of your own gray matter entirely. Call in your salesmen from the field. Get them around the table. Have them tell you how to sell more goods. They can tell you more in a half-day discussion than you and your staff can develop in months and months of effort."

Can we not take a cue, therefore, from what efficient business men have found true in this respect? Can we not organize so as to get the crossroads working and get their views reflected and incorporated in what we want to do, to a greater extent than at present? Some of the matters that have been discussed by Doctor Bush and Doctor Flanders and others are certainly right along this line. They have indicated that we should have the will to carry out some of these things. Here we are suggesting one possible way of fulfilling that will by getting all of our membership to work.

In the Army—as you know there is perhaps the oldest type of organization we have—we have what is called the staff and the line organization—one to plan and one to carry out. As we sense it, do we not have a splendid line organization? Imperfect though it is, it has done a splendid job. Perhaps our problem now is to develop more of a staff organization, an organization to pick up what is being thought at the crossroads and translate it into policies for our line organization to execute; and will not such a program as this be very beneficial in helping us to our goal, that is, to know more about commercial engineering, if you please, to know more about management engineering, more about executive engineering, more about government, and more about our 2 newest sciences of which we are still profoundly ignorant, namely, economics and psychology?

## Institute Publications

By L. A. Doggett

Dean Potter entitled his 1933 presidential address before the American Society of Mechanical Engineers, "Whither Engineering?" In the present article a brief survey of the publications of the American Institute of Electrical Engineers has been made in order to describe their course to date and their present status. Such a study is essentially a study of both the meetings and the publications of the society because the published matter closely reflects the whole activity of the Institute. In short, "whither publications?" or "whither Institute activities?" means approximately the same thing.

### Historical Survey

The publications of the AIEE from 1884 to 1902 reveal that the membership in that period was almost wholly interested in technical matters. Between 1902 and 1911 the same situation existed except for 5 papers on the conservation of national resources and a paper by Henry Floy on "The Engineer's Activity in Public Affairs, Public Utility Commission, Franchise, Valuations." In this period a code of ethics was initiated and later adopted.

From 1911 to 1917 considerable activity occurred in the discussion of matters of public interest and of economic content. For example:

June 1910: Conservation of Water Powers, L. B. Stillwell
June 1911: Depreciation, Henry Floy
August 1911 : Electrical Engineers and the Public, D. C. Jackson
September 1911: Appraisals, H. M. Byllesby
December 1911: Report on Water Power Development
Public Policy Committee
June 1914: Evolution of the Institute, C. O. Mailloux
January 1915: Rate System, O. B. Goldman
January 1915: Control of Public Utilities, F. G. Baum
July 1915: Class Rates, F. G. Baum
September 1915: Inventories and Appraisals, C. L. Cory and others
October 1915: Rates, P. M. Lincoln
October 1915: Public Utility Management, P. J. Kealy
February 1916: Municipal Operation, A. G. Christie
April 1916: Water Power Development, G. Dunn
November 1916: Inventory and Appraisal, P. Betts
November 1916: Continuous Inventories, H. E. Carver
November 1916: Growth and Depreciation, J. Loebenstein

From 1918 to 1937 papers of economic content and papers dealing with public questions have been almost negligible in number. From time to time, however, an occasional president of the Institute has dealt with public questions in his presidential address. In the last few years among the "Letters to the Editor" the membership has shown a very decided tendency to think more and write more on social and economic questions.

The historical picture is one of continuous and almost complete devotion to technical subjects except in the 1911–17 period. Thus for over 50 years the Institute has preserved its policy of "scholarly isolation." Within the bounds of this single objective the publications of the AIEE present a record of technical accomplishment of which the members can well be proud.

### Present Condition

In the last 5 or 10 years the answer to "whither publications?" is fairly specifically answered by the code of the AIEE technical program committee. This committee is a development of the old meetings and papers committee. Although the code of this committee has never been adopted in the sense that the code of ethics was adopted, it does represent the outgrowth of a long period of experience both in the old and in the new committee. This code includes a 15-item list of "acceptable subject matter" and a 4-paragraph list of "subjects not suitable for Institute presentation." Without taking the time to quote these in detail, the intent was primarily to fix the metes and bounds of the Institute publications, restricting them very definitely to electrotechnical subjects. Some latitude was allowed, however, in the inclusion of related technical fields. Item (*k*) put the stamp of approval on applications of electricity to social purposes and item (*o*) on ethical and social aspects of the profession.

### Suggestions for the Future

Before hazarding any suggestions, some review of the past as presented is in order. It seems that there is a distinct similarity of performance in all the engineering societies. A study of the record will disclose that engineers have shown little inclination to interrelate their activities with the whole of life and to deal with the reactions of their activities upon the community. In some quarters they have been described as mere technicians. Almost the whole record is characterized by engineering remoteness. Engineers have built around themselves a high wall outside of which some of our fraternity are well qualified to venture or over which some of us might well cast an occasional glance.

The effect of the recent depression upon the public at large has brought to the fore a definite criticism of the scholarly isolation policy of the scientist and the applied scientist. It is said: "They have applied themselves too narrowly." The opinion of the layman is that the scientists are responsible for the social and economic consequences of their advancement of the theory and practice of their particular branch of science. In President Roosevelt's October 7, 1936 letter to those in charge of technical education, he mentions "the social responsibility of engineering" and says that engineering must "consider social processes and problems and must co-operate, in designing accommodating mechanisms to absorb the shocks of the impact of science."

Dedication to public service is one of the chief requirements of a profession. This dedication is not unrelated to professional recognition. It is therefore suggested that

the Institute rededicate itself to the public welfare in its broadest implications. The appointment of an AIEE national power policy committee is suggested. It is further suggested that engineers should not labor exclusively within their own hereditary field; that they should not ignore the criticisms of laymen in other fields; and that they should not continue their scientific detachment and remain unconcerned with the human relationships of their activities. The Institute might well appoint a public relations committee to find ways and means to interpret the engineer to the public.

Lastly and specifically it is suggested that the publication policy strive to increase the percentage of papers on social and economic subjects. This is nothing new to our Institute as evidenced by the 1911–17 group of papers and this is in no way inconsistent with the code of the technical program committee as stated in items (*f*), (*k*), and (*o*).

## Social Responsibility of the Engineer

By Frank R. Innes

By a vote of practically 10 to 1 a group of some 180 engineers in attendance at a joint meeting of the AIEE Chicago Section, and of the electrical section, Western Society of Engineers in Chicago, March 22, this year, went on record in favor of "vigorous, effective action" by the professional engineering society in national affairs of engineering nature within its particular field. This vote was taken after the presentation and discussion of 2 papers, the first on the general aspect of the responsibility of the engineer in social and economic matters by Mr. P. B. Juhnke, and the second by your present orator on the specific responsibility of the electrical engineer in electrical-engineering matters that now occupy the forefront of national attention.

This meeting was planned to elicit indications of interest or the lack of it from the rank and file of engineers on, first, whether or not social and economic questions should be discussed at engineering meetings and, second, whether or not the professional engineering society should actively concern itself in national affairs within its technical scope. A ballot was taken on the 2 questions. The vote on the first was: "Yes," 186; "Yes, with reservations," 3; and "No," 2. On the second question, that of active participation of the engineering society in national engineering affairs, the vote was: "Yes," 158; "Yes, with reservations," 10; and "No," 17. This vote indicates positively that the engineer is interested in social and economic matters and wants to discuss them. It also indicates, almost as positively, that the engineer wants his professional society to represent him and act for him in national affairs.

Many of us self-appointed spokesmen for our profession have been talking about the social responsibility of the engineer. We have spoken in general and nebulous terms that are in themselves a denial of the engineering method we recommend. We cannot hope to be taken seriously in our assertions of the superiority of the engineering approach for solution of the social and economic problems of today unless and until we actually use that approach in our consideration of these problems and really begin to work on them in engineering fashion.

The engineering approach to any job is to resolve the job into its component parts so that the problems of each part may be handled and solved by minds qualified by training and experience for that particular work. Each kind of engineer works in a definite field. It is in this familiar way that the engineer must go to work on the big job of solving the social and economic problems that confront him.

We are electrical engineers. What is our share in this big problem of the social responsibility of the engineer? Obviously it is that part which involves electrical engineering. And to what aspect of that part should we give our first attention? Obviously again, we should give our first attention to that affair of electrical engineering in which government is now most active and in which the nation is now most interested. We are being asked by voices from outside our technical ranks to take action in this particular matter.

Doctor Raymond Moley in a recent issue of the magazine *Today* puts up to us this question: "All of us who are not engineers have been taught to believe that water power is the cheapest and most efficient and most permanent source of electrical power. Are we right or have we put our faith in a delusion?"

In various forms this question is appearing more and more in the public prints, as, for instance, in a Chicago Tribune editorial "Forty Years Behind," in which the government is charged with not being up-to-date in its power program. I have seen the same subject treated in other newspapers. I recently received a letter from Mr. Wesley Winans Stout, editor of the *Saturday Evening Post*, in which he stated he had editorialized on this subject 10 years ago.

Well, since the engineer as a professional class is being asked by the world outside to do something about this water-power matter, and since it is indicated by the vote in the Chicago meeting that the rank-and-file engineer wants something done, just what can the American Institute of Electrical Engineers do? This also is obvious. The Institute can examine the water-power program of the government and report on it to the nation commending what is found worthy in it and condemning what is unworthy.

Specifically, the Institute should investigate and report on criticisms of the program that are commonly current among engineers. Some of these criticisms are:

1. The only markets for the outputs of some of the government plants are those which can be taken away from existing utilities, the government thus endangering the investments of its citizens. Most of the other government plants are so remote from possible markets that it can be said for them that markets do not exist.

2. Today electricity can be supplied just as, or more, cheaply from fuel power plants close to the load than it can from remote water powers with long transmissions. It costs less to haul coal than to transmit electricity.

3. Water power, from an efficiency standpoint, is practically a completed art. At the same time its competitor, steam power, though less efficient on a thermal basis, has already surpassed it considering over-all plant economy. And the opportunity for further economy in the steam plant is very great.

4. Building water-power plants may aggravate the unemployment problem. It largely reduces plant operating labor and eliminates entirely labor for production and transportation of fuel.

5. Financing periods of half a century, which seem necessary to justify projects in the government program, appear indefensible in this day of rapid technical development.

These are the opinions of many engineers, not mine only. Probably there are some engineers who may see merit in the government program of water-power development, but I think all will agree that some of the criticisms mentioned may be justified in sufficient degree to warrant investigation and report to the people.

To be definite, I suggest that the Institute establish committees or boards of competent engineers to study and report on government projects of an engineering nature or to initiate and assure such studies by American Engineering Council or other co-oper ve agencies. Due to political emphasis on hydroelectric projects at this time it seems logical that this subject should receive first consideration. The findings of these investigations should be given the widest possible publicity.

It is a good thing for us to talk about the social and economic responsibility of the engineer, but it is a better thing for us to *do* something about it. The nontechnical world is asking us to act and the members of our professional organizations are telling us to act. Apparently then, we should act.

## Institute Programs

By Mark Eldredge

Programs for many organizations are arranged with the purpose of being interesting, but the subject for discussion puts the emphasis on "value to the membership," and that is the thought in these remarks.

We have 19 technical committees, all producing papers of keen interest to those members whose work lies along the lines of the specific subjects treated. These papers presented on Institute programs are not only interesting but are valuable to many of us because of the things we learn that have application in our individual fields of endeavor. Their value is measured in terms of our jobs which are so absorbing that frequently they are the beginning and end of our existence. Sometimes I think we engineers are like a colony of ants going here, going there, doing this, and doing that. We seldom take time to stand off and view in perspective the whole big job of living and note the part we play. Are we helping to build an ant hill or a path to a higher point? Do we comprehend where this or that new engineering development is taking us? Most of us are so absorbed in the daily routine that we give little thought to the part our own contribution to life adds to the world's real progress, or, if conscious of progress, we seldom consider the trend and whether the direction is right.

It seems to me there is one certain type of papers that would be most valuable to us all. Such would be studies or research on the effects certain details of technical progress have on general progress and improvement of human well-being. Since the first of the year, we have had some excellent general papers, such as, M. E. Leeds' "Engineering and Economics," John C. Parker's "Power and People," Harold G. Moulton's "Engineering Progress and Economic Progress," and R. C. Muir's "Some Engineering Contributions to Society." Between these

and the strictly technical papers lies the field I have in mind—papers that show the wide-reaching effect specific engineering achievements have had on social or national progress. In some cases, a chain or sequence of applications of some modern discovery might be shown to have had a very marked influence on the world. To be more definite, consider what a very romantic story might be told of the development of electron tubes; but, more important, what an amazing story might be unfolded of what they have already done to change and, we hope, to improve civilization. We can surmize some of the effects, but the results of research along this line might make a program of greatest value to the membership. It might awaken in us a greater realization of our ability to benefit the world.

Take another possible subject for a paper or a program: The discovery of a light-sensitive element made possible the light meter, which is doing so much to make people light conscious. What economic reaction is observable? Would not our lives be more purposeful if, while doing our routine tasks, we turned our thoughts more often to a consideration of the influence our particular bit of engineering progress is having on the world about us?

## AIEE Tradition and Policy

By J. B. Whitehead

For a number of years there has been increasing comment that engineers should take greater part in the discussion of questions of public interest and in the direction of certain types of public affairs. Such comment has often been heard within the AIEE, and more recently discussion and resolutions have been introduced into meetings of the board of directors proposing the formation of active committees not only for stimulating such discussion, but even proposing that the Institute should expend money and effort for examinations and investigations, and take public position on certain questions, in many instances necessarily, from their nature, of controversial character.

The Institute has so far, throughout its long and successful life been a conservative professional body devoted to the advancement of the electric art. It is the conviction of many of its members that its very life blood from the beginning has been its constant production of high-grade technical and scientific papers. It is certain that most of the young men who come into the Institute, and who ultimately become useful members, are those who are attracted by our strictly professional activity. Constructive and creative members of the Institute are almost invariably from this class. Few people will question that the high and strong position of the Institute throughout its more than 50 years of life, and its present healthy condition are due to its traditional policy of adhering to its fundamental purpose, "the advancement of the theory and practice of electrical engineering."

It becomes of great importance then to examine carefully any proposals for departures from our traditional policy. A review of some of the subjects that have been proposed for examination and discussion by the Institute, as a means of broadening its activities, reveals a startling conception on the part of some of our members of its proper range of discussion and action. One formal proposal that the Institute take a more active part in the examination of questions of the day lists among others the following: the effect of increase or decrease of values upon the workings of the national productive plant; comparison of American and Old World state of prosperity, and causes for the difference; the effect of unearned increment upon the state of American prosperity; the pros and cons of taxation; governmental efforts to regulate farms; better control of industrials; the overexpansion of productive facilities in utilities and railroads and the possibility of their regulation; the effect of regulation which destroys values, etc. Incidentally, it is proposed that the discussion of these questions should be free of political aspects! Another contributor suggests that a quarter of the activities of the Institute be devoted to the discussion of sales and commercial activities. Another wishes to see symposia for the discussion of all types of federal relief programs. Still another wishes to discuss, and presumably that the Institute should make public utterance on, the registration of engineers, the principles underlying public-works projects, the development of of engineers' unions and the depressing effect of federal power policies. Engineering examinations and public reports by the Institute on the Passamaquoddy and Fort Peck projects, and indeed on hydroelectric power in general, are seriously proposed.

In fact, if the complete list of all the proposals that have been made were given, it would be seen that there are few questions of the day, on whatever subject or of whatever character, which are not seriously proposed as proper matter for the expenditure of time, effort, and money by the membership of traditionally conservative AIEE. Here then are proposals from our own members for very radical expansions of our programs and wide departures from our avowed purpose of the advancement of the electric art and profession. We may well pause for a brief word of examination and comment.

No one will question the importance of every one of these problems and the interest in them of every good citizen. Every one of us would certainly wish to be identified with any movement which seemed likely to arrive at proper solutions of, or even to throw important light on, any of these contemporary problems. Especially so in these New Deal days when we so often experience irritation and impatience that so many of our public questions are settled, and public enterprises begun, without the careful study and examination which the engineer likes to see for all new undertakings.

The question, however, is where to begin and how to proceed? In most such problems great uncertainty exists as to essential fundamental facts, and premises based on recognized principles are not evident. Owing to their contemporary character, the causes giving rise to these questions are obscure, differences of opinion pronounced, and the elements of personal and group material and political advantages enter. How can an engineer deal effectively, even to his own satisfaction alone, with questions so involved in obscurity? The answer is that he cannot. Given the time and money, he might, it is true, examine a concrete government undertaking such as the Passamaquoddy power project, and even its economic feasibility; but would that answer the still deeper question of the validity of the government's purposes in undertaking it? Where would AIEE get with an examination of the Tennessee Valley Authority and its activities, when there are differences within its own board of engineers as to its proper development, and when there are questions between TVA and local power companies which have advanced through all legal stages up to the Supreme Court of the United States?

To my mind there are 2 very simple answers to the often repeated questions as to why an engineer does not take a more prominent part in public affairs. The first is that public questions are never sufficiently concrete, nor clearly defined, to permit quantitative determination, or even an enumeration of fundamental factors or elements. Second, even where such questions approach the tangible and concrete, it is by no means certain that legislation or public action will not be based on political expediency or group interest, rather than in accordance with correct economical engineering plan. Engineers are primarily rational and honest, and these virtues are not always at a premium in our present methods of solving contemporary public questions.

As contrasted with these extreme proposals, it is worth while to recall a report on Institute policy made to the board of directors in 1931 by National Secretary F. L. Hutchinson. The subject of the report was the desirability that the Institute's activities be extended in certain directions. The headings in the report indicating these suggestions, were as follows: Legislation Affecting the Engineering Profession; State Councils of Engineers; The Economic State of Engineers; Employment Service; Education of the Public Regarding the Engineering Profession; Engineering Education; Extension of Institute Work Throughout the Membership.

Not much suggestion here of the diverse economic, social, and political questions referred to hereinbefore. Moreover, it is a fact that every one of the subjects mentioned in Secretary Hutchinson's report is now being handled by well-organized committees, either of joint character with other societies as in American Engineering Council and Engineering Societies Employment Service, or within normally constituted committees of the Institute.

Happily, the extreme broadening programs mentioned have not been received with very wide acclaim, and those advocating them have taken a more moderate position recently. On the other hand, greater opportunity within the Institute for the discussion of questions of public interest, particularly where they touch the engineering profession, has been very extensively advocated. We have already taken some steps in that direction. And we are here today to discuss advisability of even further moves. Let us examine briefly the origin and character of this movement.

The Institute is open to anyone interested, no matter how remotely, in the development of the electrical art. As a consequence, we have among our members a very wide range of professional ability, attainment, and duty. It is a fine thing that this should be so. The Institute should nurture particu-

larly its lower grades of membership. It needs their support and it needs recruits from their ranks for the working forces of its manifold activities. With the rapid expansion of our industrialization, this group within the Institute has become increasingly large. As it becomes large, it is natural that it should become more vocal. We should not blind ourselves, however, to the fact that its members are not yet completely nor broadly developed professionally, and that their opinions and proposals are often without sound basis in tradition, knowledge, and experience. For example, from this group come those who occasionally raise the question of what they get in return for their dues, mentioning only ELECTRICAL ENGINEERING and the fact that they cannot understand much that it contains. It is a question whether members who persist in this attitude and do not develop in some phase of the Institute's work ever attain full realization of the Institute's high purposes.

It is a day of aggressive democratization and socialization. The great levelling processes that are being urged everywhere, and we are now discussing an example, invariably suppress independent thinking, the application of new knowledge, and the advance of civilization. Witness the widespread suppression of research and initiative in Europe. It begins to look as though the English-speaking races are the only ones in which intellectual liberty can be expected to continue to blossom in the results of scientific effort and experimental research. We must, therefore, look out especially for these dangers not only in our country, but also within the Institute.

Unfortunately such dangers do not always seem to be appreciated even among our older members. Not long ago I heard one of them voice the belief that, being a membership organization, it was the duty of the Institute, and so that of its board of directors, to ascertain the wishes of the greatest number of its members, and to legislate accordingly. This, to my mind, is doubtful doctrine. When it comes to duty, the onus should be on the opposite side, namely, it should be the duty of every member of the Institute to consider that which will best contribute to the maintenance and elevation of its high standing, not only of professional conduct, but of professional achievement. The Institute from its beginning has been primarily a technical, professional, and scientific society. Its usefulness, dignity, and authority will be steadily impaired by just so much as we depart from the pursuit of these high purposes.

We should therefore go slowly with our programs of expansion into general fields. Material for publication, from outside our own ranks, is correspondingly difficult to scrutinize. Our columns have on occasion even been opened, though fortunately not often, to nonmembers with pet theories to advertise or other axes to grind. Committees with a specific broadening purpose to my mind are of doubtful value. Committees do not write or create papers. They look for papers rather than at the quality of material in them. Good papers are produced by individuals, each with a message which must find utterance. Moreover, we already give substantial support to general discussion in that through the publication and education committeees we are devoting to it an increasingly large amount of space in ELECTRICAL ENGINEERING. Much of the material so presented is good, and it seems to me that in these and other available channels, we already have ample facilities for the publication and discussion of general questions of all types.

Let it be remembered also that those public questions which would appear to be better solved by engineers, usually involve engineers of all types, not merely those in the electrical field. Also that a number of agencies such as the American Engineering Council, the Engineers' Council for Professional Development, the United Engineering Trustees, Engineering Foundation, and others, have been set up especially to deliberate and serve us as channels of communication with all forms of public activities involving the interests of the engineering profession and the possibilities of its utilization. Certainly so far as formal expression of approval from the engineering profession on any great public question is concerned, examination and study by one or more of these bodies, and final utterance through them, would have far greater value and authority than if undertaken within a single constituent member society.

What then must be said in reply to the question constituting the subject of this meeting? My answer is somewhat as follows:

Many social, economic, political, and other public questions frequently touch the interests, either material or other, of electrical engineers. Intelligent discussion of such questions by electrical engineers, therefore, becomes both proper and desirable. The Institute already offers high favorable opportunities for such discussion through the columns of ELECTRICAL ENGINEERING, and in the meetings of Sections' representatives at conventions and in meetings in the Sections themselves. I know of no reason why a thoughtful, well-considered paper on any such subject should not be accepted for publication in ELECTRICAL ENGINEERING. It is my belief also that there should be no restriction upon the range of topics discussed at the meetings of Sections' delegates, or in the Sections themselves.

The essential principles to be adhered to in connection with these activities are: first, that the Institute, its Sections, and any gathering of Institute members, must avoid formal endorsement and opinion in the name of the Institute, on public questions of controversial character. Papers and reports should be distinctly under the names of their authors, and submitted for publication through the regular Institute channels. The second principle is that formal papers for publication should be only of the highest grade, always carrying the weight of authority. The grounds upon which these principles are advocated are that questions controversial in character cannot be settled in terms of known facts and knowledge, and lead frequently to differences of opinion, which in their turn, often lead to antagonism as between groups. Such a condition obviously leads to a disturbance of unanimity and that pursuit of common interest which has characterized all work of the Institute in the past.

In my opinion the programs of our meetings are already extremely good. I have little suggestion for their improvement. By all means let us have increasing opportunity for discussion of general subjects in sessions such as the present one. But as regards publication, let there be constant careful scrutiny of papers of both technical and especially those of nontechnical character, so that the quality of both types may be steadily improved, even if the quantity of published matter be thereby reduced.

## AIEE Directors Meet During Summer Convention

The regular meeting of the board of directors of the American Institute of Electrical Engineers was held at the Hotel Schroeder, Milwaukee, Wis., on June 24, 1937, during the annual summer convention of the Institute.

Present: *President*—A. M. MacCutcheon, Cleveland, Ohio. *Past-Presidents*—H. P. Charlesworth, New York, N. Y.; J. B. Whitehead, Baltimore, Md. *Vice-Presidents*—O. B. Blackwell, New York, N. Y.; L. T. Blaisdell, Dallas, Tex.; Mark Eldredge, Memphis, Tenn.; R. H. Fair, Omaha, Neb.; C. Francis Harding, Lafayette, Ind.; W. H. Harrison, New York, N. Y.; C. E. Rogers, Seattle, Wash.; A. C. Stevens, Schenectady, N. Y. *Directors*—F. M. Farmer, New York, N. Y.; F. Ellis Johnson, Columbia, Mo.; C. R. Jones, New York, N. Y.; P. B. Juhnke, Chicago, Ill.; W. B. Kouwenhoven, Baltimore, Md.; Everett S. Lee, Schenectady, N. Y.; K. B. McEachron, Pittsfield, Mass.; L. W. W. Morrow, Corning, N. Y.; C. A. Powel, East Pittsburgh, Pa.; R. W. Sorensen, Pasadena, Calif. *National Treasurer*—W. I. Slichter, New York, N. Y. *National Secretary*—H. H. Henline, New York, N. Y. Present by invitation: *Past-Presidents*—D. C. Jackson, Cambridge, Mass.; P. M. Lincoln, Ithaca, N. Y.; Charles F. Scott, New Haven, Conn. *Officers-Elect*—C. R. Beardsley, Brooklyn, N. Y.; V. Bush, Cambridge, Mass.; F. H. Lane, Chicago, Ill.; M. J. McHenry, Toronto, Ont.; I. Melville Stein, Philadelphia, Pa.; Edwin D. Wood, Louisville, Ky.

Minutes of the meeting of the board of directors held May 24, 1937, were approved.

A report was presented and approved of recommendations adopted by the board of examiners at its meeting on June 16, 1937. Upon recommendation of the board of examiners, the following actions were taken: 4 applicants were transferred to the grade of Fellow; 13 applicants were transferred and 25 were elected to the grade of Member; 116 applicants were elected to the grade of Associate; 88 Students were enrolled.

Disbursements in June amounting to $22,774.41 were reported by the finance committee and approved.

Authorization was given for the organization of a Tulsa (Okla.) Section of the Institute and of a Wichita (Kans.) Section.

Upon request of the committee on safety codes and recommendation of the Institute policy committee, the board authorized a change in name of the former committee to "committee on safety," a change in its activities to the consideration and investigation of matters relating to the protection of persons and property against hazard due to or resultant upon the presence of electricity or the use of electrical apparatus,

material, and appliances, and the inclusion of its chairman among the ex-officio members of the technical program committee. The matter of changing sections 81 and 68 of the by-laws accordingly was referred to the committee on constitution and by-laws.

A special committee on Institute activities had been appointed to arrange for a session at the summer convention for the discussion of the subject of desirable topics for presentation at Institute meetings and for publication in ELECTRICAL ENGINEERING, and to report to the board of directors its reaction to such discussion. The session was held on June 23, and the committee's report thereon was presented. Action was deferred, copies of the report to be sent to the members of the board for study before final consideration.

Upon request, Past-President Charles F. Scott, an Institute representative upon the Engineers' Council for Professional Development, also chairman of that organization, presented a report concerning certain recommendations of the committee on professional recognition of ECPD, which had been submitted to the board of directors for consideration and action. As a result, the board authorized the appointment of a committee of 3 members of the board to study the recommendations and report to the board of directors. The following members of the board of directors for the administrative year beginning August 1, 1937, were appointed members of this special committee: W. I. Slichter (*chairman*), C. R. Beardsley, and O. B. Blackwell.

The board voted to extend an invitation to the members of the International Conference on High Voltage Systems (CIGRE) who may be visiting the United States at the time to attend the AIEE summer convention to be held in Washington, D. C., in June 1938.

In connection with the 1937 summer convention held at the Hotel Schroeder, Milwaukee, Wis., June 21–25, 1937, the board adopted resolutions of appreciation of the effective services of the general convention committee and the various subcommittees, and of the ladies committee, and also expressed its appreciation of the courtesies and assistance extended by the Hotel Schroeder, convention bureau of the Milwaukee Association of Commerce, Allis-Chalmers Manufacturing Company, Harnischfeger Corporation, The Milwaukee Electric Railway & Light Company, Cutler-Hammer, Inc., and Wisconsin Telephone Company.

Authorization was given for the usual allowance for traveling expenses of regular delegates from Pacific District (No. 8) and the University of British Columbia Branch to a joint conference on student activities to be held in Spokane, Wash., during the 1937 Pacific Coast convention, including also the member of the national committee on Student Branches in Pacific District (No. 8). In view of the fact that special action on such joint conference is taken each year, it was voted that a special committee be appointed to study the matter and recommend a permanent policy for inclusion in the by-laws, the committee to consist of the vice-presidents of the 3 Districts concerned, the chairman of the committee on Student Branches, and the chairman of the Sections committee as chairman.

There was an expression of the appreciation of the members of the board of directors of the very faithful devotion of President MacCutcheon to the duties of his office and the large amount of time contributed by him in furthering the best interests of the Institute.

Other matters were discussed, reference to which may be found in this or future issues of ELECTRICAL ENGINEERING.

## New Name and Scope for Safety Codes Committee

The name of the AIEE committee on safety codes has been changed to "committee on safety," and its activities changed to: the consideration and investigation of matters relating to the protection of persons and property against hazard due to or resultant upon the presence of electricity or the use of electrical apparatus, material, and appliances. Its chairman now is to be included among the ex-officio members of the technical program committee. These changes were authorized by the AIEE board of directors at its meeting of June 24, 1937, upon request of the committee on safety codes and recommendation of the committee on Institute policy.

One of the general committees of the Institute, the committee on safety codes was established in 1902, and has functioned continuously since that time. Previously, the scope of the committee, as defined in section 81 of the Institute's by-laws, was to consider and investigate all matters relating to the formulation of rules for the protection of persons and property against fire, accidents, and other hazards in connection with electrical installations and equipments, and to confer with similar committees of other bodies regarding the same.

## Canadian Engineers Celebrate Semicentennial

The Engineering Institute of Canada, founded in 1887 as the Canadian Society of Civil Engineers, celebrated its semicentennial during a series of meetings held in Montreal and Ottawa, June 14–19, 1937. Although the society originally was chartered as a civil-engineering society, by 1918 a much broader scope seemed to be desirable and the name of the organization was changed to Engineering Institute of Canada. Today the organization claims members within almost every class of engineering, and these various interests were reflected in the sessions of the anniversary meetings.

The opening session of the celebration was devoted to greetings from other societies and to the conferring of honorary degrees and awards. President A. M. MacCutcheon was the official AIEE representative at this session. The technical program included 5 sessions at which 22 papers were presented. By way of diversion inspection trips were made to engineering works in the Montreal and Ottawa districts.

## Lamme Medals Awarded by SPEE and Ohio State

In addition to the Lamme medal awarded annually by the AIEE, other Lamme medals are awarded by the Society for the Promotion of Engineering Education and by The Ohio State University, Columbus. These medals are made possible by 3 bequests provided in the will of Benjamin Garver Lamme (deceased July 8, 1924). As reported elsewhere in this issue, the AIEE Lamme medal for 1936 was presented to Doctor Frank Conrad (A'02) during the Institute's recent summer convention at Milwaukee, Wis.

The SPEE awarded its tenth Lamme medal July 1, during its convention at Massachusetts Institute of Technology, Cambridge, to Dean Frederick E. Turneaure of the college of engineering of the University of Wisconsin, Madison, "for his influence upon the policies and people of the college of engineering of the University of Wisconsin; for his conception of a university as a co-operative enterprise of scholars and disciples in which freedom and power to initiate is diffused, not centralized; for the spirit of steadiness and confidence he has engendered; for the harmonious and co-operative relations within faculty and between faculty and students that have matured under his leadership; and in recognition of the high place he has filled in engineering education and in public estimation not only in his commonwealth but in the nation as well." Dean Turneaure was born on a farm near Freeport, Ill., July 30, 1866; graduated in civil engineering from Cornell University, Ithaca, N. Y., in 1889, and immediately engaged in railway engineering work; became an instructor in civil engineering at Washington University, St. Louis, Mo., in 1890; has been affiliated with the University of Wisconsin since 1892, since 1904 as dean of engineering. He is a past-president of the Society for the Promotion of Engineering Education (1908–09) and was a member of the board of investigation and co-ordination which directed the comprehensive study of engineering education carried out by that society from 1923 to 1929.

Two Lamme medals were awarded this year by The Ohio State University. One medal went to E. C. Bain, metallurgist and assistant to the vice-president of the United States Steel Corporation, New York, N. Y.; the other to Ellis Lovejoy, consulting engineer in ceramics, Columbus, Ohio. These medals were presented at the 1937 commencement exercises of the university, and, in accordance with the stipulations governing the awards, both are Ohio State graduates. Doctor Bain received the degree of bachelor of science in chemical engineering in 1912, master of science in 1916, and chemical engineer in 1923 from Ohio State. He received the honorary degree of doctor of engineering from Lehigh University, Bethlehem, Pa., in 1936. He has been engaged in metallurgical research for 15 years and is said to be the youngest engineer to receive the Ohio State Lamme medal. He was awarded the Robert W. Hunt medal of the American Institute of Mining and Metallurgical Engineers in 1929, and was Howe Memorial Lecturer of that society in 1932. Doctor Bain has

made important contributions to literature dealing with application of X rays in metallurgical research, the heat treatment of metals, and particularly the development of stainless and heat-resisting steels. He is president of the American Society for Metals. Mr. Lovejoy was graduated in mining engineering from Ohio State in 1885, 10 years before the department of ceramic engineering was established. He has spent more than 50 years in engineering research, invention, and management with the ceramic industry, and has been a consulting engineer in ceramics since 1904. He is the inventor of several original ceramic products, and the author of a number of papers, discussions, brochures, and books on various phases of the ceramic industry. He is a past-president of the American Ceramic Society.

## Middle Eastern District to Meet in Akron, Oct. 13–15

A 3-day meeting of the AIEE Middle Eastern District will be held in Akron, Ohio, October 13–15, 1937. Tentative arrangements indicate that an interesting program will be developed. Akron is a large industrial center and cognizance of such subjects as electrical applications in the rubber industry, lighting, and radio tower insulators, as well as the possibility of electrical applications for the production of iron and steel, will not be overlooked.

In addition to the technical sessions, arrangements will be made for entertainment events and inspection trips to places of interest in the vicinity. Other details will be announced when available.

Members of the Middle Eastern District meeting committee who are making the arrangements are as follows: Harold L. Brouse, *chairman*, I. Melville Stein, H. A. Dambly, A. G. Ennis, Paul Frederick, W. H. Harrison, W. C. Kalb, E. E. Kimberly, E. O. Lange, and O. C. Schlemmer; the following are chairmen of the committees indicated: A. O. Austin, meetings and papers; R. A. Hudson, entertainment and reception; H. H. Schroeder, attendance and publicity; H. C. Paiste, transportation and inspection; V. W. Shear, hotels and registration; J. T. Walther, student activities; Ralph Higgins, finance.

## Lamme Medal Nominations Due November 1

Attention is called again to the opportunity open to any member of the Institute to submit nominations for the 1937 Lamme Medal. All nominations must be received not later than November 1. (For further particulars, see ELECTRICAL ENGINEERING for June 1937, page 756.) The 1936 Lamme Medal was presented to Doctor Frank Conrad, assistant chief engineer of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., at the opening session of the recent AIEE summer convention in Milwaukee, Wis.

## ECPD Publishes Engineering Bibliography

The committee on professional training of the Engineers' Council for Professional Development has just published 5 pamphlets which, taken together, should prove helpful to those in search of competent guidance in engineering literature. Primarily intended to aid the beginning engineer in choosing his reading, the lists should also be of service to librarians as guides in book purchasing.

The bibliography appears in 5 sections: (1) mathematics, mechanics, and physics; (2) aeronautical and civil engineering; (3) chemical and industrial engineering; (4) electrical and mechanical engineering; (5) metallurgical and mining engineering. These lists represent the considered opinion of many teachers and professional engineers. The choice of works has been confined to current American publications and, in general, to those of college grade. Annotations are provided.

The separate pamphlets can be had for 10 cents each, or for 5 cents each in lots of 50 copies, assorted if desired. Requests should be sent to Engineer's Council for Professional Development, 29 West 39th Street, New York, N. Y.

## McGraw-Hill Presidency Changes

The presidency of the McGraw-Hill Publishing Company, Inc., of New York was transferred as of June 21, 1937 to James H. McGraw, Jr., as the result of the resignation of Malcolm Muir from that post.

A Princeton graduate (1915) Mr. McGraw has served his company actively in various capacities; he became treasurer in 1923, executive vice-president in 1932, and in 1935 was elected chairman of the board to succeed James H. McGraw (A '01) founder of the company. In addition to his duties as president, he will continue as chairman of the board, according to the company's announcement

Malcolm Muir resigned the presidency of the McGraw-Hill company to assume the presidency of the company publishing *News Week*. He had served the McGraw-Hill company continuously since 1905 in various capacities including the general management of *Chemical and Metallurgical Engineering*, and later of that publication together with *Coal Age* and *Engineering and Mining Journal*. He became vice-president of the company in 1916, and president in 1928.

**ASTM Elects Officers.** At the first session on June 28, 1937, of the annual meeting of the American Society for Testing Materials, election of the following officers for 1937–38 was announced: *president*—A. E. White, professor of metallurgical engineering, and director, department of engineering research, University of Michigan, Ann Arbor; *vice-president*—H. H. Morgan, manager, rail and track fastenings department, Robert W. Hunt Company, Chicago, Ill.; *members of executive committee*—P. H. Bates, chief, clay and silicate products division, National Bureau of Standards, Washington, D. C., H. F. Clemmer, engineer of material, District of Columbia, Washington, G. E. F. Lundell, assistant chief, chemistry division, National Bureau of Standards, Washington, D. C., H. G. Mougey, chief chemist and assistant technical director, research laboratories division, General Motors Corporation, Detroit, Mich., and R. L. Templin, chief engineer of tests, Aluminum Company of America, New Kensington, Pa.

## Secretary of Institution of Civil Engineers Dead

Doctor Henry Homan Jeffcott, since 1922 secretary of The Institution of Civil Engineers, died June 29, 1937. He received his education at Trinity College and Dublin University and held the degrees of bachelor of arts, bachelor of engineering, and doctor of science. At Trinity College he was "first mathematical scholar, senior moderator and gold medalist, and M'Cullagh prizeman." Doctor Jeffcott's early engineering endeavors included brief associations with Siemens Brothers and Company, Ltd., Woolwich, England, as assistant engineer, and with Whitworth and Company, Ltd., Manchester. From 1905 until 1910 he was head of the metrology department of the British National Physical Laboratory.

In 1910 Doctor Jeffcott was appointed to the faculty of the Royal College of Science for Ireland, with the rank of professor of engineering, and remained at that institution for 12 years before being appointed to the secretaryship of The Institution of Civil Engineers. During the last 8 years of his stay at the Royal College he was dean of the college faculty. From 1918 to 1921 he was secretary of the subcommittee on water-power resources of Ireland, and since 1922 had been a member of the board of studies in civil and mechanical engineering of the University of London. Formerly, he was an examiner in mechanical engineering in the University of Belfast, and in the National University of Ireland. He held several patents on mechanical devices, and was the author of numerous technical papers.

**AIME Announces Meetings.** Dates and places for 1937 fall meetings of the American Institute of Mining and Metallurgical Engineers have been announced as follows: September 13–18, regional meeting (joint meeting with the Canadian Institute of Mining and Metallurgy), Vancouver, B. C.; September 30–October 1 (tentative) petroleum division, Los Angeles, Calif.; October 7–8, petroleum division, Oklahoma City, Okla.; October 14–16, industrial and minerals division, Washington, D. C., and College Park, Md.; October 18–22, Institute of Metals and iron and steel divisions, Atlantic City, N. J.; and October 27–28, coal division, Pittsburgh, Pa.

## H. L. Cooper, Hydroelectric Consultant, Dies

Hugh Lincoln Cooper, president of Hugh L. Cooper and Company, Inc., New York, N. Y., and a world-renowned builder of hydroelectric power plants, died June 24, 1937, at his home in Stamford, Conn., after a brief illness. Colonel Cooper was born April 28, 1865, at Sheldon, Minn. Although he never received a formal engineering education, he received the honorary degree of doctor of laws from the University of Missouri and Parsons College, an honorary degree of doctor of engineering from Syracuse University, and an appointment as honorary professor of civil engineering at the State School of Engineering of the Republic of Brazil. He began his engineering career in 1881, as an apprentice engineer for the Chicago, Milwaukee, and St. Paul Railway Company, but after 3 years joined the engineering staff of the Chicago Bridge and Iron Company, and in that company he first established a reputation for himself as a structural designer.

In 1891 he went to Spokane, Wash., as northwestern manager of the San Francisco Bridge Company, where for 3 years he designed and built bridges, including a 500-foot steel arch for the Spokane Falls and Northern Railroad Company; however, he believed that hydroelectric development extended a great opportunity for engineering achievement, and in 1894 he began bidding independently on small water-power construction projects in the state of Washington. In 1897 he sought and gained a position as assistant chief engineer for the Stillwell-Bierce and Smith-Vaile Company, manufacturers of water wheels, of Dayton, Ohio, so that he might learn the fundamentals of turbine design.

Colonel Cooper's first big hydroelectric project was a 20,000-horsepower plant in the mountains of Brazil, for the Sao Paulo Tramway, Light and Power Company. From there he went to the Mexican Power and Light Company as chief engineer, and then to the Electrical Development Company of Ontario as chief hydraulic engineer. In 1901 he established his own consulting engineering practice, and for the next 12 years supervised the construction of many hydroelectric plants, including the 165,000-horsepower Keokuk development on the Mississippi River. During the World War he served as a Colonel in the Corps of Engineers of the United States Army, but was recalled from France to supervise the construction of the Muscle Shoals dam and power house on the Tennessee River. His most recent engineering achievement was the supervision of the construction of a 750,000-horsepower plant for the Union of Socialistic Soviet Republics, the Dnieprostroy Dam. He was a member of the American Society of Civil Engineers, American Institute of Mining and Metallurgical Engineers, The American Society of Mechanical Engineers, Society of American Military Engineers, American Institute of Consulting Engineers, Institution of Civil Engineers (Great Britain), and the Institution of Water Engineers (Great Britain).

# Current Items From American Engineering Council

## Proposed Increase in Engineering-Experiment Stations

Council is being called upon by members of Congress, engineers, and educators in the land-grant-college groups to support legislation proposing to increase the number of engineering-experiment stations and for advice regarding the attitude that should be taken toward such legislation. It has also come to Council's attention that there is competition between the "A and M" colleges and state universities for the allocation of funds for the construction and operation of engineering-experiment stations.

So much confusion has arisen regarding this legislation that President Roosevelt has appointed 3 committees to study it. The National Research Council was first called upon to appoint a committee headed by Doctor Charles W. White. After that committee had gotten into action, some question arose as to whether it should make a final report, and the President appointed a committee on industrial training headed by Doctor Floyd Reeves of Chicago, Ill., who was formerly director of personnel with the Tennessee Valley Authority. A third committee has just been started by the National Resources Committee to investigate human resources, which is understood to include questions regarding engineering educational facilities in land-grant colleges.

In addition to this legislation, it is interesting to note that money is now being appropriated from relief funds to colleges for research and other purposes through 3 different organizations: under relief projects set up under the Works Progress Administration; under the National Youth Administration, which operates under a committee of which Mr. Joseph Roach is chairman and Mr. Audrey William is director, with substations in each state dealing with appropriating funds to the colleges and universites in each state; and a program of expenditure under Doctor Frank Persons of the Department of Labor for special purposes.

Such appropriations add to the confusion of purpose in current legislation and indicate that engineers should make a careful study of the entire situation before approving any of the proposed legislation or procedure. It is probable that some more acceptable form of federal support for engineering-experiment stations may result from the studies now being made by the president's committees and it may be advisable to wait for their recommendations.

Council's natural position in this matter is to represent the engineering viewpoint and the engineering profession of the country in the public welfare, and the staff is reluctant to go into controversy beyond that point in support of any legislation. Therefore, Council is endeavoring to confine its work in this connection to the accumulation and dissemination of information concerning the several pieces of legislation, including the opinions of member engineering organizations and Council's own committees.

Copies of the proposed bills have been mailed by Council to various interested parties. The AEC staff is contacting the chairmen of the President's committees and will advise its member organizations of additional information on this important issue as such information becomes available.

## Statistical Yearbook of World Power Conference

One of the objectives of the World Power Conference is the preparation of inventories of the resources of the world in fuel and power. The first inventory entitled "Statistical Yearbook of the World Power Conference," now ready for distribution, represents an excellent attempt to compile and publish international statistics of power resources, development, and utilization upon a comprehensive and comparable basis. Some of the information has not been published before in any country. As a collection of statistics on this particular subject, the work is probably unique and for this reason may prove most valuable to those interested in the development of world power resources.

Engineers, economists, statisticians, and others who require such information as comparable figures of coal consumed in the USA and the USSR, or of electricity generated in metallurgical works in Poland and Japan, or estimates of the world production of petroleum or wood, or the proportion of electricity generated by water power will find much of the information which was available in 1933 and 1934 in this compact volume which is being sold at $5 per copy by the American National Committee, World Power Conference, Interior Building, Washington, D. C.

## March of Rural Electrification

Rural electrification has increased from virtual stagnation during the depression to the highest peak in history. Without taking into consideration the new distribution lines constructed with federal financing, more new customers were connected to farm power lines in 1936 than in any other year since "electricity started to the country." Plans for 1937 indicate that privately financed lines will exceed those of 1936 and that the use of electric energy in rural areas is "on its way."

A large part of the increase in the rural use of electricity is said to be due to the

abandonment by utility companies of the practice of requiring farmers and rural industry to contribute to the cost of the lines which serve them. In many areas, distribution lines are being constructed to the consumers' property line without cash or deferred payment for such lines. Another contributing factor to the expansion is reported to be found in reductions in the cost of rural lines.

The Rural Electrification Administration reports that REA lines now equal privately financed lines. Plans and specifications prepared by engineers in private practice and approved by the engineering staff of REA are required on all projects, and Council is frequently called upon to suggest candidates for engineering positions in Washington and in the states. The compensation either by fee or salary is not always in keeping with that paid by private industry, but the engineering profession is being permitted to make its contribution to public as well as private rural electrification, and the appreciation of the value of engineering knowledge and experience is increasing and spreading to the less populated areas.

# Letters to the Editor

CONTRIBUTIONS to these columns are invited from Institute members and subscribers. They should be concise and may deal with technical papers, articles published in previous issues, or other subjects of some general interest and professional importance. ELECTRICAL ENGINEERING will endeavor to publish as many letters as possible, but of necessity reserves the right to publish them in whole or in part, or reject them entirely.

ALL letters submitted for consideration should be the original typewritten copy, double spaced. Any illustrations submitted should be in duplicate, one copy to be an inked drawing but without lettering, and other to be lettered. Captions should be furnished for all illustrations.

STATEMENTS in these letters are expressly understood to be made by the writers; publication here in no wise constitutes endorsement or recognition by the American Institute of Electrical Engineers.

## Mechanic Impedance In MKS Units

*To the Editor:*

The Giorgi, meter-kilogram-second (mks) system of units was adopted by the International Electrotechnical Commission (IEC) at Brussels in 1935.[1,2] The advantages of the mks system are notable and have been fully discussed in various papers.[3–5]

The purpose of this paper is to present the algebraic analogies of electric and mechanic impedance in a system of units that emphasizes the homogeneity of the 2 concepts. Such a system is the practical mks system of Giorgi.

Ohm's law governing continuous electric current flow in an electric circuit was published 110 years ago. In its well-known form it is:

$$I = E/R \text{ amperes} \qquad (1)$$

where $E$ is the impressed electromotive force, in volts, and $R$ is the electric resistance in *ohms*. This equation is in the mks system.

### Mechanics of Freely Falling Bodies

We may write, in analogy with Ohm's law, the velocity, v, of a freely falling mass:

$$v = F/R \text{ meters per second} \qquad (2)$$

where F is the gravitational force exerted on the falling mass in *joules per meter* or *newtons** and R is the mechanic resistance to motion of the mass. (The retarding influence of the air is neglected.) The gravitational force exerted on a mass M kilograms is gM newtons where g is the earth's gravitational acceleration at the position occupied by the mass. In mks units g is approximately 9.8 *meters per (second)*.[2] The mechanic resistance, R, may be written as M/t, M being the mass in kilograms and t the time of free fall, in *seconds*. Substituting these values in equation 2, we have the well-known equation:

$$v = gt \text{ meters per second} \qquad (3)$$

The mechanic resistance of the mass is thus expressed in *kilograms per second* and increases inversely as the time of free fall.

### Mechanic Impedance to Alternating Impressed Forces

When the mechanic force, F, impressed upon the mass, M, is not a uniform force of the gravitational type, but a simple sinusoidal alternating or vibrational force:

$$F = F_m \sin \omega t \text{ newtons} \qquad (4)$$

This vibromotive force tends to set up an alternating or vibrational velocity in the mass, according to the expression:

$$v = \frac{F_m \sin \omega t}{Z} \text{ meters per second} \qquad (5)$$

Here $Z$ is the mechanic impedance of the mass to vibrational motion. If the frequency of the impressed vibrational force is steadily maintained at $n$ *cycles per second*, the angular velocity of alternation is, according to a-c electric theory:

$$\omega = 2\pi n = 2\pi/T \text{ radians per second} \qquad (6)$$

T being the period of vibration in *seconds*. Equation 5 is similar to the well-known a-c equation.

$$i = \frac{E_m \sin \omega t}{Z} \text{ amperes} \qquad (7)$$

where $i$ is the instantaneous alternating current in a circuit having a steadily impressed alternating voltage $E_m$ sine $\omega t$ and $Z$ is the electric impedance of the circuit in *ohms*. It is known that there is a complete algebraic analogy between the mechanic impedance, $Z$, and the electric impedance, $Z$.

$$Z = R + jX = R + j(L\omega - S/\omega) \text{ ohms} \qquad (8)$$

If the electric circuit contains a resistance, $R$, *ohms*, a simple inductance, $L$, *henrys*, and a capacitance, $C$, *farads*, the electric impedance is a plane vector or complex quantity, $Z$, *ohms* with a real component, $R$, and an imaginary component, $j(L\omega - S/\omega)$ *ohms* where $S = 1/C$, an elastance in *farads*, and $j = \sqrt{-1}$. That is, the reactance $X$ is the difference between the inductive reactance, $jL\omega$, and the elastive reactance, $jS/\omega$.

If in equation 7 we replace the expression $E_m$ sine $\omega t$ by $E$, effective, or root-mean-square *volts*, it takes the well-known form:

$$I = E/Z \text{ effective amperes} \angle^{**} \qquad (9)$$

the familiar form of Ohm's law in simple a-c circuits.[6]

Returning to equation 5, the mechanic impedance, Z, takes the form:

$$Z = R + j(M\omega - S/\omega) \text{ kilograms per second} \angle \qquad (10)$$

Here R is the mechanic resistance offered by the medium surrounding the mass to vibrational motion, M is the mass of the body in *kilograms* and S is the elastic force of displacement in *newtons per meter*. It is here assumed that the mass is subjected to elastic restraint directly proportional to the displacement of the mass from its equilibrium position.

In equation 5 if we substitute the effective or root-mean-square value, F, of the impressed vibromotive force for $F_m$ sine $\omega t$, the effective value of the vibratory velocity steadily produced in the mass will be:

$$V = F/Z \text{ meters per second} \angle \qquad (11)$$

which becomes mechanic Ohm's law for vibrational velocity in the steady state. Mechanic equation 11 is the counterpart of electric equation 9 when the mechanic impedance, Z, is expressed in *kilograms per* second or *mechanic ohms*.

The $j$ operator appearing in equations 8 and 10 may be attributed to the geometric dimensional property of any small circular angle, $d\beta = ds/r$ where $ds$ is the small increment of arc perpendicular to the instantaneous radius vector $r$; so that, in the plane of reference, $ds = j\,r\,d\,\beta$. Hence, any angular velocity contains, inherently, the dimensions of a perpendicularity.

It may here be noted that the impedances dealt with in the field of acoustics are essentially mechanic impedances and may be expressed in the mks system in *kilograms per second* or *mechanic ohms*.

* The mks unit of force is known to be the *joule per meter* or that force which, exerted steadily over a distance of one *meter*, does work equal to one *joule*. This name is, however, relatively long and cumbersome. It has been suggested by several writers that this unit of force be provisionally called the *newton* until such time as action by the IEC may assign an international name. 1 newton = $10^5$ dynes.

** The angle sign $\angle$ indicates, as is well known, that the unit is not a simple but a complex quantity, or a plane vector. It may be read *"complex amperes"* or *"vector amperes."*

## Analogy of Magnetic Circuit and Long Transmission Line

*To the Editor:*

The solution of magnetic problems has been greatly simplified by the use of the circuit analogy. In such problems, it is generally assumed that the iron constituting the magnetic path carries all the magnetic flux and that the flux "flows" as a result of an applied magnetomotive force. With the exception of the air gap to which the flux is directed, it is generally assumed that the medium surrounding the magnetic circuit is a perfect magnetic insulator. If such an assumption is not made, the usual

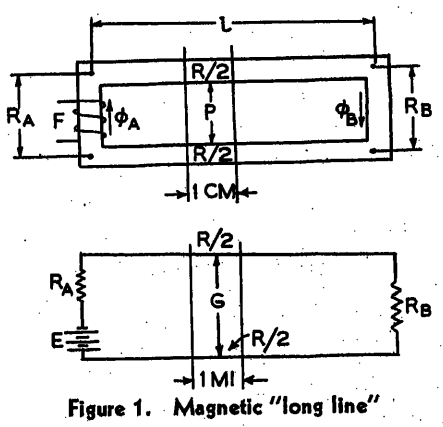

**Figure 1. Magnetic "long line"**

method is to apply arbitrary corrections to take into account the leakage flux and fringing effects.

It is at this point that the circuit analogy becomes faulty, since electric circuits are generally insulated by media which may be considered perfect. The only type of electric circuit which takes leakage currents strictly into account is the long transmission line, the characteristics of which have been worked out in detail and are readily available. The magnetic analogy of the long transmission line is one in which appreciable transverse leakage exists. It must be assumed that all the leakage flux is of a transverse nature and that the longitudinal leakage is negligible. A sketch of such a circuit is shown in figure 1.

If the constants of the material making up the circuit are known, then the following units are defined:

**Magnetic**

$\phi$—Flux
$\mathfrak{F}$—Magnetomotive force
$\mathcal{R}_1$—Reluctance per loop centimeter
$\mathcal{P}_1$—Leakage permeance per loop centimeter
$\alpha$—Magnetic hyperbolic angle per loop centimeter
$\mathcal{R}_0$—Characteristic reluctance

**Electric**

$I$—Current
$E$—Electromotive force
$R_1$—Resistance per loop mile
$G_1$—Leakage conductance per loop mile
$\alpha$—Electric hyperbolic angle per loop mile
$R_0$—Characteristic impedance

where $\alpha = \sqrt{\mathcal{R}_1\mathcal{P}_1}$, $\theta = \alpha l$, and $\mathcal{R}_0 = \sqrt{\mathcal{R}_1/\mathcal{P}_1}$.

If the analogous units are used, the relations developed for the electric long line

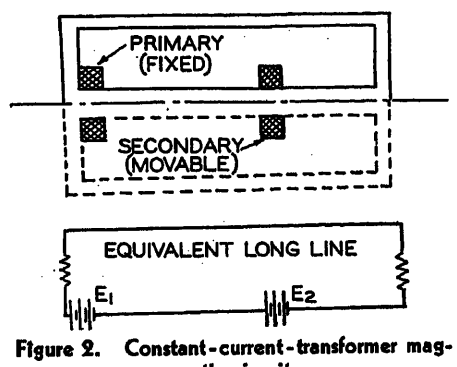

**Figure 2. Constant-current-transformer magnetic circuit**

can be used directly for the long magnetic circuit. Some useful formulas follow (refer to figure 1):

$$\phi_B = \mathfrak{F}_A \times \frac{1}{(\mathcal{R}_B+\mathcal{R}_A)\cosh\theta + \left(\mathcal{R}_0 + \frac{\mathcal{R}_B\mathcal{R}_A}{\mathcal{R}_0}\right)\sinh\theta} \quad (1)$$

$$\phi_A = \phi_B\left(\cosh\theta + \frac{\mathcal{R}_B}{\mathcal{R}_0}\sinh\theta\right) \quad (2)$$

$$\text{Leakage flux} = \phi_A - \phi_B \quad (3)$$

The particular problem to which this method of analysis may be applied is the constant-current transformer, which depends for its characteristics on the leakage flux produced by a magnetic circuit which is of the type described. The magnetic circuit of this transformer, along with its electrical analogy, is shown in figure 2.

The characteristics of a 5-kva 220-volt constant-current transformer, including the leakage inductance, necessary size of counterweights, shape of the sectored disk necessary to maintain optimum regulation, and other pertinent data were computed with ease from the physical constants of the magnetic circuit by the use of long-line formulas adapted to this particular magnetic problem. Tests made on the transformer showed a close agreement between the calculated and measured results.

This is, in general, an effective method of attacking the problem of the leaky magnetic circuit, providing, of course, that it satisfies the long-line conditions imposed on it.

Very truly yours,

J. R. RAGAZZINI (A'33)
Tutor, The College of the City of New York, New York, N. Y.

## Copper and Aluminum Cable Fusing Time-Current Formulas

*To the Editor:*

In the "Letters to the Editor" of the October 1935 issue of ELECTRICAL ENGINEERING, pages 1127–8, there is a letter by H. J. Reeves (A'30) regarding copper and aluminum cable fusing time-current formulas. There seemed to be a discrepancy in equation 2 as given; consequently, I communicated with Mr. Reeves and found that the equation had been misprinted. The equation should read as follows:

$$S_1 = \frac{2.3\,hH}{I^2\dfrac{r_0H}{y+t_0} - 1} \times \log_{10}\frac{\left(\dfrac{t_f-t_a}{t_0-t_a}\right)\left(I^2\dfrac{r_0H(y+t_f)}{(y+t_0)(t_f-t_a)} - 1\right)}{I^2\dfrac{r_0H}{t_0-t_a} - 1} \text{ (seconds)} \quad (2)$$

Very truly yours,

F. J. HORACEK
Junior Engineer, Consolidated Edison Company of New York, Inc., New York, N. Y.

## Tensor Analysis

*To the Editor:*

In ELECTRICAL ENGINEERING for March 1937, page 386, is published a very concise report about the sessions on tensor analysis at the 1937 AIEE winter convention.

Electrical engineers of the whole world, occupied in theoretical work, pay greatest attention and interest to the penetration of tensors into theoretical electrotechnics. This powerful mathematical method meets very contradictary appraisal. For that reason it would be natural to expect that the leader in this problem—United States of America—will publish all the discussion on tensors completely.

Therefore I think I shall express the opinion of all electrical engineers of the whole world, if I shall ask you earnestly to publish completely the report of the discussion on tensors at the winter convention.

Very truly yours,

V. N. LEBEDEV
Electrical Engineer, Dnepropetrovsk, U.S.S.R.

# Personal Items

H. B. DATES (A'98, F'32, member for life) professor and head of the department of electrical engineering, Case School of Applied Science, Cleveland, Ohio, has been elected president of the Illuminating Engineering Society. Professor Dates was born July 15, 1869, at New Britain, Conn., and received the degrees of bachelor of science in electrical engineering and electrical engineer (honorary, 1908) at Massachusetts Institute of Technology and Case School of Applied Science, respectively. From 1894 until early in 1896 he worked as a laboratory tester and inspector for the Westinghouse Electric & Manufacturing Company at Newark, N. J., and East Pittsburgh, Pa. In 1896 he received an appointment as professor of physics and electrical engineering at Clarkson School of Technology, where he organized the departments of physics and electrical engineering, planned the curricula, and equipped the laboratories. Professor Dates remained at Clarkson until 1903, when he became professor of electrical engineering and dean of the college of engineering at the University of Colorado. He has been head of the school of electrical engineering at the Case School of Applied Science since 1905, where, in addition to his regular teaching and administrative duties, he has served as a consulting engineer for the Cleveland Board of Education and for several commercial organizations. Professor Dates is a member of the Institute's committee on production and application of light, and was the first chairman (1907–08) of the Cleveland Section. He is a past-vice-president of the Illuminating Engineering Society, a member of the United States National Committee of the International Commission on Illumination, and a member or former member of several committees of that society. Professor Dates is the author of many books and papers on illumination. He is a member of the Society for the Promotion of Engineering Education, Sigma Xi, and Eta Kappa Nu.

F. V. MAGALHAES (A'07, F'19) assistant to vice-president, Consolidated Edison Company of New York, Inc., New York, N. Y., has been appointed executive assistant to the president. Mr. Magalhaes was born January 14, 1880, at Sao Paulo, Brazil, and received the degree of electrical engineer at the Polytechnic Institute of Brooklyn (N. Y.) in 1906. Following his graduation he was associated briefly with the Brooklyn Rapid Transit Company and the General Railway Signal Company before entering the meter department of The New York Edison Company in 1907. After 2 years he was made superintendent of the meter department, and in 1917 became superintendent of the test department also. From 1926 to 1928 he was superintendent of distribution and installation, but left the company in 1928 to become vice-president of the Hall Electric Heating Company. That company was liquidated in 1932, at which time Mr. Magalhaes became commercial representative for the General Electric Company at Lynn, Mass. He was appointed assistant to the executive vice-president of The New York Edison Company in 1935, and when the properties of that company and several others were merged recently under the Consolidated Edison Company name, he was retained in a similar capacity in the new organization. Mr. Magalhaes has been a member of the Institute's board of examiners since 1931, having served previously 1923–28, has been Institute representative on the electrical committee of the National Fire Protection Association since 1928, and since 1930 has been representative on the National Fire Waste Council, previously serving for the year 1928–29. He is at present a member of the committee on standards, has served on several other Institute committees, and for some years was secretary and vice-president of the United States National Committee of the International Electrotechnical Commission.

E. A. HARTY (A'22, M'36) designing engineer, General Electric Company, Lynn, Mass., has been awarded the AIEE North Eastern District prize for initial paper for his paper "Aging in Copper Oxide Rectifiers." Mr. Harty was born November 13, 1897, at Constantinople, Turkey, and received the degrees of bachelor of science and electrical engineer from Robert College (Turkey) in 1920. Following his graduation he entered the United States Department of State as a clerk in the American Consular Service, but in the following year became a mechanic in the construction department of the Shippley Construction and Supply Company, Brooklyn, N. Y. After serving briefly as an electrician for the New York, New Haven, and Hartford Railroad Company, he entered the student training course of the General Electric Company, Lynn, in 1923. In 1924 Mr. Harty was appointed a research assistant in the Thomson research laboratories of the General Electric Company, and for the ensuing 5 years his work embraced all phases of the design and production of copper-oxide rectifiers. Since 1929 he has been designing engineer on copper-oxide rectifiers, in which capacity he has also been responsible for the maintenance and improvement of the quality of such products. Mr. Harty is the author of several technical articles and papers, including 2 papers presented before the AIEE Lynn Section.

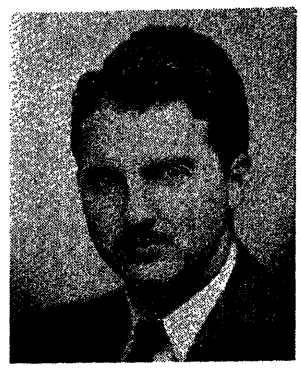
C. W. LEIHY (A'30) engineering editor of *Electrical West* and Pacific Coast editor of *Electrical World* has resigned from these positions to take over the editorship of *Electric Light and Power* with headquarters in Chicago, Ill. A native of Portland, Ore. (1905) Mr. Leihy received his education in that state and graduated in electrical engineering from Oregon State College, Corvallis, in 1926. Immediately following graduation, Mr. Leihy became affiliated with the General Electric Company and spent 2 years at Schenectady, N. Y., in the design and commercial departments, after which he was transferred to that company's Seattle, Wash., office as sales engineer. In the fall of 1930 he joined the McGraw-Hill Publishing Company's Pacific Coast organization in San Francisco, Calif. Mr. Leihy has maintained direct contact with electrical-engineering activities throughout the 11 far-western states, and has taken an active part there in AIEE affairs. He is a captain in the United States Field Artillery Reserve.

J. S. CARROLL (A'24, M'37) associate professor of electrical engineering, Stanford University, Calif., has received honorable mention in the 1936 AIEE national prize awards for best paper in theory and research

F. V. MAGALHAES

H. B. DATES

E. A. HARTY



C. W. LEIHY

E. M. HUNTER

F. G. BOYCE

A. C. HERWEH

M. F. GILL

for his paper "Laboratory Studies of Conductor Vibration." Doctor Carroll was born November 26, 1891, at Orderville, Utah, and was graduated from the University of Utah with the degree of bachelor of science in electrical engineering in 1920. Following his graduation, he received an appointment to the faculty of the University of Utah as an instructor in electrical engineering, and remained there for 3 years before accepting a similar position at Stanford University in 1924. At that time he enrolled in the graduate engineering school at Stanford, and in the same year received the degree of electrical engineer from that institution; subsequently he undertook further graduate study and received the degree of doctor of philosophy in 1929. He was appointed assistant professor of electrical engineering in 1926, and has been associate professor since 1930. Doctor Carroll has been particularly active in high-voltage research work, having served as director of the Ryan high-voltage laboratory at Stanford, and is the author or co-author of many AIEE papers on that branch of engineering research.

A. C. HERWEH (A'37) instructor in electrical engineering, University of Cincinnati (Ohio) has received the 1936 AIEE Middle Eastern District prize for initial paper for his paper "An Open Arc Type of Stroboscope." Mr. Herweh was born January 29, 1907, at Cincinnati, and received the degrees of electrical engineer (1932) and master of science in engineering (1936) at the University of Cincinnati. From 1929 until 1932 he was a design engineer for the Union Gas and Electric Company. After serving for one year (1933–34) as assistant foreman in charge of loudspeaker production of the Crosley Radio Company, Mr. Herweh was designated a teaching fellow in the electrical-engineering department of the University of Cincinnati, and since 1936 has been a full-time instructor in electrical engineering. He is a member of Tau Beta Pi and Eta Kappa Nu.

M. F. GILL (A'14, M'33) formerly co-ordinator for the Pennsylvania Power & Light Company, Allentown, recently was appointed assistant to the president of the Kansas Gas and Electric Company, Wichita. Mr. Gill was born October 4, 1888, at Paris, Texas, and was graduated in electrical engineering at the University of Texas in 1910. Upon graduation he entered the employ of the General Electric Company, Schenectady, N. Y., as a student engineer but returned to Texas in 1913 as resident engineer on construction for the Texas Power and Light Company, Dallas; later he became office engineer and assistant chief engineer, in which position he was in charge of the engineering office of that company. After brief periods of service with the Stone and Webster Engineering Corporation, the United States Army, and the Phoenix Utility Company, he became assistant manager, and later manager, of the Texas Electric Service Company, Brackenridge. In the position of manager Mr. Gill was in responsible charge of all phases of operation, engineering, and construction of the company. In 1928 he was appointed general superintendent of the Phoenix Utility Company at Allentown, Pa., and remained in that capacity until 1935, when he became co-ordinator for the Pennsylvania Power & Light Company.

F. G. BOYCE (A'12, M'15) manager of electrical production, transmission, and construction, Consumers Power Co., Jackson, Mich., recently was elected vice-president of the company. Mr. Boyce was born February 8, 1884, at Philadelphia, N. Y., and was graduated from the Bliss Electrical School in 1907, following which he served for 2 years as a lineman before entering the employ of the Allis-Chalmers Manufacturing Company, Milwaukee, Wis., in 1909. He remained with that company until 1913, serving successively as an electrical tester, assistant foreman of the electrical testing department, and erecting engineer. Mr. Boyce then became construction foreman for the Stone and Webster Engineering Corporation and was placed in charge of the construction of several substations along the Mississippi River for the distribution of power from the Keokuk hydroelectric station. On completion of that work he took charge of construction, operation, and maintenance of power plants and substations for the Milwaukee Electric Railway and Light Company. He became affiliated with the Consumers Power Co. in 1917, after a brief association with the Goodyear Tire and Rubber Company at Akron, Ohio. He was made assistant manager of electrical production and transmission at that time, and in 1936 became manager of electrical production, transmission, and construction.

E. M. HUNTER (A'28, M'37) central station engineering department, General Electric Company, Schenectady, N. Y., has received the 1936 AIEE North Eastern District prize for best paper for his paper "Tests on Lightning Protection for A-C Rotating Machines." Mr. Hunter was born October 20, 1902, at Portsmouth, N. H., and received the degrees of bachelor of science in electrical engineering (1926) and electrical engineer (1930) at Worcester Polytechnic Institute; in 1931 he received the degree of master of science at Union College. After completing the General Electric test course in 1925, he was transferred to the a-c turbine-generator engineering department, where he was assigned to special design problems and the supervision of factory and field tests. Since 1928 he has been in the central station engineering department, and much of his work has been concerned with system stability studies, especially in relation to design problems. Recently much of his effort has been devoted to a study of the protection of machinery and systems against lightning. He is author or co-author of several AIEE papers on these 2 related fields.

W. E. MITCHELL (A'06, F'22) vice-president and general manager of the Georgia Power Company, Atlanta, has been elected a vice-president of the Edison Electric Institute for the term 1937–38. Recently he was also elected president of the Southeastern Electric Exchange. Mr. Mitchell was born June 23, 1882, at Milton, Mass., and received the degree of bachelor of science in electrical engineering at Massachusetts Institute of Technology. Following his graduation he entered the test course of the General Electric Company, Schenectady, N. Y., in 1903, but upon completion of the course in 1905 he went to South America as an assistant electrical engineer for the Sao Paulo (Brazil) Tramway, Light, and Power Company. In 1907 Mr. Mitchell became electrical engineer and operating superintendent of the Bahia Tramway, Light, and Power Company, where he remained until 1911, when he returned to the United States. After a brief period of service with the General Electric Company in San Francisco, Calif., he entered the employ of the Alabama Power Company as an electrical engineer in 1912, and subsequently became operating manager. During the World War Mr. Mitchell was managing director of the Anniston

Steel Company, but returned to the Alabama Power Company in 1918 as assistant general manager and held that position until he was elected president of the Georgia Power Company in 1927.

R. H. CARD (A'22, M'35) engineer for the American Telephone and Telegraph Company, New York, N. Y., has received honorable mention in the 1936 AIEE national prize awards for initial paper for his paper "Earth Resistivity and Geological Structure." Mr. Card was born at Pikeville, Tenn., July 28, 1897, and was graduated from the University of Tennessee with the degree of bachelor of science in electrical engineering in 1919, following which he entered the preliminary training course of the long-lines department of the American Telephone and Telegraph Company. In 1922 he was transferred to the division plant superintendent's office at Philadelphia, Pa., where his duties embraced supervisory work on inductive co-ordination. After 5 years Mr. Card was appointed division engineer in the Philadelphia offices, and was placed in charge of various aspects of transmission engineering, including inductive and structural co-ordination of power and telephone lines within the Philadelphia area. Since 1927 he has been stationed in the office of the long-lines engineer at New York, pursuing investigations of crosstalk and inductive co-ordination for the entire long-lines plant of the company.

E. L. BAILEY (A'19, M'25) electrical engineer for the Chrysler Corporation, Detroit, Mich., has received honorable mention in the 1936 AIEE national prize awards for initial paper for his paper "Induction Heating at Low Temperatures." Mr. Bailey was born January 3, 1885, at Lawrence, Kans., and was graduated from the University of Kansas with a degree in electrical engineering in 1907. Immediately following his graduation he entered the test course of the General Electric Company, Schenectady, N. Y., and upon his completion of the course in 1909 was transferred to the engineering department of the Chicago, Ill., offices of that company. Later he was transferred to the Detroit, Mich., offices of the General Electric Company as district engineer. During the World War he became superintendent of the Gas and Electric Company, Port Huron, Mich., and later a sales engineer for several electrical machinery manufacturers in Detroit. In 1925 he joined the electrical engineering staff of the Fisher Body Division of the General Motors Corporation, and in 1930 became affiliated with the Chrysler Corporation in his present position.

A. H. LAUDER (A'24) motor and generator engineering department, General Electric Company, Schenectady, N. Y., co-author of the paper "Pull-In Characteristics of Synchronous Motors," with S. B. Crary, Jr. (A'31) and D. R. Shoults (A'35) has received honorable mention in the 1936 AIEE national prize awards for best paper in theory and research. Mr. Lauder was born December 27, 1900, at Evanston, Wyo., and received the degree of bachelor of science at the University of Wyoming in 1922. During his senior year he served as an instructor in applied electricity, and following his graduation entered the testing department of the General Electric Company. After completing the test course, Mr. Lauder was transferred to the a-c engineering department, but later was transferred to the motor and generator engineering department, where he has remained continuously. His work in that department consists principally of the design of synchronous machines.

D. R. SHOULTS (A'35) industrial department, General Electric Company, Schenectady, N. Y., co-author of the paper "Pull-In Characteristics of Synchronous Motors," with S. B. Crary, Jr. (A'31) and A. H. Lauder (A'24) has received honorable mention in the 1936 AIEE national prize awards for best paper in theory and research. Mr. Shoults was born June 23, 1903 at Storms, Ohio, and received the degree of bachelor of science in electrical engineering at the University of Idaho in 1925, following which he entered the test course of the General Electric Company. In 1926 he was placed in charge of some of the tests on large motors and generators, and after 3 years was transferred to the industrial department, where his work has been concerned with electrical applications in the paper, lumber, and rubber-mill industries. He is the author of several technical articles.

S. B. CRARY, JR. (A'31) central station engineering department, General Electric Company, Schenectady, N. Y., co-author of the paper "Pull-In Characteristics of Synchronous Machines," with A. H. Lauder (A'24) and D. R. Shoults (A'35) has received honorable mention in the 1936 AIEE national prize awards for best paper in theory and research. Mr. Crary was born May 17, 1905, at Marquette, Mich., and was graduated from Michigan State College with the degree of bachelor of science in electrical engineering in 1927. Upon graduation he entered the test course of the General Electric Company, and has remained in the employ of that company continuously; in 1928 he was transferred to the transformer design department, but served there only briefly before being assigned to the central station engineering department in 1929.

R. D. MAILEY (F'30) vice-president in charge of engineering and manufacture, General Electric Vapor Lamp Company, Hoboken, N. J., recently was awarded an honorary degree of doctor of science by Stevens Institute of Technology as "an electrical engineer and physicist in whose laboratory were developed to their present efficiency as illuminants the mercury-arc lamp, the high-pressure mercury lamp, the sodium lamp, and other notable vapor-lamp equipment . . . . . internationally recognized expert in his field of physical research and industrial development." Mr. Mailey is a member of the Institute's committee on production and application of light.

JACK DELMONTE (A'36) who has been a laboratory technician in the engineer research laboratories of the Firestone Tire and Rubber Company, Akron, Ohio, now is assistant to the chief engineer of development and research, Chicago (Ill.) Flexible Shaft Company. Mr. Delmonte is a native (1913) of New York, N. Y., and an electrical engineering graduate of New York University. He pursued graduate studies in electrical engineering at Massachusetts Institute of Technology and the University of Pennsylvania. Before becoming associated with the Firestone Tire and Rubber Company, he was employed in the Naval Aircraft Factory, United States Navy Yard, Philadelphia, Pa.

E. M. WILLIAMS (Enrolled Student) graduate student in electrical engineering Yale University, New Haven, Conn., with R. F. Huminski, co-author of the paper "Frequency Multipliers," has received honorable mention in the 1936 AIEE national prize awards for Branch paper. Mr. Williams was born February 2, 1915, at New Haven, and received the degree of bachelor of engineering at Yale University in 1936. His present course of study leads to the degree of doctor of engineering. He presented a paper "A High-Voltage Parallel-Plate Electrostatic Voltmeter," at the North Eastern District student convention, Buffalo, N. Y., May 7, 1937.

H. B. FUGE (A'37) assistant engineer, Diehl Manufacturing Company, Elizabethport, N. J., has received honorable mention in the 1936 AIEE national prize award for Branch paper for his paper "A Direct Reading Linear Accelerometer." Mr. Fuge was born December 31, 1915, at Brooklyn, N. Y., and received the degree of bachelor of engineering at the Polytechnic Institute of Brooklyn (N. Y.) in 1936. Immediately after his graduation he entered the employ of the Diehl Manufacturing Company as an assistant in the engineering laboratory. In January 1937 he was promoted to assistant engineer, and has been assigned to fractional-horsepower motor design work.

D. R. BARNEY (Enrolled Student) graduate student in electrical engineering, Massachusetts Institute of Technology, Cambridge, has received honorable mention in the 1936 AIEE national prize awards for Branch paper for his paper "Tidal Power." Mr. Barney is a native (1915) of East Orange, N. J., and an electrical engineering graduate of the Newark College of Engineering. He expects to receive his master's degree in electrical engineering in February 1938.

A. D. FLESHLER (A'34) junior electrical engineer, Transit Commission, New York, N. Y., has been promoted to assistant electrical engineer. Mr. Fleshler is a native (1895) of Bessarabia, Russia, and a graduate of Cooper Union Institute and New York University. Before becoming affiliated with the New York Transit Commission he was employed by the Westinghouse Electric & Manufacturing Company and the Ajax Electric Company.

J. H. TREADWELL (Enrolled Student) Menard, Texas, has received the 1936 AIEE South West District prize for Branch paper for his paper "A Rotating Ball Slip Meter." Mr. Treadwell was born February 22, 1915, at Menard, and is at present enrolled as a student in electrical engineering at The Rice Institute, where he expects to receive the degree of bachelor of science in electrical engineering in 1938.

F. W. SMITH (A'05, M'12) retired president of the Consolidated Edison Company of New York, Inc., New York, N. Y., recently received the honorary degree of doctor of engineering from Stevens Institute of Technology. A brief biographical sketch of Doctor Smith appeared in the June 1937 issue of ELECTRICAL ENGINEERING, page 770, at the time of his retirement.

F. X. LAMB (A'36) chief of the commercial division, engineering department of the Weston Electrical Instrument Corporation, Newark, N. J., recently went to Japan to represent the Weston company as consulting engineer and adviser to the Nippon Electric Company, Tokyo. Mr. Lamb has been associated with the Weston company for more than 15 years.

ASGER VILSTRUP (A'20, M'27) chief electrical engineer, British Columbia Electric Railway Company, Ltd., Vancouver, has been elected chairman of the Northwest Electric Light and Power Association for the term 1937–38. A biographical sketch of Mr. Vilstrup appeared in the February 1937 issue of ELECTRICAL ENGINEERING, page 289.

T. S. TAYLOR (M'21) professor of physics, Washington and Jefferson College, Washington, Pa., recently resigned to become manager of the engineering laboratory and experimental department of the Diehl Manufacturing Company, Elizabethport, N. J. Doctor Taylor formerly was a research physicist for the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

R. C. GIESE (A'19, M'32) division plant engineer, American Telephone and Telegraph Company, Chicago, Ill., has been made district plant superintendent, with offices at Springfield, Ill. Mr. Giese is a native (1893) of Des Moines, Iowa, and attended the State University of Iowa. He has been associated with the American Telephone and Telegraph Company since 1919.

MATTHEW LUCKIESH (A'11, M'15) director of the lighting research laboratory, General Electric Company, Nela Park, Cleveland, Ohio, recently was elected an honorary member of the American Academy of Optometry, in recognition of his contribution to optometric science.

B. H. RULE (A'36) formerly a meter and test engineer, Department of Light and Power of the City of Vernon, Calif., recently was appointed electrical engineer in the astrophysical observatory of California Institute of Technology, Pasadena.

M. V. MAXWELL (M'36) who has been an assistant engineer in the Bureau of Reclamation, Denver, Colo., recently became district engineer in the Detroit, Mich., offices of the Westinghouse Electric & Manufacturing Company.

H. P. BARLOW (A'36) who has been a switchman in the central office of the Associated Telephone Company, Ltd., Ontario, Calif., has been transferred to the Long Beach offices of that company in the capacity of assistant traffic engineer.

M. D. ENGLE (A'21, M'26) superintendent of the station engineering department, Edison Electric Illuminating Company of Boston, Mass., recently was elected a member of the executive committee of the National District Heating Association.

J. T. MOONEY (A'25) has resigned his position with the Lago Oil and Transport Co., Ltd., Aruba, Netherlands West Indies, to become superintendent of the generating plants of the Loup River Power District, Columbus, Nebr.

W. M. SHOBER (A'22) formerly a distribution engineer, Department of Water, Light, and Power, City of Springfield, Ill., now is an electrical installation engineer for the Aluminum Company of America, Alcoa, Tenn.

E. W. HOVER (A'25, M'32) formerly an electrical distribution engineer for the Central Hudson Gas and Electric Corporation Poughkeepsie, N. Y., recently was appointed electrical engineer in the Rural Electrification Administration, Washington, D. C.

ROBERT TRIPLETT (A'32) who has been a junior engineer for the Mackay Radio and Telegraph Company, San Francisco, Calif., now is employed as a receiving engineer at the Point Reyes station of RCA Communications, Inc. Inverness, Calif.

E. C. KELTON (M'26) lieutenant colonel, Engineers Corps, United States Army, who has been stationed at the Army Industrial College, Washington, D. C., as an instructor, has been transferred to Fort McKinley, Philippine Islands.

LIONEL HOECHSTETTER (A'35) has resigned his position as junior engineer with the Westchester Lighting Company, Mount Vernon, N. Y., to become an electrical engineer for the Electricoil Company, New York, N. Y.

J. C. WINSLOW (A'26) electrical engineer for the Westinghouse Electric & Manufacturing Company, Springfield, Mass., has been transferred to the Lima, Ohio, offices of that company.

W. R. WOOD (A'33) has left the employ of the United Fruit Company, New York, N. Y., to become a d-c motor design engineer for the General Electric Company, Lynn, Mass.

GODFREY MORGAN, JR. (M'36) assistant engineer with the Public Service Electric and Gas Company, Camden, N. J., has been transferred to the Princeton, N. J. offices of that company.

E. L. ANGELL (A'34) who has been a clerk in the right of way department of the Narragansett Electric Company, Providence, R. I., has entered the test course of the General Electric Company, Pittsfield, Mass.

H. F. PARK (A'35) formerly chief draftsman for the Fidelity Electric Company, Lancaster, Pa., recently was employed by the Rural Electrification Administration, Washington, D. C.

L. B. LEVESCONTE (A'36) switchgear representative, Westinghouse Electric & Manufacturing Company, Newark, N. J., has been transferred to the Chicago, Ill., offices of that company.

F. C. POAGE (A'25) formerly assistant to the superintendent of power, Idaho Power Company, Boise, has joined the staff of Ebasco Services, Inc., with headquarters at New York, N. Y.

P. W. SEAL (A'33) formerly an engineering assistant, Consolidated Edison Company of New York, Inc., New York, N. Y., now is electrical foreman with the Allegheny Steel Company, Tarentum, Pa.

C. F. WAYER, JR. (A'32) who has been employed by the General Electric Company, Bloomfield, N. J., now is an assistant examiner in the United States Patent Office, Washington, D. C.

B. B. BROWNELL (A'36) formerly employed by the Delco Products Corporation, Dayton, Ohio, now is a junior electrical engineer with the Electro-Motive Corporation, LaGrange, Ill.

K. C. WHITE (A'35) who has been employed by the General Electric Company, Schenectady, N. Y., has been appointed an instructor in electrical engineering at Cornell University, Ithaca, N. Y.

E. H. SCHOENFELD (A'35) formerly employed by Heintz and Kaufman, Ltd., South San Francisco, Calif., now is an engineer for the United Geophysical Company, Pasadena, Calif.

F. J. ELSER (A'32) recently was employed as a radio transmitter tester for the Westinghouse Electric & Manufacturing Company, Chicopee Falls, Mass.

F. B. CONLON (A'31) formerly a sales engineer with the Sheffler Gross Company, Philadelphia, Pa., now is employed by Airtemp, Inc., Dayton, Ohio.

## Obituary

GUGLIELMO MARCONI (HM '17, John Fritz Medalist '23) Italian inventor famous for establishing wireless telegraphy on a commercial basis, died quietly of heart paralysis July 20, 1937 at the ancient palace in Rome where he lived and worked. He was born in Italy on April 25, 1874, and was educated privately. Destined by his father to be a musician, Marconi nevertheless turned to science, and by 1895 the idea had become firmly rooted in his mind that a system of telegraphy through space could be provided by means of electromagnetic waves, the existence of which already had been determined by earlier experimenters.

Marconi was the first to devise practical means by which these waves could provide a new method of communication. In 1896 he went to England, taking out during that year the first patent ever granted on wireless telegraphy. An extended series of experiments followed, and his first commercial company was organized in 1897. During the next few years Marconi took out many patents on new devices for wireless telegraphy, and had much to do with the remarkable growth of this new industry in many countries of the world. In December 1901 a prearranged wireless signal was flashed from a station on the coast of Cornwall, England, to another on the rocks of Newfoundland some 2,000 miles away. After several unsuccessful attempts, communication finally was established between these 2 stations. These and other related efforts of Marconi attracted to him the attention of the world during 1901 and 1902. On January 13, 1902, at the annual dinner of the Institute held at the Waldorf-Astoria Hotel, Marconi was the guest of honor in recognition of his contributions to wireless telegraphy. He also was one of the pioneers in the use of short waves for radio communication. During the World War, Marconi served in both the Italian army and navy, and also visited America as a member of the Italian War Commission to the United States Government. He was appointed a delegate to the Peace Conference in Paris in 1919. Among the many honors received by Marconi during his lifetime are the Nobel Prize for Physics in 1909, the Albert Medal of the Royal Society of Arts of Great Britain, and the 1932 Kelvin Medal of the Institution of Civil Engineers of Great Britain. He has been decorated with the Italian order of St. Maurice and St. Lazarus, and with the Grand Cross of the Crown of Italy. In 1915 he was nominated senator of the Kingdom of Italy. In the United States, Marconi has received the Franklin and John Fritz medals and the Medal of Honor of the Institute of Radio Engineers, and other citations. Much of Marconi's time in late years has been spent aboard his yacht "Elettra" on which he had a completely equipped experimental laboratory.

PETER WILLIAM SOTHMAN (A'07, M'09, F'17) consulting engineer, Mount Tabor, N. J., died June 25, 1937. Mr. Sothman was born May 20, 1870, at Haderslev, Denmark, and was graduated from the Technological Institute of Charlottenburg (Germany) in 1891, with a diploma as electrical and mechanical engineer. Following his graduation, he became construction engineer for Siemens and Halske Company, Berlin, Germany, in which capacity he supervised the construction of several central stations and substations in Germany, South Africa, Russia, and Switzerland. In 1897 he became chief engineer and director of a power plant of Allgemeine Electricitaets Gesellschaft at Strassburg, Germany, and at the same time acted as expert on high-voltage transmission for several German cities. In 1899 Mr. Sothman was appointed technical commissioner for the German government and expert for all the courts in Alsace Lorraine and Baden; concurrently he served as commissioner of law for the Verein Deutscher Electrotechniker and as commissioner and director of the Technological School of Strassburg. He was honored as "ehren doctor Von Academie de Parisienne," in 1905, and in the same year came to the United States and established his own consulting engineering offices at New York, N. Y. In the following year Mr. Sothman was appointed chief engineer of the Hydro-Electric Power Commission of Ontario, in which position he was responsible for the design and construction of several of the Commission's generating plants and transmission lines. He returned to New York in 1912 to establish the consulting engineering firm of the Sothman Corporation, and for the ensuing 25 years continued in that work in the city of New York and its vicinity.

CHARLES L. CADLE (A'08) president of the New York State Electric and Gas Corporation, Binghamton, N. Y., died July 3, 1937. Mr. Cadle was born March 10, 1879, at Mentor, Ohio, and was graduated from the Case School of Applied Science in the class of 1904, following which he became battery manager for the Cleveland (Ohio) Electric Railway Company. In the following year he became associated with the Electric Railway Improvement Company, Cleveland, and in 1907 was promoted to the position of assistant general manager; however, after only one year in that position he went to Rochester, N. Y., to become electrical engineer for the Rochester Railway Company. Mr. Cadle remained with that company until 1912, when he was appointed to a similar position in the New York State Railways Company, with offices at Rochester. In 1919 he became chief engineer of that company. After serving briefly as superintendent of public works at Albany and pursuing for a time his own consulting engineering business, he became general manager of the Rochester Gas and Electric Company in 1926. In 1932 he was appointed vice-president of the Utilities Management Corporation, New York, N. Y., and in 1935 president of the New York State Electric and Gas Corporation.

ROGER S. TAYLOR (A'17) plant superintendent, Susquehanna Electric Company, Conowingo, Md., died April 27, 1937. Mr. Taylor was born October 7, 1881, at Dukenfield, Cheshire, England, and received his formal education at the Technical School at Ashton-under-Lyne. In 1898 he came to the United States and obtained employment in the motive-power department of the Philadelphia (Pa.) Rapid Transit Company. He remained with that company until he transferred his affiliation to the Philadelphia Suburban Gas and Electric Company in 1912 and was placed in charge of that company's plants at Pottstown and Phoenixville. In 1916 Mr. Taylor joined the operating staff of the Philadelphia Electric Company, later becoming assistant power-plant superintendent and power-plant superintendent, and remained with that company for almost 10 years before becoming associated with the Susquehannah Electric Company as plant superintendent.

NORMAN MCLEOD BAXTER (A'26) transmission engineer, Ohio Public Service Company, Elyria, died June 24, 1937. Mr. Baxter was born at Halifax, Nova Scotia, June 27, 1883, and attended University Delhousie (Nova Scotia) and the University of Nebraska. In 1905 he became affiliated with the Lincoln (Nebr.) Gas and Electric Light Company as a draftsman, but later was placed in charge of construction and eventually became superintendent of gas and electric distribution before transferring to The Lorain County Electric Company, which later became a part of the Ohio Public Service Company, as general superintendent in 1916. From 1919 to 1922 Mr. Baxter was associated briefly with a public utility company in Connecticut and with the engineering department of The Toledo (Ohio) Edison Company. In 1922 he returned to the employ of the Ohio Edison Company as transmission engineer, and served continuously in that capacity for almost 15 years.

RALPH T. ROSSI (A'18, M'34) assistant plant engineer, RCA Communications, Inc., New York, N. Y., died May 28, 1937. Mr. Rossi was born in New York, N. Y., April 27, 1878, and received his formal technical education through private instruction in Europe. From 1904 until 1916 he was associated briefly with several consulting engineering firms and construction companies in New York. In 1916 he became superintendent of distribution for the Public Service Electric and Gas Company, Trenton, N. J., where he remained for 3 years before becoming affiliated with RCA Communications as assistant engineer in charge of construction in 1919. Mr. Rossi was responsible for the construction of many of the transmitting and receiving stations of RCA Communications on every continent except Australia. He was a member of the Institute of Radio Engineers.

WALTER CARY (A'07, M'14) vice-president, Westinghouse Electric & Manufacturing Company, New York, N. Y., died July 3, 1937. Mr. Cary was born April 26, 1871, at Milwaukee, Wis., and was graduated from Harvard University in 1893 with the degree of bachelor of arts. In 1894 he entered the employ of the Gibbs Electric Company, Milwaukee, as secretary of the company, but 4 years later became vice-president of the Milwaukee Electric Company. In 1910 he became president of the Milwaukee Electric Company, and in 1904 vice-president and general manager of the Westinghouse Lamp Company, New York, N. Y. He had been vice-president of the Westinghouse Electric & Manufacturing Company since 1918.

WILLIAM M. O'BRIEN (A'36) service department, Northwestern Electric Company, Rainier, Ore., was drowned May 2, 1937. Mr. O'Brien was born August 5, 1909, at Portland, Ore., and was graduated from Oregon State College with the degree of bachelor of science in electrical engineering in 1935. He had been associated with the Northwestern Electric Company since his graduation. He was a member of the Society of American Military Engineers.

# Membership

## Recommended for Transfer

The board of examiners, at its meeting on July 21, 1937, recommended the following members for transfer to the grade of membership indicated. Any objection to these transfers should be filed at once with the national secretary.

**To Grade of Fellow**

Bonney, R. B., educational director and employment supervisor, The Mountain States Telephone and Telegraph Company, Denver, Colo.
Pearson, E. F., chief engineer, Northwestern Electric Co., Portland, Ore.
Stevenson, A. R., engineer, General Electric Company, Schenectady, N. Y.
Terry, I. A., assistant engineer, motor and generator engineering department, General Electric Company, Schenectady, N. Y.

4 to Grade of Fellow

**To Grade of Member**

Arnold, N., assistant professor of engineering drawing, Purdue University, Lafayette, Ind.
Atkinson, F. W., electrical engineer, Owens-Illinois Glass Company, Newark, Ohio.
Brosemer, R. O., assistant engineer, General Electric Company, San Francisco, Calif.
Chapman, F. W., superintendent, Commissioners of Public Works, Greenwood, S. C.
DeWeese, F. C. engineer, Carolina Power and Light Company, Raleigh, N. C.
Eggertson, E. G., assistant electrical engineer, American Gas and Electric Company, New York, N. Y.
Evans, G. T., assistant chief engineer, The Bristol Company, Waterbury, Conn.
Ferri, L. F., protection engineer, The Ohio Public Service Company, Elyria.
Gaston, J. R., manager, industrial transformer division, American Transformer Company, Newark, N. J.
Geer, G. D., superintendent of distribution, Texas Electric Service Company, Sweetwater.
Gehr, G. A., communication engineer, Los Angeles County Department of Forester and Fire Warden, Los Angeles, Calif.
Houston, H. H., electrical engineer, Federal Power Commission, San Francisco, Calif.
Knerr, L. R., assistant engineer, California Railroad Commission, San Francisco.
Lyman, W. J., electrical planning engineer, Duquesne Light Company, Pittsburgh, Pa.
Miner, R. R., electrical engineer, Kansas Gas and Electric Company, Wichita.
Plummer, C. E., chief electrical engineer, Modesto Irrigation District, Modesto, Calif.
Ritter, A. S., planning engineer, Commonwealth Edison Company, Chicago, Ill.
Rogers, T. A., instructor, department of electrical engineering, University of California, Berkeley.
Rogers, T. I., engineer, American Telephone and Telegraph Company, New York, N. Y.
Snyder, W. R., electrical engineer, Manila Electric Company, Manila, P. I.
Wagner, H. H., head design engineer, Pennsylvania Transformer Company, Pittsburgh, Pa.

21 to Grade of Member

## Applications for Election

Applications have been received at headquarters from the following candidates for election to membership in the Institute. If the applicant has applied for direct admission to a grade higher than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the national secretary before August 31, 1937, or October 31, 1937, if the applicant resides outside of the United States or Canada.

Adkins, P. LeR., Mountain States Power Company, Albany, Oregon.
Allard, E. P., Philadelphia Navy Yard, Philadelphia, Pa.
Beisber, M. F., Line Material Co., Memphis, Tenn.
Bloedorn, E., Acro Welder Manufacturing Company, Stegeman Machinery Company, Milwaukee, Wis.
Cramer, J. F., Central Nebraska Power and Irrigation District, Hastings.
Darroch, J. W., Berkeley Steel Construction Company, Berkeley, Calif.
Duffy, E. (Member), New Orleans Public Service, Inc., New Orleans, La.
Eistrat, T., California State Board of Equalization, Sacramento.
Ferrill R. M. (Member), Tennessee Electric Power Company, Chattanooga.
Foreman, W. R., Department of Water & Power, Boulder City, Nevada.
Frakes, J. H., Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.
Goodridge, H. L., 157 Pleasant Street, Malden, Mass.
Grant, V. H., Bureau of Aeronautics, Navy Department, Washington, D. C.
Hero, A. A., General Electric Company, New Orleans, La.
Hildenbrand, C. F., Electric Light and Power Company of Baltimore, Baltimore, Md.
Kelley, J. R., Department of Water and Power, Los Angeles, Calif.
Kirk, D. H., Baton Rouge Electric Company, Baton Rouge, La.
Kobke, W. J., Brooklyn Edison Company, Inc., Brooklyn, N. Y.
Mahannah, W. D., Florida Power and Light Company, Ft. Pierce.
McDougald, A. D., Navy Department, Mare Island, Calif.
McHenry, J. C., Lorain-Medina Rural Electric, Inc. Wellington, Ohio.
McKinley, W. H., 1930 *B* Street, San Diego, Calif.
McReynolds, A. C., Columbia Electric Company, Kennewick, Wash.
Miller, A. N., International Business Machines Corporation, Endicott, N. Y.
Palmer, J. E., Pacific Gas and Electric Company, Fall River Mills, Calif.
Pappas, P. S., Great Lakes Dredge and Dock Company, New York, N. Y.
Parrish, J. L., Tennessee Valley Authority, Norris, Tenn.
Peatfield, R. R., New York and Queens Electric Light and Power Company., Flushing, N.Y.
Phillips, E. J., Jr. (Member), Simmons-Boardman Publishing Corporation, Chicago, Ill.
Preston, J. D. (Member), Florida Power and Light Company, Miami.
Purcell, W. W. R., Alabama Power Company, Birmingham.
Ryan, J. J., Signal Engineering and Manufacturing Company, New York, N. Y.
Santos, E. J., 88 Charlotte St., Detroit, Mich.
Schenck, S. B. (Member), Bessemer and Lake Erie Railroad Company, Greenville, Pa.
Shaffer, E. E., City Hall, San Diego, Calif.
Stanley, H. C., American Gas and Electric Company, New York, N. Y.
Woodward, B. W., International Sound Photos System, San Francisco, Calif.

37 Domestic

**Foreign**

Bapat, M. N., Tata Hydro Companies, Bombay India.
Epple, R. J., Mene Grande Oil Company, Maracaibo, Venezuela.
Hydari, M., Messrs. Crompton Engineering Company, Ltd., Madras, India.
Kusumoto, S., in care of Hitachi Engineering Works, Sukegawa-cho, Ibaraki-ken, Japan.
Natarajan, K., First Line Beach, Madras, India.

5 Foreign

## Addresses Wanted

A list of members whose mail has been returned by the postal authorities is given below, with the addresses as they now appear on the Institute record. Any member knowing of corrections to these addresses will kindly communicate them at once to the office of the secretary at 33 West 39th St., New York, N. Y.

Charlton, H. C., 4827 Wilson Avenue, Montreal Que., Canada.
Evans, Maldwyn F., Canadian Comstock Company, Ltd., Toronto, Ont., Canada.
Gregory, G. A., 1217 Jefferson Street, Olympia, Wash.
Hardy, John E., 1741 Pennsylvania Avenue, Denver, Colo.
Jones, K. B., Trumbull Electric Manufacturing Company, Inc., Ludlow, Ky.
Phillips, Eugene H., 3006½ South Hoover, Los Angeles, Calif.
Phillips, Robert J., 94–26—34th Road, Jackson Heights, N. Y.
Roberts, Fred A., 2010 West Michigan Street, Indianapolis, Ind.
Schaefer, Philip E., 5154 St. Paul Avenue, Chicago, Ill.
Sikofsky, George L., 1206 East New York Avenue, Brooklyn, N. Y.
Stivender, P. M., Allis-Chalmers Manufacturing Company, 135 South La Salle Street, Chicago, Ill.

11 Addresses Wanted

# Engineering Literature

## New Books in the Societies Library

Among the new books received at the Engineering Societies Library, New York, recently are the following which have been selected because of their possible interest to the electrical engineer. Unless otherwise specified, books listed have been presented gratis by the publishers. The Institute assumes no responsibility for statements made in the following outlines, information for which is taken from the preface of the book in question.

GREAT BRITAIN, DEPARTMENT of SCIENTIFIC and INDUSTRIAL RESEARCH. REPORT for 1935–36. London, His Majesty's Stationery Office, 1937. 195 pages, tables, 10x6 inches, paper (obtainable from British Library of Information, 270 Madison Ave., New York, N. Y., $0.95). Affords a summary of the work carried on during the year in the various establishments of the Department.

HOUSE WIRING, by T. W. Poppe and H. P. Strand. New York, Norman W. Henley Publishing Company, 1937. 256 pages, illustrated, 7x4 inches, paper, $1.00. A manual for the wireman, giving directions for planning and installing the wiring in dwellings.

A COURSE in ELECTRICAL ENGINEERING. volume 1. DIRECT CURRENTS. By C. L. Dawes. 3 edition. New York and London, McGraw-Hill Book Company, 1937. 751 pages, illustrated, 8x6 inches, cloth, $4.00. An enlarged edition of a standard textbook on electrical engineering, the first volume of which covers direct currents. Includes fundamental electrical characteristics, magnetism, electrostatics, and d-c machinery.

SOUND WAVES, Their Shape and Speed. By D. C. Miller. New York, Macmillan Company, 1937. 164 pages, illustrated, 9x6 inches, cloth, $2.75. Contains a chapter upon electric-spark photography of sound waves and its application to the study of projectiles in flight and the acoustics of auditoriums.

WAHRSCHEINLICHKEITEN und SCHWANKUNGEN Vorträge von M. Czerny, K. Franz, F. Lubberger, J. Bartels and R. Becker. Edited by F. Lubberger. Berlin, Julius Springer, 1937. 100 pages, illustrated, 10x6 inches, paper, 8.40 rm. A group of 5 treatises on the fundamentals, theory, and application of probabilities and variations.

WAVE MECHANICS, Elementary Theory. By J. Frenkel. 2nd edition. London and New York, Oxford University Press, 1936. 312 pages, illustrated, 10x6 inches, cloth, $6.75. Contains chapters on light, matter, motion of particles or systems of particles, statistical mechanics, application of the quantum statistics to electron theory, and theory of chemical forces.

MITTEILUNGEN aus den FORSCHUNGSANSTALTEN. Bd. 5, Heft 2, February 1937. Berlin, VDI-Verlag. 52 pages, illustrated, 12x8 inches, paper, 3.15 rm. Includes a report on end sleeves for high-tension cables and a description of a new portable mirror galvanometer for spectroscopic analyses of metals.

THOMAS' REGISTER of AMERICAN MANUFACTURERS. 27th edition 1937. New York, Thomas Publishing Company, illustrated, 12x9 inches, cloth, $15. ($10. to former subscribers). Contains classified and indexed lists of manufacturers of all kinds; lists of banks, boards of trade and other commercial organizations, trade papers, leading manufacturers, and trade names.

# Industrial Notes

**Western Electric Sales.**—Sales of the Western Electric Co. totalled $97,355,000 for the first six months of this year as compared with $65,651,000 for the corresponding period last year.

**Near-Record Business for G-E.**—During the first six months of this year the General Electric Co. received orders amounting to $217,265,619, an increase of 59 per cent over the $136,968,597 received during the same period last year. The record first half year was in 1929 when orders amounted to $220,716,456. Orders during the second quarter of 1937 amounted to $111,518,589, compared with $77,398,718 for the corresponding quarter of 1936, an increase of 44 per cent. The second quarter of this year was the largest, for orders received, since the third quarter of 1929.

**General Cable Appointment.**—R. S. Hopkins has been appointed by the General Cable Corporation as manager of the New York City sales office, 205 East 42nd St.

**Roller-Smith Appointment.**—H. R. Kimball, 176 Federal St., Boston, has been appointed by the Roller-Smith Co., New York, as district sales agent for New England.

**B-L Electric Appointments.**—According to a recent announcement of the B-L Electric Mfg. Co., St. Louis, Mo., producers of rectifiers and condensers, changes in executive personnel have been made as follows: Harold J. Wrape, president; Irvin W. Veigel, treasurer; Carl E. Peters, secretary; R. W. Mansfield, superintendent; Carl H. Massot, purchasing agent.

**New Motors.**—The Century Electric Co., St. Louis, Mo., announces a new complete line of fractional horsepower motors in sizes from $^1/_6$ to $^3/_4$ hp, repulsion start induction, single phase, split phase, capacitor, polyphase and direct current. This line is designed with interchangeable mounting dimensions for a given horsepower size.

**Westinghouse Furnaces to Ford.**—The Ford Motor Co. has purchased from the Westinghouse Electric & Mfg. Co., 12 additional bell type furnaces for annealing automobile body stock. Each furnace will be rated at 230 kw with a capacity for annealing two coils 52 inches in diameter, 48 inches in height, giving a total loading of 32,000 pounds per charge. This new installation will give the Ford Motor Co. a total of 38 bell annealing furnaces, 24 of which are of Westinghouse manufacture.

**Ground Rods.**—Sectional Copperweld ground rods and couplings for deep, low-resistance grounds are a new development, announced by the Copperweld Steel Co., Glassport, Pa. Cold-drawn for rigidity, the Copperweld sections are threaded on both ends and joined as they are driven by means of a threaded bronze coupling. It is claimed that sectional Copperweld rods may easily be driven to depths of 40 or 50 feet.

**Porcelain Case Capacitors.**—A line of porcelain case, high voltage, mica capacitors is announced by Aerovox Corporation, 70 Washington St., Brooklyn, N. Y., for use in radio transmitters and for other electronic purposes. Each unit is housed in a glazed porcelain case and is provided with heavy brass terminal studs and lock nuts. Capacities range from .00005 to .1 mfd. as well as d-c test voltages from 2000 to 12,500.

**Reversing Motor Starter.**—Allis-Chalmers Mfg. Co., Condit Works, Boston, has announced a new reversing motor starter designated type AP-7-R, furnished for $7^1/_2$ hp, 550 volts or less. The starter consists of two type AP-7 motor starter units, mechanically interlocked so that either unit cannot be closed if the other is closed. The starter units are equipped with Ruptors—enclosing chambers which confine and depotentiate the arc formed by circuit interruption. Other features include large, silver, double-break contacts; solenoid operated, vertical make and break; unit construction, pole units consisting of individual molded bases mounted on a steel chassis, and enclosed temperature overload relays, affording positive motor protection; undervoltage protection inherently provided.

# Trade Literature

**Switches.**—Bulletin 54, 8 pp. Describes group operated air switches, tilting insulator type. Pacific Electric Mfg. Corp., 5815 Third St., San Francisco, Calif.

**Circuit Breakers.**—Bulletin GEA-2406A, 4 pp. Describes type FKO outdoor oil-blast circuit breakers; 7500 volts, 400 and 600 amperes, 50,000 kva, 2 or 3 poles, framework or pole mounted. General Electric Co., Schenectady, N. Y.

**Bakelite.**—Bulletin, 16 pp., "The Versatile Service of Bakelite Materials." Describes the development of Bakelite resinous materials, their general characteristics, properties and applications. Bakelite Corp., 247 Park Ave., New York City.

**Testing Equipment.**—Bulletin, 8 pp. Describes R-F signal generators, R-F oscillators, service laboratories, oscillographs, power supplies, vacuum-tube voltmeters, etc. The Clough-Brengle Co., 2815 W. 19th St., Chicago, Ill.

**Rectifier Tubes.**—Bulletin, 44 pp. Describes various types of gaseous discharge rectifier and control rectifier tubes. Characteristics and applications are presented at length. Prices are listed. Electrons, Inc., 127 Sussex Ave., Newark, N. J.

**Splices and Tapes.**—A new and revised edition of this book, which includes such chapters as the importance of a perfect splice, requirements for a splicing compound, for adhesive tape, and instructions for joining, The Okonite Co., Passaic, N. J.

**Switchgear.**—Bulletin GEA 2605, 18 pp., "Modern Switchgear." Summarizes 137 separate products from the complete line of G-E switchgear and contains publication numbers of descriptive bulletins giving additional information. General Electric Co., Schenectady, N. Y.

**Rubber Substitute.**—Bulletin 16 pp. Describes Neoprene, an engineering material with rubber-like properties which resists the deteriorating effects of oil, heat, sunlight, chemicals and oxidation. Among its applications is that of insulating electrical cables. E. I. du Pont de Nemours & Co., Wilmington, Del.

**Neon Transformer.**—Bulletin 143. Describes a neon transformer, the Acme "Autopak," to illuminate neon signs and displays installed in automobiles. No special equipment or extra generator is necessary as current is supplied from the regular automobile generator. The Acme Elec. & Mfg. Co., 1446 Hamilton Ave., Cleveland, O.

**Temperature Instruments.**—Catalog 1060C, 56 pp. Describes indicating and recording temperature and pressure instruments. Much of the data on the latest developments in these instruments has not heretofore been published. Numerous illustrations show the manner of operation and how the instruments are serving the process industries. C. J. Tagliabue Mfg. Co., Park & Nostrand Aves., Brooklyn, N. Y.

**Cables.**—Bulletin C-27, 20 pp. Describes Anaconda Duraseal cable, a non-metallic sheathed cable for direct burial in the ground. In addition to complete descriptions of the types available and their uses, helpful information relative to application, installation and other engineering data are included. Anaconda Wire & Cable Co., 25 Broadway, New York City.

**Motors.**—Catalog 60 pp. Describes construction features, advantages and applications of practically every commercial type of motor. Included are engineering data on various types of special motor applications and construction. A detailed analysis is presented on the characteristics of squirrel-cage motors, motors for centrifugals, etc. The Louis Allis Co., Milwaukee, Wis.

**Insulation Test Set.**—Catalog E-54(1), 4 pp. Describes a new insulation resistance test set, using a guarded circuit, entirely free from the effects of leakage currents. Switches are designed to simplify operation and eliminate calculation. Calibration of the galvanometer deflections is facilitated by the specially designed Ayrton shunt. Simply turning the shunt to the calibrating portion automatically connects the circuit for calibration. Results are obtained by merely dividing the calibration reading by the test reading. The instrument conforms with the ASTM "Standard Methods of Test for D-C Resistance of Insulating Materials." Leeds & Northrup Co., 4962 Stenton Ave., Philadelphia, Pa.

**Westport 230/33-kv substation of the Consolidated Gas, Electric Light and Power Company, Baltimore, Md. The transformers are 42,000-kva units**

# High Lights

**Coupling Between Earth-Return Circuits.** Induced voltages recorded in communication circuits paralleling d-c electric railways, at times of short circuit on the railway, have shown marked divergencies from computed values. Because of the numerous factors that might contribute to these divergencies, experimental studies of the transient coupling between parallel earth-return circuits, free from the effects of shielding conductors, and with concentrated rather than distributed grounds, have been made in order to provide a better understanding of the problem (*pages 1159–64*).

**American Engineering Council.** From its very beginning, in 1920, American Engineering Council has aimed to aid the engineering profession in presenting a united front in matters of interest to government and to the public. A review of some of the problems, policies, and activities of AEC, prepared by the president of Council, appears in this issue (*pages 1082–4*). A report on coal-price fixing and the Bituminous Coal Act of 1937, from a current "news letter" of AEC is included in the news section (*pages 1211–12*).

**Electricity in Steel Mills.** This issue contains 4 papers on the applications of electricity in the manufacture of steel products. One summarizes the entire range of electrical applications in steel mills (*pages 1115–23*); a second describes a 72-inch strip mill (*pages 1105–14*); another describes more specific uses of electricity in the measurement and control of tension in cold-strip mills (*pages 1141–4*); and a fourth indicates the important characteristics of carbon brushes for steel-mill equipment (*pages 1165–8*).

**Limiters.** One solution to the problem of providing short-circuit protection for secondary distribution networks consists of the use of "limiters," which are reduced metallic sections incorporated in connectors, lugs, or other connecting devices used in normal cable installation procedure. A large eastern metropolitan power company has installed 16,000 of these devices on its distribution system during the past year (*pages 1191–6*).

**Inductances for Ultrahigh Frequencies.** With short-wave (or ultrahigh-frequency) radio receivers becoming common, it is important that the inductances for these receivers be properly designed. From the results of experimental and analytical studies of the resistance of small single-layer inductances for frequencies between 4 and 25 megacycles, a procedure has been deduced for the "optimum" design of such inductances (*pages 1169–76*),

**Middle Eastern District Meeting.** Akron, Ohio, world's largest rubber manufacturing center, will be the scene of a 3-day meeting of the AIEE Middle Eastern District, October 13–15, 1937. A program including 23 technical papers, an excellent variety of inspection trips to local industries, and sports and social events has been arranged. A District student conference also will be held during the meeting (*pages 1205–07*).

**Engineers' Income.** The earning power of engineers varies widely, according to information obtained in a comprehensive survey of the profession in which incomes for 1929, 1932, and 1934 were reported. Striking differences exist within each professional class, and within each group classified on the basis of educational background (*pages 1089–1104*).

**Matrices in Engineering.** The matrix not only is "a convenient notation that summarizes in a natural and convenient form whole groups of operations, but . . . it is . . . possible to solve the sets of differential or algebraic equations written in matrix form in a most convenient manner" (*pages 1177–90*).

**Resistance Welder Control.** Fully automatic repeat control devices are needed to obtain maximum operating speeds in resistance-welding machines without sacrificing the quality of the welds. Operating speeds of 350 or more welds per minute are said to be made practical with a new type of control equipment(*pages 1145–8*).

**Selection and Training of Engineers.** Many members of the Institute will recall having heard Retiring - President MacCutcheon speak on this subject at their local Section meetings during the past year. In response to many requests, Mr. MacCutcheon has prepared this address for publication (*pages 1085–8*).

**Noise Test Code.** A proposed test code for apparatus noise measurement has been developed by an AIEE subcommittee. The purpose of this code is to establish uniform methods of conducting and reporting sound-level tests on apparatus. Discussion is invited (*pages 1079–82*).

**Silver-Tellurium Alloys.** Compensation of temperature errors in electrical instruments may be accomplished by the use of series resistors having negative temperature coefficients of resistance. A method of making such resistors of tellurium and silver has been described (*pages 1128–33*).

**Electric Shock.** That low-voltage house circuits can give fatal shocks is shown by the death of from 100 to 200 persons annually in the United States from this cause. Preventive measures will reduce the hazard, and resuscitation will save many victims (*pages 1077–9*).

**Alternator Short Circuits.** Formulas for armature currents in the faulted phases and for the main field current at any time after the short circuit have been developed for a double line-to-neutral short circuit of an alternator (*pages 1149–55*).

**Engineering Education.** An eminent engineering educator has prescribed a new type of engineering curriculum for undergraduate students, intended to produce engineers interested in assuming places in public leadership (*pages 1073–6*).

**Prize Awards.** National and some District prize awards for 1936 AIEE technical papers were announced in the June issue; additional awards, for Districts 5 and 8, have now been announced (*page 1208*).

**Flywheels for A-C Units.** A compendium of the theory of flywheels for a-c generating units and of the parallel operation of such units is included in a paper in this issue (*pages 1158–60*).

**The 2-Reaction Theory.** Extensions of the 2-reaction theory as applied to multiphase synchronous machines are included in 2 papers in this issue (*pages 1124–7 and 1197–1201*).

**Rectifier Regulation.** Several factors may affect the "angle of delay" which is used in calculating the regulation of grid-controlled rectifiers, and their effect should be included in the determination (*pages 1134–40*).

**Letters to the Editor.** Comments on AIEE publications and incandescent-lamp voltages appear in the "letters" columns of this issue (*pages 1212–13*).

# DISCUSSIONS

Appearing in this issue are discussions of the following papers:

**Watt-Hour Meter Bearings**—Kinnard and Goss **1202**

**First Report of Power System Stability**—Subcommittee Report **1204**

Statements and opinions given in articles and papers appearing in ELECTRICAL ENGINEERING are the expressions of contributors, for which the Institute assumes no responsibility. # Engineering Education and Democracy

By ROBERT E. DOHERTY
FELLOW AIEE

**Most engineers are agreed that the engineering profession is not sufficiently active in civic and governmental affairs; that engineers are not sufficiently insistent in voicing their opinions to public officials who administer affairs vital to the profession. With a view to the future, an eminent educator here prescribes one form of engineering education intended to build engineers interested in assuming their places as effective citizens in our democratic government.**

PREVIOUSLY I have had the privilege of discussing before the Institute[1] and elsewhere[2,3,4,5] certain problems of engineering education, especially those relating to the undergraduate program. On such occasions I have stressed the importance of a thorough understanding of fundamental science and have expressed concern over the relatively high degree of specialization in undergraduate work at the expense of such understanding; I have contended, moreover, that educators should give to students a start toward that rounded-out education which is so essential to professional activity on a high plane, and which is indispensable in placing engineers in effective leadership alongside other professional men. This latter phase I shall now discuss further, and emphasize as much as possible the critical necessity for prompt attention to this matter. Educational machinery for readjustment moves slowly; the process of bringing young men from freshman year to professional maturity requires from 15 to 20 years; and social and economic change continues at an accelerated rate with little or no intelligent control. Hence time is important.

Increasing complexity confounds us. Technology with all its blessings yet subverts traditional habits and attitudes of mind; narrow specialists multiply endlessly; interdependence of individuals and of communities increases apace; pressure groups spring up on all sides; rackets thrive; selfish interest reigns supreme. Surrounded by all of this, we find ourselves, our hopes for our children, and the great possibilities of American democracy, primarily in the hands of confused lawyers and economists. They are not to be condemned; on the contrary, they are to be given great credit for at least some serious thought regarding the matter. Merely, things have moved too fast for them. But to what extent has the engineering profession taken a hand? It has added fuel to the technological flame that has illuminated and warmed the whole social community with physical comfort and convenience, but apparently it has not occurred to the profession that the flame, though beautiful and interesting, may yet consume us. Engineers, who understand technology, must give more thought to consequences. They, in common with lawyers, economists, and other responsible professional people, must consider a new kind of educational preparation for their oncoming generations, for if these generations grow up with the limited understanding, and with the attitudes that characterize present professional groups, it would seem our hopes are forlorn, because the enemy's strength now is growing faster than ours.

Believing, as I do, that new professional attitudes are essential and that these can be created in sufficient strength only by education of the professional generation yet in college, or just graduated; and believing further, that the accomplishment of adequate changes in educational programs will require, first, the adoption of a significantly modified philosophy by both educators and industrialists; and still further, that to change attitudes in older generations regarding education itself is difficult—believing these things, I have grown to be less optimistic. In any case, the first basis for optimism will be a concerted move toward a readjusted philosophy.

What are the fundamental attitudes from which our thinking should proceed? More specifically, what is *the* fundamental attitude? What others are implied?

Unquestionably we must start from the premise that competent citizenship is the first responsibility, and that the more the individual's educational opportunity is extended, the greater this responsibility. This aspect of educational philosophy, although recognized here and there, is almost wholly overlooked in higher education. Great credit and gratitude are due those educators that preside over primary and secondary education for their attitude in this connection, but the matter must not rest at that point. Competency as a citizen requires more than a preliminary knowledge of the origin, purpose, and form of our government, the early disposition to co-operate and accept majority opinion, and the other attitudes cultivated in the first levels of education. It requires, as well, especially of the better minds that have had the privilege of higher education, an understanding of principles and forms of government, a cultivated ability and attitude to weigh the complex issues that arise; and some feeling of obligation to decide intelligently and give support to

---

Essentially full text of an address presented at a meeting of the AIEE Lehigh Valley Section, Bethlehem, Pa., May 14, 1937.

ROBERT E. DOHERTY is president of Carnegie Institute of Technology, Pittsburgh, Pa. Doctor Doherty served as a designing engineer for the General Electric Company, Schenectady, N. Y., from 1910 until 1920, when he became an assistant to Doctor C. P. Steinmetz (A'90, M'91, F'12, and past-president). Upon the death of Doctor Steinmetz in 1923, Doctor Doherty became consulting engineer for the General Electric Company, and served in that capacity until he became professor of electrical engineering at Yale University in 1931. In 1932 he was appointed dean of the school of engineering, and in 1936 was elected president of Carnegie Institute of Technology. He has served on many of the Institute's technical and general committees, and has contributed much to technical literature.

1. For all numbered references, see list at end of article.

the decision. Our experiment in democracy rests foursquare upon the assumption that the citizens themselves are competent to settle issues wisely. My question is: If most of those, including engineers, whose minds are trained to think carefully, are to be directed merely to enterprises that create still more of the social and economic complexities that confound us, who will do the thinking in our community and national life? For, after all, are we not interested quite as much as a nation in where we are going and taking our children, as in the thrill and fascination of the journey itself? If we are not interested as trustees of American freedom, then are we not interested as parents of our children? I can answer the question. If more professional people, who presumably are trained to think, do not take interest in these matters, then the future talent exercised upon the problems of state will be unchanged, and the result is clear. The American experiment is too great, its ramifications too complicated, its growth in complexity too rapid, its values too precious to be guided by emotion and selfish interest. A successful issue of the experiment demands guidance that is based on intelligent, dispassionate study, and this cannot come from a mere handful of men; it must, by the very nature of democracy, come from large numbers. If this nation is to endure as a free nation, we must not forget, as we certainly have done, the fundamental philosophy of 1776 that competent citizenship is our first responsibility, and that this responsibility becomes proportionally greater as the educational privilege is extended.

If this point of view is once again seriously accepted, then new attitudes are implied in higher education and business. Professional education must devote to this end more of the precious time in its programs, and this means either that the programs must be extended, or that industry and business must be willing to accept graduates with training less specialized then they now have. I wish to discuss the problems into which we should thus be led, confining myself to engineering education and to industries that absorb engineering graduates.

What would engineering education do if industry gave it a free hand? The following is what it might do, and what I think it ought to do: The indispensable parts of engineering education, in my opinion, are an understanding of mathematics and the basic physical sciences; a characteristic habit of mind engendered by dealing with the purpose of utility and with definite facts, laws, and predictable outcomes; and thus a combination of these which has been termed "the engineering method." Science alone is not enough; neither is a superficial dabbling with the method without the science. Both are necessary. So the first step is to provide these, or else we shall be beyond the limits of engineering education. But having provided them, we shall have a curriculum that qualifies by definition; and anything further on the technical, scientific side is to be regarded as specialization.

But I am now proposing that we change the definition. It should include as well the requirement of an adequate background and discipline for the new responsibility: that of dealing with problems involving social elements. Both as a citizen and as a professional man active in matters that affect environmental relationships in society, the engineer is under obligation to be prepared for this responsibility, and he should not be regarded as an engineer in the professional sense without it. The civic aspect of this responsibility already has been discussed. I now add the professional, since the educational preparation for the one is also for the other.

Some two-thirds of all engineering graduates eventually have entered work involving personnel management, and perhaps half that number have assumed this reponsibility in a major way. The dark labor situation that recently has sprung up throughout the country indicates the extent to which engineers, even though involuntarily, are rapidly being thrown by the onrushing technological tide into positions where their plans and decisions may have pervasive social implications. No other group is in such a key position as are engineers to make great contributions to industrial peace. By virtue of such a position, which yearly is growing in importance, engineers' professional responsibility is an additional reason for their active interest and competency in dealing with social and economic problems, and in framing an educational program these aspects of responsibility should be recognized as on equal footing with technical responsibility so far as their being essential factors is concerned.

What, then, are the practical implications regarding the curricula? Stated generally, they are the necessity for a redistribution of time and emphasis, and the question of whether industry is willing to assume a share of the responsibility by accepting graduates with broader and more thorough training, but with less specialization.

Before entering these particular matters I wish, in the interest of clarity of discussion, to dispense with certain questions that are closely related. In the first place the thesis of this discussion should not become confused or lost by the mention of the 5-year curriculum. In the view of that portion of past industrial generations that built rapidly and inefficiently, the way to get increased output was merely to extend the plant. With allowances there is a parallel here which might be profitably drawn when the 5-year plan is pressed. Unquestionably some students desire, and can afford the time and money, to spread their education over 5 or 6 years at undergraduate level, and they should be able to do so. Moreover, a relatively small part of them should extend formal education into graduate study in higher scientific levels. These would constitute the supply of professional technical specialists. All of this seems clear. However the great mass of those who study engineering should not be required to take an added year or two out of their professional lives either because we feel, like the past generation of industrialists, that the only way to change is to add, or because certain phases of present industries require at graduation specialized skills that could equally or better be learned on the job. I am convinced that if industry will do its part, graduates can be prepared, along the lines I have indicated, within the 4-year period.

I believe industry will do its part. There are many

leaders of industry whose views I do not know, but practically every one of them whose opinion I have read or heard has not urged specialization, but breadth of view. The classical report of the Society for the Promotion of Engineering Education (1923–29) includes composite opinions of industrial leaders and practicing engineers regarding the character of education desired in an engineer; and questionnaires of similar purpose have been analyzed and reported in numerous other publications. One certainly cannot conclude from the well-known results of these inquiries that in general industry demands specialized training at the expense of fundamental breadth and humane understanding. Yet the necessity of retaining existing courses of specialized nature seems to hinge on the idea that a graduate will not be able to get a job if he does not have them. To whatever extent it is true that industry, by insisting upon the teaching of special, routine skills, prevents us from educating our students along broader lines that seem to be so clearly necessary, then to that extent it becomes our responsibility to convince industry that its position is ill-advised. The stakes are too large in this matter to permit a narrow view of a small part of industry to dictate general educational policy. In any case, I set down as the problem before us, a 4-year program that will recognize the educational policy outlined, and yet be a preparation for entering those fields that now employ engineering graduates.

The first critical question is the distribution of time between the technical and social phases, or stems, of the curriculum. This will depend in a limited way upon such factors as the field of activity for which students are preparing. For instance, a course looking primarily to management would demand a larger portion of the curriculum for the social phase than one looking primarily to technical engineering. Moreover, if the students were divided into general course and honors groups, as presumably they will be more and more, the programs of the honors group probably would include more time for the social stem. Naturally, individual judgment as to the division of time also will vary. My own opinion is that the social stem should be accorded from one quarter to perhaps one third or more of the total time, depending upon the factors referred to.

There is an additional specification regarding the time distribution: the social stem should be continuous. The purpose is to build up a habit of mind; to create a desire to become broadly educated; to cultivate a *stem* which will continue to grow after graduation. And I am clear that this cannot be accomplished by discontinuous effort. The program must be continuous and sequential, beginning in the freshman year and extending through the senior year into professional life.

The second critical question is the specific nature of the social and economic side of the program. What subjects should be included? How should they be taught? I have found only one way in which to answer these questions. It is first to state specifically the outcomes desired, and then frame the program so that it will achieve these outcomes. Perhaps the program cannot be defined in traditional terms; merely of subjects to be studied and courses to be taken. The things that cultivate those definite outcomes must be considered, and traditional courses in history, English, economics, government, and sociology, will not accomplish the purpose. In the first place, there would not be enough time for the student to cover these subjects in the traditional way, and secondly, even if he did so, he would not achieve the ends.

What, then, should be the outcomes? I recommend (1) a clear historical understanding of the parallel growths of science and engineering, on the one hand, and social customs, relations, and institutions, on the other, and how these have reacted on each other. In other words, a historical perspective of social evolution, especially since the invention of the machine: (2) The ability to read purposefully in order to make a critical analysis of a problem involving social and economic elements, and arrive at an intelligent opinion about it. The ability to analyze technical problems does not, as sometimes assumed, imply an ability to analyze these others: (3) The ability to organize thoughts logically and with purpose: (4) The capacity to use the English language and thus express those thoughts effectively: (5) Appreciation of English literature: And (6) a continuing interest in all these matters, and thus the desire to become educated.

These outcomes imply the general character of the social stem of the curriculum. They imply extensive and carefully selected reading and seminar or class discussion during the first 2 years, in order to acquire general background and to establish clear conceptions of both the decisive turning points in social development and the attempts that have been made by social scientists to generalize from the recorded experience. This preliminary study must not be too detailed. It must be directed toward establishing an over-all pattern that can be examined as a whole. What is essential is a clear picture of the general features of the highway system by which civilization has reached its present stage—the junction points, the sign posts and traffic signals, the most general character of the main routes, and possibly some of the important detours. The less essential features of the individual highways, of the scenery and towns along the way, and of detailed social customs must be left to future study when more time may be spent in a particular section. I cannot emphasize too strongly the importance I attach to such an integrated view. It must be achieved at all costs, but it does not cost much. There is adequate time in 2 years if only one can restrain the habitual insistence of many textbook authors upon the gorging of details, and of instructors thus to administer them. With such a general picture in mind, subsequent study of problems and subject matter regarding a particular area then becomes both intelligent and interesting.

In the last 2 years only a few special problems should be studied; that is, definite social and economic questions about which the student would be required to read under competent guidance, and come to an intelligent opinion. He should have 3 or 4 of these in the junior year, one or 2 in the senior, each being more difficult than the last, and have the responsibility of defending his solution, pre-

sented in an essay before a small seminar—not more than 7 or 8 participating students, each of whom had read the essay. Such a program would not involve many scheduled classes, especially in the last year. There would be seminars only at times when problems were ready for review, and a few other meetings found to be necessary to keep students under way. These latter would occur more frequently at the beginning of the junior year, and almost not at all in the second semester of the senior year. But the transition from frequent meetings to few is necessary. The rest of the time would be devoted to reading, study, and writing.

I wish to stress especially this feature of independent study of a question. It gives actual experience in *doing*. One can read for background, take course after course in this and that, but until one has actually gone through the process of reading around a question and has one's self thus formed an intelligent judgment that must stand the test of critical discussion—until then, one has missed a fundamental first step in achieving a disciplined intellect. And if that educational experience is not acquired in college, it may never be.

May I add one or 2 more comments about this particular feature of the plan? I may be accused of proposing graduate activity in undergraduate work. Perhaps I am. Undergraduate students may seem immature, but I feel that the character of much undergraduate work tends to keep them so. I am convinced that the sooner they can be introduced to the *method*, however simple the problem, of high-grade graduate activity, the more we shall help students achieve intellectual maturity.

Or it may be said I am proposing merely an honors course, after the English model. Perhaps I am. There is this distinction, however, that simplifies our problem: Here the student's reading centers around a specific question, not a whole field. Indeed, he may be led to read in 2 or 3 fields to solve his problem, but his entire activity has a perfectly definite focus, and the character of the problem always can be adjusted to his ability and available time.

Finally, it may be suggested, and with some reason, that such a program would be too expensive and administratively complicated, but it is not as bad as it appears. The first 2 years would be largely class work as to time and schedule, but with emphasis different from the usual. And in the last two, although much of the guidance may be individual in character, the conferences would not be frequent—perhaps biweekly. And those aspects of the work which, in the earliest part of the junior year may seem to require more frequent meetings, are those which can be handled in group meetings. Moreover, I acknowledge that a portion of the class may require group guidance for an extended period, and these should be so guided. Although the program may involve careful planning, the values are too great to forego, especially for those students who can pursue the work with a minimum of guidance.

Returning now to the other features of the program implied in the proposed outcomes, I have mentioned the ability to organize thought and to express it effectively. A rigorous discipline in achieving logical relationships of ideas, and in writing, should be a characteristic of the program throughout the whole 4 years. Through the medium of essays, very simple at first, the student's mind should be kept in constant challenge as to logical thought and statement.

With respect to an appreciation of English literature, I confess I see no better way to foster this than the best type of English courses. The purpose should be to create an interest and desire to read for pleasure; it should not be to cover as much literary ground as possible. By the way, one theory I have heard for covering much ground is that it is the last chance to tinge the poor engineer with a little culture! Thus the requisites I would specify are interesting subject matter, interesting class discussion, interesting essays.

Summarizing, I have thus outlined the nature of the program I would recommend as the social stem of the engineering curriculum. The educational values are as follows: All reading and study would be focused upon a definite, clearly visible objective; counsel of a mature mind; experience in pursuing independent critical study, in discriminating between the important and the trivial, in forming intelligent judgments, and in organizing thought logically and with purpose; the discipline of intelligent criticism by other minds; and the unmatched incentive to fruitful effort by the student of his "coming to bat" before, and in competition with, his associates. And I think I am justified in adding that it will create in many students the desire to continue reading and study after graduation. Experimentation for 4 years with such a program in junior and senior years gives me confidence that the outcomes implied in the proposed educational policy can be achieved reasonably; they certainly can be fully achieved with the better minds.

Is it worth while? Is America worth while? I do not suggest that this particular program is the final answer to the problem. It is still at experimental stage. And there may be many other ways to accomplish the purpose. But I do insist that we cannot escape the responsibility of striving toward the outcomes I have indicated, and insist, further, that the present typical educational programs do not achieve them. And even if adequate programs may cost slightly more, and require sacrifices in the specialized courses on the technical side, I repeat the question, Are they not worth while? For what is to be gained by preparing engineers to continue their building of a physically magnificent structure only to have it torn down ultimately by the uncontrolled, unintelligent forces of selfish interests and vandalism?

# Electrical Accidents

By W. B. KOUWENHOVEN
FELLOW AIEE

**Six factors influence the result of an electric shock: type of circuit, voltage, resistance, current, current pathway, and duration of contact. Preventive measures will reduce the hazard, and resuscitation will save many victims, according to information summarized in this article, which is based on reports previously published.**

MAN-MADE electric shocks are not modern. The first shock recorded in literature was reported by Galvani in 1780. The first fatal electrical accident occurred in France in 1879. In the United States the present death rate due to electrical accidents is one per 100,000 of the population. Approximately one-half of the electrical accidents reported result in fatalities. Some fatal accidents occur on low-voltage circuits and the house circuits account for the deaths of between 100 and 200 persons annually. With the increased availability of electric power and the new uses that are advocated, there is the possibility that electrical accidents may increase. It is the duty of engineers to acquaint the public with the dangers that do exist, so that undue hazard may be avoided.

Maclachlan[1] has published an excellent study of 479 cases of electric shock for which complete data are available. He showed that men are more commonly injured than women and that the ages of the greatest incidence of shock lie between 15 and 30, perhaps owing to the greater carelessness of youth. Accidents are more common in the summer months, as the result of the smaller protection offered by the clothing and the presence of perspiration, which lowers the skin resistance. Maclachlan found that accidents are more common at the end of the working day when fatigue is at a maximum. He reported that the current path through the body is generally from the right hand to the feet.

## Factors Involved

In every electrical accident there are 6 factors which influence the result. These are, first, the type of circuit with which contact is made; second, the voltage of the circuit; third, the resistance offered to the flow of current; fourth, the value of the current; fifth, the current pathway through the body; and sixth, the duration of the contact with the circuit.

### Type of Circuit

The type of circuit[2] with which contact is made affects the resulting injury. For example, low-voltage alternating current is more dangerous than the corresponding continuous voltages. On the contrary, d-c circuits above 1,000 volts are more dangerous than a-c circuits of the same voltage. Experimental studies[3] have shown that there is little if any difference between commercial 25- and 60-cycle circuits.

The tetanic contraction of the striated musculature of the body caused by contact with d-c circuits is not as severe as that produced by alternating current. The latter will sometimes throw the victim clear of the circuit. Experiments made with the lightning discharge of an impulse generator on animals showed no evidence of musculature contraction.

### Voltage

High-voltage circuits are recognized as dangerous and are carefully avoided by everyone. The public considers the low-voltage house circuits as perfectly safe; this, however, is not the case, as already has been stated. The contraction of the muscles when good contact is made with a low-voltage circuit is usually insufficient to throw the victim clear. He is held in contact with the circuit and death may result. Many of these low-voltage accidents could be avoided if the public appreciated the danger and realized that electricity, although a good servant, is a bad master.

### Resistance

Greatest protection against electric shocks, particularly those caused by low-voltage circuits, lies in the skin. The resistance that dry skin offers to the flow of electricity ranges from 70,000 to 100,000 ohms per square centimeter. Its value depends to a certain extent upon the callousness of the skin. Once the current enters the body, the tissues offer only a relatively low resistance to its flow.

When the skin is thoroughly moistened by washing or perspiration, its resistance falls to less than one one-hundredth of its dry value. It is under these conditions that contact with the low-voltage circuit is dangerous. Contact with electric circuits should be made impossible in kitchens, bathrooms, cellars, and industrial locations where moisture is present.

Considerable heat is generated in the epidermis at the points of contact with the circuit, because of its high resistance. If the victim cannot release his hold and contact with the circuit continues for even a short time,[4] the temperature may be raised to a sufficient degree to produce blisters. These break down the skin and destroy completely any protection that it had initially offered to the flow of current.

An address presented at the exercises commemorating the 25th anniversary of the engineering school of The Johns Hopkins University in February 1937.

W. B. Kouwenhoven is professor of electrical engineering and assistant dean of engineering at The Johns Hopkins University, Baltimore, Md. He is a director of the AIEE, and a past vice-president. Doctor Kouwenhoven has served on many Institute committees, and is the author of several papers on the subject of electric shock.

1. For all numbered references, see list at end of paper.

### Current

The sensitivity to electric currents varies widely. Some individuals can detect the presence of currents of one milliampere or less, while others require several times that amount in order to be certain that a circuit is alive. In any electrical accident, Ohm's law determines the current that flows, and it is the passage of this current through the body that determines the injury produced. The question naturally arises: What value of current is dangerous? The writer believes, because of the results of laboratory experiments and field data, that an alternating current of one-tenth of an ampere at commercial frequencies is sufficient to cause death provided it flows through the vital organs. This does not mean, however, that a current of 20 amperes will make death more certain. In fact the opposite is more often the case. The reason for this apparently anomalous statement is due to the fact that the flow of a small current through the chest may be sufficient to destroy the normal rhythm of the heart and to throw that organ into ventricular fibrillation. Under these conditions, the circulation of the blood ceases and death ensues as the human heart rarely recovers its regular beat spontaneously. A large current, however, produces a severe contraction of the body musculature including that of the heart and holds that organ at rest. Then when the circuit is broken, provided the duration of the contact is brief, the heart automatically resumes its activity.

### Current Pathway

The path that the current follows in its passage through the body is of great importance. In general, if no vital organ lies in the pathway, no serious injury results. For example, in experiments with rats when the electrodes were attached to the 2 hind legs, all but 2 of the animals survived a 2-second shock from a given circuit without injury. When, however, the electrodes were shifted to the forelegs all of the animals died. The currents and voltages were the same in both experiments. Once the current is inside the body, it spreads out in a more or less fusiform shape, assuming uniform specific resistance for the tissues. It is difficult to believe that any appreciable current passes through parts of the body that lie far outside of the main current pathway. There are, however, accident cases on record where unconsciousness followed the passage of a current between 2 fingers on the same hand or 2 points on the same leg. In such cases, no current flows through the central nervous system and the action must have been caused by the sudden shock and the resulting vasomotor changes.

The brain appears to be relatively easily injured by the passage of an electric current, and in legal electrocution one electrode is placed on the head. Fortunately, in most industrial accidents the brain does not lie in the current path; however, the heart and respiratory apparatus are often injured. In many electrical accidents the current in passing through the body produces a block in the nervous system. This prevents the normal stimuli from the brain reaching a given organ. If that organ is the breathing mechanism, the victim will die of asphyxia, unless artificial respiration is given promptly.

### Duration of Contact

The duration of the contact with the circuit is extremely important in determining whether an individual will survive or not. There is usually little data available in cases of human accidents as to the length of time that the current flowed through the body. In our first series[5] of experiments on animals in which they were subject to shocks of different voltages, the importance of the time factor was clearly demonstrated. In general, the higher the voltage, the shorter the time during which the circuit may remain closed and there be hope of resuscitation. Fortunately, due to the violent contraction of the muscles when contact is made with high-voltage circuits, the shock is usually of short duration.

## Preventive Measures

It is the duty of qualified persons to acquaint the public with the rules for the safe handling of electrical circuits and devices. It is the duty of the designing engineer and architect to reduce the low-voltage hazard by specifying highest grade equipment and so installing it as to make humanly impossible, as far as practicable, contact with a live circuit, especially in damp locations. The floors of such places are usually of concrete or similar electrically semiconducting material. Keeping in mind the fact that in most accidents the current flows from the hands to the feet, the building designer might well consider the question of providing an insulating floor covering. The manufacturer of power-operated hand tools and their accessories should use ample amounts of the best grades of insulation because the best is none too good.

## Resuscitation

The problem of the resuscitation of a shock victim divides itself into 2 fields, namely, the treatment of the fibrillating heart and of cases of paralysis of respiration due to nerve shock.

### Countershock

The statement has been made that small amounts of current are sufficient to throw the heart into ventricular fibrillation, but that when a large current flows, the heart is held quiet because of the strong musculature contraction. Experiments were carried out in which the heart was first thrown into ventricular fibrillation and then a larger current applied for a short time in order to ascertain if it were possible to arrest the fibrillation and recover normal heart action. These experiments[6] were successful. Ventricular fibrillation was stopped in dogs whose hearts had been left in that state for periods up to 5 minutes by the use of a "countershock" of 6 or 7 amperes at 330 volts applied by means of electrodes located on either side of the animals' chests. In these cases, the hearts have resumed normal operation and the animals have recovered. Ferris and Williams[7] have also experimented with the countershock method of resuscitating the fibrillating heart, and, using larger animals, have duplicated these results.

In the experiments carried on over a period of time at

The Johns Hopkins University, fibrillation has been stopped after having been allowed to continue for periods of more than 5 minutes. Although circulation has been re-established for a time in some of these cases, experimenters have not succeeded in saving the animals.

[**Editor's Note:** The method of countershock has not yet passed beyond a laboratory stage. Immediate application of artificial respiration is the recommended procedure.]

### Artificial Respiration

The most common result in electrical accidents is a physiological block or break in conduction in the nervous system controlling the operation of respiration. The victim will be apparently dead; he will not be breathing and his heart beat may be so faint as to make it impossible to detect the pulse. The nerves have been paralyzed by the current and no longer transmit the stimuli from the brain to the lungs. The block will often disappear in time if given a chance. Artificial respiration by the Schaeffer prone-pressure method should be applied at once and be continued either until the victim recovers or until rigor mortis sets in.

Remember that death from electric shock is often only apparent and that lives have been saved by the prolonged application of artificial respiration.

# A Proposed Test Code for Apparatus Noise Measurement

## An Advance Report Presented for Purposes of Discussion

PREPARED under the auspices of the subcommittee on sound* of the AIEE standards committee, this preliminary report is intended to provide some basis for standardized technique in the relatively new field of apparatus noise measurement. Because of the newness of apparatus noise investigations, and the importance of the subject, the subcommittee anticipates some possible inadequacies in this report, and solicits criticisms and comments from readers. To facilitate specific discussions, paragraphs are numbered.

1. This test code is intended for use as a guide in the measurement of sound levels and the investigation of the various elements that contribute to the total noise produced.

2. Often, after apparatus is installed, questions arise as to the true causes of the observed sound level, and the best way in which to reduce it. Also, it is often desirable to design apparatus for a given installation to meet a specified sound level. These objectives require knowledge of the sound produced by the apparatus and of the effects on the sound level of reflections and absorption due to the ambient conditions. In this connection, it is necessary to make numerous measurements of sound levels, both in the factory and in the field.

Published at the request of the AIEE standards committee. Manuscript submitted July 27, 1937; released for publication July 30, 1937.

* Personnel of Subcommittee on Sound of AIEE Committee on Standards, 1936–37: P. L. Alger, *chairman;* A. P. Fugill, C. R. Hanna, H. B. Marvin, R. G. McCurdy, and H. M. Turner.

3. The purpose of this code is, therefore, to establish reasonably uniform methods of conducting and reporting such sound level tests, so that wherever or by whomever tests are made, the results will be of value for record and will be truly comparable with tests made at other times and places.

4. It is recognized that additional codes, sponsored by appropriate industry committees, may be desirable in the future for the conduct of sound level tests on specific types of apparatus, such as fans, motors, gears, etc. The present code contains only general recommendations, which will serve as a guide in the development of the technique of sound-level testing and a common foundation for future codes for specific types of apparatus.

## Scope

5. This test code contains general instructions for conducting and reporting sound-level tests on apparatus. It is based upon the 1936 American standards *Z*24.1 (Acoustical Terminology), *Z*24.2 (Noise Measurement), and *Z*-24.3 (Sound-Level Meters).

## General Considerations in Apparatus Noise Measurement

6. To appreciate the necessity of a test code for sound measurement, it is well to review a few of the important

physical phenomena attending the transmission and radiation of sound which have to be considered in formulating the code.

### Radiation of Sound

7. The distribution of sound about sources other than a few simple types is usually very complex. The out-of-phase as well as the multifrequency vibrations which exist on the surfaces of large sounding bodies such as transformers, motors, and generators, and other apparatus give rise to sound patterns that defy mathematical analysis. In practice, however, several simplifying assumptions can often be applied to help us understand the nature of sound radiation from apparatus. If the wave length of the emitted sound is large compared with the dimensions of the source the sound will be radiated quite uniformly in all directions. But if the wave length is short compared with the dimensions of the source, important directive effects will appear. This suggests that for large sound sources with complex radiating surfaces, a considerable number of sound measurements at different points about the source should be made and averaged to determine the sound level of the source.

8. Many small sound generators such as fractional horsepower motors, small contactors, electric clocks, etc., are inefficient and nondirective radiators of low-frequency sound, but they can be excellent radiators of sound of higher frequencies. Such sounding bodies can often produce marked increases in sound of lower frequency when their vibrational energy is transmitted to surfaces large enough to be efficient radiators. This principle, along with resonance, is often used to amplify the feeble tone of a tuning fork. A conventional horn-type loud speaker reproducing music outdoors provides an excellent example for illustrating directive radiation. The lower-frequency components of the music can be heard about equally well in all directions. The higher-frequency components, since they are effectively directed, can be heard best along the axis of the speaker.

9. A study of the radiation of single-frequency sounds from generators of simple shape reveals several interesting facts that should be kept in mind when noise measurements are made. If we assume a vibrating disk of dimensions such that the wave length of the emitted sound is short compared to the diameter of the disk, we find that for a range of distances along the axis, dependent upon the wave length and the distance, the intensity of the sound goes through a series of maxima and minima before a distance is reached beyond which the intensity decreases inversely as the square of the distance. If we assume a pulsating sphere which is small compared to the wave length of the emitted sound the intensity in free space will decrease inversely as the square of the distance. In this latter case, the sound level will decrease 6 decibels each time the distance is doubled.

### Room Effects

10. Particular attention should be given to sound radiated from room surfaces in response to vibrations transmitted through the apparatus supports. Sound produced in this way can be controlled by providing suitable vibration isolating supports for the apparatus.

11. When sound generators are placed within rooms the sound will usually be reflected back and forth many times from the surfaces, and so give rise to a complicated distribution of intensity within the space. At any point within the room the sound level is the resultant of 2 effects; namely, the direct sound which reaches the point without first being reflected, and the indirect sound which arrives after suffering one or more reflections from surrounding surfaces. In general, there will be little correlation between intensity and distance to the source. The intensity may not decrease inversely as the square of the distance; instead it may even be found that at certain points remote from the source the sound is more intense than at positions much closer.

12. The effect of room reflections upon sound measurements can usually be made small by placing the microphone close to the source, and by taking a number of measurements about the source. The use of effective sound-absorbent materials on the interior surfaces of the room will help materially in reducing the effect of indirect sound.

13. An analysis based on reverberation theory leads to the conclusion that if a given amount of sound is generated within a room, the average energy density due to diffusely reflected sound is inversely proportional to the total absorbing power of the room. Hence, assuming that a given absorbing power is constant with respect to the important frequencies in the sound, and converting the expressions relating the intensities at a point in the room where the sound is mostly indirect to the corresponding decibel expressions, the following relation approximately applies:

$$(SL)_1 - (SL)_2 = 10 \log_{10}\left(\frac{A_2}{A_1}\right)$$

where $(SL)_1$ is the sound level in decibels in a room having a total absorption of $A_1$, and $(SL)_2$ is the sound level when the absorption is $A_2$.

## Ambient Sound Levels

14. Measurements made in many locations have shown that the sound levels existing in factories, offices, and residences usually fall within the ranges given below:

| | Sound Level in Decibels |
|---|---|
| Factories† | 60–90 |
| Offices | 40–75 |
| Residences | 30–55 |

## Instrument Standards

15. A sound level meter in accordance with American tentative standards for sound-level meter Z24.3 should be used for measuring sound level.

16. Three response curves are provided for in the standards, curve *A* for a 40-decibel sound level, curve *B* for a 70-decibel level, and a flat response curve *C* for higher

**Table I. Correction for Ambient Sound Level**

| Difference in decibels between ambient plus apparatus sound level and ambient sound level | 2 | 3 | 4 | 6 | 8 | 10 |
|---|---|---|---|---|---|---|
| Correction to be applied to ambient plus apparatus sound level to obtain apparatus sound level | −4.3 | −3.0 | −2.2 | −1.3 | −0.8 | −0.4 |

levels. Each of these curves is desirable for use under proper conditions, but it is recommended that curve *A* be used for usual apparatus noise measurements, curve *C* for very high intensities where low frequency noise is predominant, and that curve *B* be used only in special cases.

17. This recommendation is supported by the fact that it is important to have sound-level readings representative of the level that is actually heard under operating conditions. If the apparatus sound level is high, the apparatus is usually placed remote from the point where quietness is desirable. Therefore, the sound level actually heard is much lower than that measured, and hence it is desirable to make the measurements with the scale corresponding to the lower level, that is, the *A* scale.

## Factory Tests

18. Factory noise measurements on apparatus are to be made under such conditions that the increase in the measured sound level produced by reflections from surrounding surfaces is small. Also, the microphone should be placed in a position free from disturbing air currents, vibration, electric or magnetic fields, or other external influences, which may affect the readings obtained. The ambient sound level at the test locations should be at least 6 decibels, preferably 10 decibels or more, lower than the sound level due to the apparatus. In general, this requires a special noise box or room with efficient sound-absorbing material placed on the floor, walls, and ceiling. Corrections for ambient levels in factory tests are not generally permissible due to the uncertainties introduced.

Note: Free field conditions for the test room should be attained in so far as it is practicable, but when reflections of importance cannot be avoided their effects upon the measured apparatus sound level may be checked by making a series of sound level measurements with the apparatus placed in various parts of the room, maintaining constant at all times the position of the microphone with respect to the apparatus. If the source is constant the variation in the magnitude of the sound level measured is an approximate measure of the effect of room reflections. The effect of room reflections may also be checked by comparing measurements made outdoors in an open space with measurements made inside of the room.

19. The apparatus under test may be mounted, at the manufacturer's discretion, so that the sound transmitted through the supports will be negligible.

20. Make measurements at several locations near the apparatus to obtain a close approximation to the average sound level produced by the apparatus under free field conditions. When a given type of apparatus consistently produces the same general sound pattern, it is often possible to make production tests at some one point which has proved to be representative of the sound level as determined by averaging the measurements about the machine. The arithmetic average value of the readings is usually satisfactory, but when point to point variations exceeding 10 decibels occur, the weighted energy average, or 10 times the logarithm of the average of the antilogarithms of $^1/_{10}$ the separate decibel values, should be employed.

Note: *Example*

| Microphone Position | Sound Level (Decibels) | Antilogarithm of 1/10-Decibel Sound Level |
|---|---|---|
| *A* | 60 | 1,000,000 |
| *B* | 50 | 100,000 |
| *C* | 40 | 10,000 |
| | | 3)1,110,000 total |
| | | 370,000 average |

$\log_{10} 370{,}000 = 5.54$

$10 \log_{10} 370{,}000 = 55.4$ or the desired decibel value

21. When reporting sound-level measurements, the dimensions of the room and the nature of the floor, walls, and ceiling, the sound level of the room, the condition of operation of apparatus under test, the position of the microphone, and the frequency response of the sound-level meter should be recorded. The type of mounting and other information indicative of the degree of transmission of sound to the supports should also be reported.

22. To promote uniformity and facilitate the comparison of measurements, it is suggested that one of 3 standard distances from the microphone to the apparatus be adopted in making factory noise measurements, these distances being 6 inches, one foot and 3 feet. For very small apparatus with a sound level of less than 35 decibels and major dimensions less than one foot over-all, the 6 inches distance is suggested. For fractional-horsepower motors in general and for measurements where the apparatus is large compared to the space in which measurements are made, the distance of one foot is suggested. For large rotating machines, office equipment, domestic applicances, etc., the 3-foot distance is suggested. In locating the microphone with respect to the apparatus, the distance should be measured to the nearest major surface, minor surface projection being disregarded. When directional microphones are used, the method of orientation with respect to the apparatus outlined in the introduction of the American tentative standards for sound level meters *Z*24.3 should be employed. It is recognized that definite values for these distances, the number of readings to be taken, etc., will ultimately be decided by those interested in formulating codes for sound-level measurements on each specific line of apparatus. The suggestions here are offered for consideration as a logical starting point in formulating such specific codes.

## Standard Factory Measurement Positions

23. When measurements at more than one position are made, and it is desired to obtain one over-all value to represent the noise produced by the apparatus, it is recom-

mended that the readings taken at several points be averaged in accordance with the method outlined under "Factory Tests," paragraph 20.

## Field Investigations

24. The first step should be to measure the sound level produced while the apparatus is in operation, with the microphone placed at the standard factory test positions, if possible. In any case, the positions should be chosen so near the apparatus producing the noise that the effects of wall reflections or other environmental conditions are a minimum. Then shut down the apparatus and measure the ambient sound level of the room.

25. Further procedure will depend on which of 4 different types of situations are encountered.

(*a*). Apparatus noise much lower than the ambient noise, indicated by no change in reading when the apparatus is shut down. The readings of the apparatus noise in this case are not correct, and indicate only that the apparatus noise does not exceed ambient noise level.

(*b*). Apparatus noise higher than ambient noise. If the apparatus noise is more than 6 decibels above the ambient level (as will be the case when the apparatus plus ambient, and the ambient, levels differ by more than 7 decibels) the apparatus noise is affected but slightly by ambient. In this case, it will be desirable to compare the ambient noise level in this particular location with the ambients of similar installations elsewhere, and also the apparatus noise level with that of similar apparatus when measured in the factory under standard test conditions.

(*c*). Apparatus noise of same order as ambient noise. Under these conditions the sound level of the apparatus may be approximated by the use of the following table which is based upon the fact that the sound level meter adds the weighted energies of the various sounds that reach the microphone.

(*d*). The effects of wall reflections and other environmental conditions may be determined by comparing readings at different positions in the vicinity of the apparatus with those at the standard positions. If the reduction of sound level with respect to distance deviates considerably from that obtained under free field conditions, or if marked variations in sound level occur from point to point, sufficient measurements should be made to establish the general character and location of local increases in sound level. These may be produced by reflecting surfaces, structure-borne noise transmission, focal points of reflections, etc.

# The American Engineering Council

## An Outline of Some of the Problems, Policies, and Activities of This Jointly Sponsored Engineering Agency

By A. A. POTTER

President, American Engineering Council

INTEREST in co-operation among different engineering groups and the need for an agency to provide, on behalf of our profession, tangible service to public agencies, prompted, in 1920, the organization of the American Engineering Council with Herbert Hoover, then Secretary of Commerce, as its first president. From its very beginning it has been an organization of organizations intended to aid the engineering profession in presenting a united front in matters of interest to our government and to the public. While the Founder and other major engineering societies have been aiding in professional development of the engineer, the American Engineering Council has been supplementing their efforts by relating the engineering profession to public welfare and by making our government, as well as the public at large, conscious of the value of the engineers' services and contributions. It has served during the past 16 years as a clearing house for questions of public nature which require technological knowledge and engineering experience, and it has acted as an advisory body for the various engineering societies in connection with problems of government. At the same time the American Engineering Council has been an agency of inquiry into economic and social problems as affected by technology.

A report to the Council of the American Society of Mechanical Engineers, read at its semi-annual meeting, Detroit, Mich., May 17, 1937. Published by permission A.S.M.E.

Doctor Potter, dean of the schools of engineering and director of the engineering experiment station, Purdue University, Lafayette, Ind., and past-president of the American Society of Mechanical Engineers and of the Society for the Promotion of Engineering Education, now is serving his second term as president of American Engineering Council.

## Four Major Functions

The major functions of the American Engineering Council are performed through four groups of committees, which are concerned with public affairs, engineering economics, operations within the Council, and united action of its member societies. These committees, through 17 subcommittees, are in close contact with trends in the conservation and utilization of our national resources, relation of the engineer in private practice to government, patent legislation, public works, aeronautics, surveys and maps, rural electrification, merit system in public service, inquiries in the fields of social and economic activities of

our country, and similar problems in which engineers may have opportunities for co-ordinated action.

The problems of the American Engineering Council have taken a new slant since 1934. Instead of the normal process of legislation on engineering matters, the AEC has had to work during the past 3 years with a group of administrative departments, whose legislative authority and funds had been established by administrative order. Government departments and bureaus had to be "reeducated" about the American Engineering Council, and its work had to be changed from an orderly process of committee reports and committee hearings and procedures to the specific acts of keeping up with rapidly changing conditions.

Much of the work of the American Engineering Council had to go unreported because it had to do with contacts and associations with individuals in the government, and one of its main tasks had been to make and keep friends with the constantly changing and greatly expanding agencies of the government. Much of the work had to be confidential and some intangible, but a few of the high points may be discussed.

The American Engineering Council has had a constant demand for engineers from government agencies and a large portion of the time of the staff had to be devoted to employment problems for the government bureaus and departments. This service included not only the recommendation of engineers to the various government agencies but also aid to administrative agencies in planning the handling of such work as emergency mapping under the WPA, Rural Electrification Administration programs, Rural Resettlement plans, and NRA codes.

The American Engineering Council is constantly being consulted as to salaries to be paid to engineers and is guided in such requests by the reports of the Founder member societies. It is also invited to suggest names of consultants for various enterprises.

The American Engineering Council has been instrumental in placing numerous engineers in important consulting and line engineering governmental positions, those appointed to such positions seldom knowing the part that the AEC has played in placing them, as it has always been careful to submit a number of names and not to promote the employment of any particular individual.

As part of this employment service, the American Engineering Council had attempted also to analyze and to make a survey of the employment of engineers by government, classified by divisions. Government bureau chiefs are fully appreciative of this service and realize that advice and recommendations by the American Engineering Council are based solely upon the ability and technical competence of engineers and not on questions of political preferment.

During the past few weeks, at a request of one of the national member societies, the American Engineering Council made an exhaustive examination of those laws, regulations, interpretations, and procedures affecting the engagement of technical talent and engineering service by the federal government outside of the civil service. Conditions in more than 30 of the principal agencies known to be using technical talent were investigated, and the results when finally compiled, should prove of great value to the engineering profession.

## Advice on Policy

The American Engineering Council has been called for service in connection with matters of policy affecting emergency government setups. A concrete illustration is its relation to the National Resources Committee. Immediately after this committee was set up, as the National Resources Board, the executive secretary made contact with its chairman and director. This was followed by a conference with the chairman, arranged by the American Engineering Council, at which were present the secretaries of the member national societies and from which grew out contacts which closely related engineers to the work of this committee.

Many of the earlier reports of the American Engineering Council on such questions as flood control and the policies for the development of water resources were transmitted to the National Resources Committee and the recommendation of this new agency of government has reflected, in part at least, the recommendations of the member organizations of the American Engineering Council and of its committees. Specifically, the proposal for improvement in collecting water-resources data and the whole question of the development of water resources on the basis of conception of the "water shed," rather than on the basis of states alone, were in the earlier reports of the American Engineering Council.

The authors of the number of reports issued by the National Resources Committee were recommended by the American Engineering Council. Even the most recent report, "Technological Trends and Their Social Implications," has been influenced by advice from the American Engineering Council.

## Mapping and Surveying

This is a matter which is having the active interest of the American Engineering Council and has been helpful in educating the Budget Bureau on the value of an adequate mapping program. The American Engineering Council has worked with the Federal Bureau of Surveys and Maps in rounding up the opinions of organizations with reference to this program. Its aid to individual states has resulted in definite progress. A concrete example is Indiana which has appropriated a considerable sum at the 1937 session of its legislature for mapping.

## Various Interests

The Upstream Engineering Conference, the Third World Power Conference, and the plans for the World Management Conference are examples of activitites by the American Engineering Council in the interest of united action.

The American Engineering Council, through a committee of which a secretary of a Founder society was chair-

man, was instrumental in this study by the Bureau of Labor Statistics of the United States Department of Labor. This study made available data regarding 60,000 engineers with reference to such questions as employment conditions, compensation, and distribution in different fields.

## Engineering Economics

The activities of the American Engineering Council in studies in engineering economics have been helpful in projecting the engineering profession into the fields of thinking and action relating to our national social, economic, and industrial questions. Among the early contributions of the Council in this field may be mentioned the reports on "Waste in Industry," which had a profound effect upon the conduct of industry the world over; the "Twelve-Hour Shift in Industry" (1921), which demonstrated the merits of the shorter working day; "Civil Aviation" (1924), which focused the national point of view upon the development of commercial aviation; "Radio Broadcasting," which was instrumental in bringing about present policies and practices; and "Water Resources," which was helpful in appropriations for the installation of the national hydraulic laboratory.

Among the recent engineering economic studies of major value may be mentioned the inquiry of the balancing of forces which has greatly influenced economic thought and action during recent years.

There is need for accurate knowledge to show the real effect of science and technology upon social security; such information should go a long way in overcoming the present tendency to make the engineer the major scapegoat of our social ills, by showing that engineers create employment, wealth, comfort, values, and other factors which definitely contribute to social security. The American Engineering Council is now endeavoring to ally itself with representative economists, sociologists, and statisticians in order to study questions of this type and to guide in the public interest some of the questions of larger policy which lie in the fields of both engineering and economics.

There is also need for factual reports, for the benefit of the public, by committees of leading engineers on the engineering projects of our government. Engineers have an opportunity to show, through nonpartisan and unbiased services, their competency and integrity, and to make the public more conscious of engineering contributions. The American Engineering Council hopes that before long it will be in a position to finance the preparation and distribution of more reports, on behalf of our profession, which bear upon public welfare.

## National Problems

The American Engineering Council is concerned with national questions to which engineers may contribute co-operatively and in problems in which the engineering societies may have opportunity for co-ordinated action. It is not a super organization intended to manage or to interfere with the autonomy or with the specialized fields of it member societies. It is striving to serve the public and to bring about a better appreciation on the part of all, and particularly of government agencies, of the importance and value of the engineer's contributions. It is endeavoring to bring about concerted action on the part of engineers in public questions of national scope, and a definite interest on the part of the engineering profession in a well-balanced social structure and good government. By representing the engineering profession in matters of public welfare, government, and of joint interest to all engineering societies, the American Engineering Council serves the engineer and the public.

---

# The Making of Industrial Physicists

THE human material for the construction of an industrial scientist may be qualitatively described with considerable ease; but to write for it an engineering specification with inspection techniques and with prescribed tolerances is at present impossible. Unless, however, we would credit evolution with having changed human nature within the times of recorded history we will agree that, despite his specialized training, modern scientific point of view, and wealth of precise instruments, the industrial scientist of today is the man of yesterday and of yesteryear and so on back into prehistoric days. What did this type of human being do in the past? Was he king or priest? Captain or explorer? Medicine man or scribe? Trader or pirate? None of these. He was thinker and craftsman. His was the type that invented the wedge, the inclined plane, the lever, and the screw. He surveyed and built the pyramids; designed and constructed triremes, roads, and aqueducts; shaped the tools of his day; and led the way from stone to bronze to steel.

His urge was the instinct of workmanship, a pleasure in the act of creation or construction which is its own reward. Neither driven by acquisitive instinct nor maddened by lust for power or fame, his satisfaction was his work; he sought little reward; and died unknown. More practical than the philosophers; spending little of his time in teaching or writing; and no follower of the Muses, he burned with a quiet steady flame of the same divine fire that suffused the great teachers and poets of his time. The captains and the kings depart; but what he wrought is the hidden basis of our material grandeur.

From a paper presented by John Mills (A'11, F'23) director of publication, Bell Telephone Laboratories, Inc., at the annual meeting of the Society for Promotion of Engineering Education, Cambridge, Mass., July 1, 1937.

# The Selection and Training of Engineers

## A company may choose an engineer, or the engineer may choose a company; certain qualities should be sought in either instance

By A. M. MacCUTCHEON
PRESIDENT AIEE 1936–37

IN CONSIDERING this subject a clear, concise, definite, and comprehensive conception of an engineer is essential. The dictionary definition "one versed in or practicing any branch of engineering," does not meet the requirements. Several practicing engineers submitted definitions, the most amusing of which was, "an engineer is a man who can do with one dollar what any man can do with 2 dollars." An engineer's wife felt that "an engineer is one with whom it is rather difficult to live but quite impossible to live without." Of the definitions submitted, the following was the best: "an engineer is one who through training, study, and practice successfully adapts and controls the materials and forces of nature to the benefit and advantage of himself, his fellow engineers, and the rest of the human family." This is quite similar to that prepared by the American Engineering Council, "engineering is the science of controlling the forces and utilizing the materials of nature for the benefit of man and the art of organizing and directing human activities therewith."

Two young men were presenting to a general in the Army Engineering Corps the design of a new and novel pump, and hoping for its adoption. He was not interested because the pump had not been proved. In answer to their inquiry he assured them that he considered himself an engineer and one of the young men stated, "an engineer is one who can tell whether a thing will work before it has been tried, for any fool can tell afterwards."

Each young engineer in training and each engineer engaged in their training should have a clear conception of "an engineer" for that is what their combined effort is intended to produce. Engineers are often charged with being poor salesmen and in some cases this criticism is justified, since they are poor salesmen of themselves and their services. Their engineering should be to the advantage of themselves but this viewpoint should not be overemphasized. Today each engineer should ask himself whether his engineering is in the interest of the human family and if it is not, is he in the truest sense an engineer. Society should recognize that the engineer should be suitably rewarded for his engineering efforts and achievements, since otherwise able young men will not continue to enter the profession.

Selection is defined as the act of choosing. Shall the young engineer be chosen by the company, or the company chosen by the young engineer? This will depend upon the relative standing of each, compared with the others in their field. To a young engineer, it is most important whether he will select a job or whether he will seek one. If his standing and achievements among his fellows are high, he will usually have the privilege of selection. Following are the qualities which a company seeks in a young engineer, listed in approximately the relative order of importance: integrity, dependability, determination, resourcefulness, forcefulness, adaptability, co-operativeness, diplomacy, friendliness, broadmindedness, and knowledge. While the last quality is of great importance to a company selecting a man, the first 10 may be even more important. The more knowledge possessed by a man, the more valuable he will be but of all these 11 qualtities, a deficiency in knowledge is most easily remedied. If the young engineer has the privilege of selection, it is just as important that the company he selects should possess the first 10 qualifications and to these should be added: an able and experienced personnel and leadership, a good financial standing, and a definite record of accomplishment. In either case the decision should be based on the probable situation 10 years later. No young man should be satisfied to be an average engineer unless his definition is analogous to Sam's definition of an average tip.

A clergyman, unused to traveling, was making the trip from Birmingham to New York. He was pleased to find that the Pullman porter had, at one time, been the sexton of his church. Throughout the journey Sam took good care of the minister and as Sam was brushing him off, while crossing the Jersey meadows, he asked Sam about what was the average tip that a traveler gave in going from Birmingham to New York. Sam answered, "Well boss, the average tip is about $5." As the minister left the train he handed Sam a $5 bill. Sam's eyes popped and he said, "Boss, you is the first man what ever come up to the average."

When a company selects a young man, graduating from technical school, it should consider the record of his accomplishment even as far back as when he was in high school. It should consider his standing among his fellow students. If he is respected, admired, and followed it is likely that his business associates will respect him and follow him. During his time in college what did he do for his class, and what did he do for his college? This is of importance as an indication of what he is likely to do for his company. His scholastic standing is of much importance for he has gone to a technical college with a definite purpose and if his standing has not been good he has

---

A. M. MacCUTCHEON is vice-president in charge of engineering, Reliance Electric and Engineering Company, Cleveland, Ohio.

failed in his purpose. This is an indication that he will not be successful in his purpose after graduation. Membership in such societies as Tau Beta Pi or Eta Kappa Nu is of importance as an evidence of accomplishment but scholarship is not the only qualification to be considered for he may be an excellent scholar and definitely lack in the other 10 qualifications.

If the young man is to have the privilege of selection he should consider the accomplishment of the company in the business which it has been carrying on, and its standing with its competitors, for if the competitors do not think well of a company it is questionable whether it is truly successful. He should consider the company's activities in connection with the professional and trade societies having to do with and endeavoring to advance the interests of that class of business. If a company is not interested in such activities it is not doing its part in the development of the broad field of its activity. Lastly, he should consider the salary which is being offered by the company. While this is important it should not be overemphasized. Of far greater importance is the salary which he will receive 10 years later.

The company should offer a salary competitive with other companies in its line of activity. While many individuals give far too much consideration to the matter of salary, some give too little. The salary received is the most tangible evidence of accomplishment. While an engineer should receive a salary commensurate with the contribution that he makes to the success of the company, he should recognize that fair salaries cannot be paid unless the company is successful. A broadminded engineer may willingly accept a relatively low salary over a considerable period and without dissatisfaction because he believes in the ultimate success of the company and that when this success is achieved, the company will suitably recognize his contribution in making the company successful. If an individual is not satisfied with his financial return, and is convinced that the company is not and will not be fair to him, he should not stay with that company for one of the greatest deterrents to a man's success is a long continued dissatisfaction with his financial return, about which he does nothing constructive. If a young engineer selects the right company and makes himself so valuable that he cannot be replaced without a considerable penalty, he will usually have to give very little consideration to the matter of financial returns. Great weight should be given to the financial standing of a company, and of particular importance is the record during such a period of business depression as existed from 1930 to 1934.

In the selection of young engineers, company representatives should make trips to the educational institutions and study the young men in their student environment. Many companies have done this for years, and the practice is becoming almost universal. It is equally as desirable that the young engineer should visit companies in order to prepare himself for the making of an intelligent decision. Because of limited finances, university restrictions, and lack of experience, the young man is handicapped in such an investigation. Twenty years ago a technical graduate was not discouraged if he had not located, by the time of graduation. This time of selection has gradually moved backward. Those men and companies, whose records of accomplishment permit them to be the selectors, have usually made their decision prior to the first of April. Certain advantages would result from a mutual agreement between the technical schools and industrial organizations that December should be a period of contact and investigation with decision to be reached early in March. The Christmas holidays offer an opportunity for the visiting of plants and the period immediately before and during the midyear examinations should be free from interruption. Some specialization during the last semester would be possible. Several companies are now offering to the young engineer who is so fortunate as to be in that group which has the privilege of selecting, the opportunity of visiting the plant that he may familiarize himself with the activities and the personnel of the company, and decide whether the association would be mutually advantageous.

## Training Before Graduation

The larger part of the technical training of the young engineer is received in the technical school prior to his selection and necessarily independent of the company with which he is to be associated or the particular type of work in which he will engage. Such generalized training is broadening but not so immediately useful as training of a more specialized type. There should be a sufficient amount of specialized training as to develop a proper conception of the intimate relation between training and accomplishment. Broad technical training should be continued after graduation and still closer contact and co-operation between educators and industrial managements is most desirable that the training before and after graduation may be fully co-ordinated, the one supplementing the other.

Comments made by one connected with a manufacturing company, on the training prior to graduation, are made from a narrow viewpoint and are offered only as suggestions for the consideration of the engineer educators whose lives are devoted to the training of young engineers and who are intensively studying the technique of engineering education.

Admiral Sims, in his story, so effectively illustrates the influence of a varying viewpoint. A young American was ordered to England to take charge of the London office. He met and married a delightful English lady whose mother was strongly pro-British. Many arguments resulted between the young man and his mother-in-law as to the relative merits of the 2 countries. In the course of time a daughter was born and some 3 years later the father was ordered back to the States. On the evening before they sailed, the mother-in-law requested the privilege of putting her granddaughter to bed. She descended the stairs smiling broadly and said to her son-in-law, "You should have heard your little daughter's good-night prayer. 'Goodbye God, we're going to America tomorrow.'" "But," said the son-in-law, "what she meant was—'Good,

by God we're going to America tomorrow.' "

To one in manufacturing it sometimes seems that the technical schools still lay more emphasis on the giving and acquiring of information than on the methods of proper engineering attacks, engineering analysis, and the securing of engineering information. While the imparting of knowledge to the young engineer is of great importance, instruction in the proper application of the "engineering method" is of still greater importance. Because of the necessary generalization much of the information gained is not usable after graduation. Training in the engineering methods is most valuable no matter with what company the young engineer may be associated. As a simple example of a somewhat unusual training, consider the course given in Columbia by Professor Lucke to a group of electrical engineers who had requested a course on gas engines. Most of the work was done in the laboratory where there were 10 gas engines. Under Professor Lucke's direction the laboratory assistant did something to each of these gas engines so that they would not properly function. The students were divided into 10 squads; each squad assigned to a particular engine. The problem was to determine what was wrong with the engine, make the necessary correction, and leave the engine running properly. Text books, specifications, and diagrams were available for consultation. Both Professor Lucke and the laboratory attendant would answer any questions which might be asked with one exception, "What is wrong with this gas engine?" There was an intense competition as to which group would first have their engine functioning properly. These electrical men received an unusual training in how to attack an engineering problem, analyze it, and solve it. The qualities of determination, resourcefulness, forcefulness, adaptability, co-operation, diplomacy, and friendliness were being developed in each one of the students.

In each engineering school should there not be a course "how to get results. How to handle other people and get them to do what you wish them to do?" Such a course would give valuable training to any man, particularly to engineers; a course just as valuable to the design or research engineer as to the engineer who would later serve in an executive capacity. The ability to handle people and get results is subject to development through training and this training is greatly needed by all engineers. Such a course might be given by the case method so successfully used in the training of lawyers. Successful executives would undoubtedly co-operate by giving lectures, citing unusual instances of results secured through properly approaching, informing, and co-operating with others. The best engineering plan has little value unless the engineer can convince others of the soundness of the plan and persuade them to use it. The following is a simple illustration of securing results and properly handling other people. An important new machine was being designed. Successively the designer compelled himself to view the design as a member of the sales department, the manufacturing department, the service department, and, most important of all, as the user. He prepared a series of briefs summarizing the design from each viewpoint. He presented the appropriate brief to at least one in each of these groups and asked for criticism and suggestions. He adopted any suggestions that seemed to him practicable. He avoided any prolonged arguments, but stated in writing why certain suggestions could not be adopted. All of this was done before the routine delivery of drawings and specifications. Each interested group was prepared for and committed to solving their problems in connection with the design before the problems actually reached them. Throughout the manufacture, tests, installation, and final operation, the design engineer stood ready to give information, answer questions, and render assistance. The design was highly commended by all who came in contact with the machine. While this designer held an important position in the organization, he was not an executive. Often engineers have been handicapped by failure to recognize who should be consulted and who should receive information.

In most technical schools there are a certain number of shop courses and at least some of these should be retained. The young engineer should receive a training in manual dexterity and this can best be accomplished prior to the age of 23. The theoretical and the concrete should always be associated.

If such work is to be retained, should not the electrical department specify shop courses directly related to electrical equipment; and should not each electrical engineer in training experience the thrill of designing, building, and testing at least one piece of such equipment? While the primary purpose of the technical school is a thorough grounding in the technical fundamentals, and with only 4 years allowed for all that is to be accomplished, will not a certain number of shop courses, properly coordinated, so effectively supplement the technical training as to give a better result with the same effort?

The training of the young engineer by the company which he has selected or which has selected him, is equal in importance to the training while in the technical school. The course should be carefully planned before the young men enter the company's employ and in consultation with the professors in the technical schools who have given their lives to the training of engineers. The course should be open to modification upon suggestions from the young men in training. There should be a sympathetic interest on the part of all departments in the organization and to this end each department should clearly understand the value of such training in the interest of the company. Lectures should be given by the company executives acquainting the group in training with the history, the development, the ideals, and the policies of the company. Some time should be spent in every department and, in addition, there should be visits to the plants of customers where the young engineers can see machines which the company makes, in actual operation. In this way they can be acquainted with the customer's viewpoint.

Both the company and the group in training should recognize the necessary compromise between the theoretical and the practical. The primary purpose of the organization is the manufacture of the product and while the training of the young engineer is of importance there

are times when this training must suffer if it conflicts with the primary purpose of the organization.

The American Institute of Electrical Engineers effectively participates in the training of young engineers. In most of the engineering schools, student branches have been established and these are an integral part of the AIEE. Within the branch, technical papers are prepared and presented, affording valuable training to the young engineer who prepares the paper and valuable information to the other young engineers who hear the paper presented. To the student member of the Institute is available ELECTRICAL ENGINEERING, containing the technical articles presented before the national and regional conventions.

Engineers are sometimes prone to neglect the human relationships and one of the most delightful privileges of an engineer is to meet with other engineers and exchange ideas. This opportunity is offered through the AIEE Branches while the young man is in technical school and through the local Sections after he has joined a commercial organization.

The most effective agency in the training of a young engineer is the engineer himself. He has more to do with his training than the technical school or the company with which he is associated. The arranged training courses simply present an opportunity that he may effectively train himself. In accomplishing this training he should grasp every opportunity to become acquainted with all others in the organization, including the workman in the plant. He should accept every opportunity for contact with outside engineers. He should join in the work of the professional organization of engineers in the city where he lives. He should seek to find answers to every unanswered question in his mind about the company's product. He should never walk through the plant without asking himself what he can find out that he has not previously known. What a man learns for himself, he seldom forgets. He should feel free to make suggestions, for he has a fresh and uninfluenced viewpoint.

One of the most important phases in the training of an engineer is to develop in him the probability of being right. While no engineer will always be right, this is the limit which he should strive to approach. The closer he comes to the limit, the more successful he will be. In his endeavor to approach this limit, he should remember that there is a great value in what may be termed "secondary checks." A secondary check may be defined as a brief comparison between the solution of a new problem and the proved solution of a somewhat similar problem, which comparison will indicate, at least qualitatively if not always exactly quantitatively, whether the new solution is correct. Through a free use of secondary checks costly errors will often be avoided.

The young engineer should be trained in how to accept and delegate responsibility. He should recognize that no man should be asked to accept responsibility without having a corresponding authority. A leading executive once said, "the president of a company is responsible for the work of every man in that company; the chief engineer for the work of every engineer who reports to him; each engineering division head is responsible for the work of everyone in his division; the chief draftsman responsible for all the work of the drafting room including that of the blueprint boy." This is the correct theory of responsibility looking from above downward. On the other hand, looking from below upward, the blueprint boy should be trained to feel responsible for everything regarding blueprints and blueprint service. The draftsman should feel responsible for every drawing he makes. While he should accept advice from the man above him, he should consider the finished drawing as his, for which he alone is responsible. Accepting responsibility for the work of all the men under him, the chief engineer should not feel that the president above him is responsible for the engineering. He should ask for and welcome advice and guidance, but the finished engineering he should consider as his, and his responsibility. A close following of this theory of responsibility should produce unusually good results.

In any course of training there should be sincere co-operation between the technical school, the company, and the young engineer himself. From Columbus comes a story illustrating an unusual degree of co-operation between engineers.

A Columbus engineer was called to Dayton and advised his wife he would return about 11 o'clock that evening. His wife was tired and retired at 9 p.m. When she awoke in the morning she found that her husband had not returned. She became deeply concerned, made a list of 20 engineers living in Dayton and who were acquainted with her husband and to each one of the 20, sent an identical telegram, "Do you know where John is, or what he is doing?" John's automobile had given trouble so that he had stopped in Dayton for the night and had the necessary repairs made the following morning. He reached home about 10 a.m. About 11 o'clock the wife began to receive replies to her telegrams. Exactly 20 replies were received and each reply said the same thing, "Do not worry; John is spending the night with me."

A company which selects a young electrical engineer owes to him a deep responsibility for they are influencing his whole life. They should not invite him to join the organization unless there is likely to be an opportunity such as he deserves. They should never forget their responsibility to him. They should offer to him every opportunity for development and should endeavor to give him a suitable financial return. On the other hand, the young electrical engineer should also fully realize the measure of his responsibility. He has accepted a position which would have been offered to another man. He should use every effort to fully measure up to the opportunities which are open to him. He should recognize that no company should offer an opportunity to a man who does not earn it and that his opportunity with the company largely depends upon his contribution to the company. If there is the fullest co-operation between the company, the technical school, and the young engineer himself, the engineering profession should be carried to far greater heights than have ever been reached in the past.

# Engineering Income and Earnings, 1929–34

**In this, the fifth article[1] of a series reporting a survey of employment in the engineering profession by the United States Bureau of Labor Statistics, income data for engineers of various professional classes and ages are presented, based on information given for the years 1929, 1932, and 1934. Comparisons may be drawn among professional classes, ages, and educational backgrounds.**

REPORTS from 52,589 professional engineers to the Bureau of Labor Statistics, in its survey of the engineering profession,[1] undertaken at the request of the American Engineering Council, make it possible to relate the income data to many aspects of professional engineering activity. These income data are probably the most comprehensive ever presented in regard to a professional group. The following general findings appear from analysis of the reports.

In 1929, 50 per cent of the 30,032 reporting engineers earned more than $3,412, and 50 per cent earned less than that amount. Twenty-five per cent earned more than $5,012, but only 10 per cent had incomes in excess of $7,466 per annum. On the contrary, 25 and 10 per cent of the engineers earned, respectively, less than $2,509 and $1,878 per year.

Comparison of the incomes for 1932 and 1934 with those reported for 1929 shows that from 1929 to 1934, the sharpest absolute declines occurred in the 2 higher income groups. Their percentage decreases were least, however, averaging 31.2 and 31.6 per cent, whereas the middle values of income declined by 33 per cent, and the 2 lower levels by 41.3 and 53.6 per cent, respectively.

Almost two-thirds of these decreases in earned annual income occurred between 1929 and 1932. There were further decreases from 1932 to 1934.

Among the several professional classes, the divergences in earning capacities were most marked in the higher levels of income. Furthermore, the ranking of the profession on the basis of earnings opportunity was the same in the highest 10 and 25 per cent only.

In 1929, without regard to the age distributions of the different classes, 10 per cent of the mining and metallurgical engineers earned more than $9,912 per year, chemical and ceramic engineers ranked second with 10 per cent earning more than $9,103, and were followed in order by mechanical and industrial engineers ($8,508), electrical engineers ($7,185), and civil engineers ($6,507). At the upper 25 per cent level, mining and metallurgical engineers reported earnings of $6,301 per year, and those of the other professional classes ranged from 4 per cent lower for chemical and ceramic engineers, to 28 per cent lower for civil engineers. This order of professional classes was also maintained in 1932 and 1934.

In 1929, the earnings of the mining and metallurgical engineers were highest in the middle and 2 lower levels of income, while those of the electrical engineers were lowest. At these 3 levels, the earnings of the former were $4,010, $2,839, and $1,985; for the latter they were $3,277, $2,339, and $1,662, respectively. Over these 3 levels, the relative positions of the 3 remaining professional classes changed. There were further shifts in 1932 and 1934.

The data also show that, over the period 1929 to 1934, relatively the smallest shrinkages in earnings were reported by the civil engineers, while the chemical and ceramic engineers suffered the greatest reductions. Over the 5 income levels, the former ranged from 29.0 to 47.2 per cent, the latter from 35.6 to 63.8 per cent.

Analysis of the income data reported by all engineers in 1929, 1932, and 1934 shows that earnings advanced with age in 3 distinct phases, showing initial periods of exceptionally rapid rise, followed by 2 others of slower rates of increase. The age spans of these phases varied with the income level.

With advancing age, the spread in earnings became most accentuated beyond the age of 38. Thus, at the ages of 44 and 60, the incomes of the upper 25 per cent differed from the median or middle value by 41.0 and 51.0 per cent. The corresponding incomes of the upper 10 per cent at these ages were greater than the median by 116.0 and 157.0 per cent. Even in 1932 and 1934, this advantage in earning capacity was maintained.

The earnings of the engineers in the lower income levels ceased to increase at a relatively early age. These showed a level period before beginning to decline, whereas the higher levels of income showed continuous increases for a considerably longer period, after which, however, they declined at a much greater rate.

Over the period 1929 to 1934, a rise in earnings occurred for the youngest engineers who were in the profession in 1929 and who were 30 years of age or less in 1934. Thereafter there were progressively larger declines for the older engineers.

Comparison of the earnings of engineers of identical ages in 1929 and 1934 shows that the average income of engineers who had been out of college for 2 years declined 43 per cent. The income of those who had been out 5 years declined 35 per cent. For older engineers the decline approximated 30 per cent.

Consideration of the incomes reported by engineers of different educational backgrounds shows that those with a formal engineering education did receive a higher income. The differentials in earnings, however, did not accrue in equal measure for all 5 professional classes.

1. An article prepared by Andrew Fraser, Jr., of the Division of Hours, Wages, and Working Conditions, Bureau of Labor Statistics, United States Department of Labor, which article was published in the August 1937 issue of *Monthly Labor Review*. Articles reporting other phases of this survey were published in ELECTRICAL ENGINEERING as follows: "Professional Aspects of Engineering Education," August 1936, pages 863–7; "Unemployment in the Engineering Profession," February 1937, pages 216–23; "Employment in the Engineering Profession," May 1937, pages 524–31; "Security of Engineering Employment," June 1937, pages 655–61. A detailed report of the survey will be published later in bulletin form by the Bureau of Labor Statistics.

## Table I. Comparison of Gross and Net Numbers of Older* and Younger** Graduate and "Other" Engineers Reporting Annual Earnings in 1934

Without regard to employment status reported

| Professional Class | Graduate Engineers | | | | Other Engineers | | | |
|---|---|---|---|---|---|---|---|---|
| | Total | Older Group | Younger Group Graduated in— 1930–32 | 1933–34 | Total | Older Group | Younger Group Born in— 1907–09 | 1910–14 |

| Gross number reporting income | 86.5 | 83.9 | 92.5 | 91.3 | 84.5 | 85.5 | 83.3 | 68.8 |
| Net number reporting income | 75.2 | 77.2 | 58.5 | 91.3 | 74.7 | 75.5 | 66.7 | 68.8 |

* Includes all engineers who were professionally active prior to 1930.
** Includes all engineers who entered the profession in the years 1930–32 and 1933–34.

At about 28 years of age the "other" engineers had lost an initial advantage in earning capacity. At that point, the 1929 earnings of the graduates ranged from $2,725 to $3,000 per year, those of the corresponding "other" engineers from $2,430 to $2,650.

With advancing age, the spreads in earnings in favor of the graduates became very marked indeed. For example, at 5, 20, and 37 years after graduation, the earnings of first-degree mechanical and industrial engineers exceeded by $175, $925, and $1,322 per year those of the engineers of the same professional class whose college course was incomplete, and surpassed by $225, $1,160, and $1,815 per year those of engineers with a noncollegiate technical school education.

Even among the graduate groups there was variation in the increase in earning capacity between the several professional classes. Thus, the 1929 earnings of first-degree civil engineers who had been out of college for 5 years were only $2,050 less than the earnings of those who had graduated 30 years before, whereas the corresponding difference for chemical and ceramic engineers was $3,600. The ranges in earnings of the remaining graduate groups fell between those reported by the civil and chemical and ceramic engineers.

In general, the earnings of the "other" engineers ceased to increase at an earlier age than those of the graduates.

## Scope and Method of Study

Analysis was made to determine the changes in the income and earnings of professional engineers during the period 1929 to 1934. The reports covered 2 distinct features of income for the years 1929, 1932, and 1934: (1) earned annual income received from all personal services and (2) average monthly compensation from engineering work only. The annual figures are a measure of what en-

## Table II. Comparison of Gross and Net Numbers of Older* and Younger** Graduate and "Other" Engineers Reporting Monthly Engineering Income† in 1934

Without regard to employment status reported

* Includes all engineers who were professionally active prior to 1930.
** Includes all engineers who entered the profession in the years 1930–32 and 1933–34.
† In the text, "monthly engineering income" and "engineering income" are used interchangeably.

gineers were able to earn during each of the 3 years. This was determined not only by the rate of earnings but also by the volume of employment. The monthly figures are a measure of the rates at which engineering services were purchased.

Both income and earnings are shown in relation to (1) professional class, (2) age, (3) type of education, and (4) regional location. A discussion of earned annual income from all sources, by age, is included for engineers engaged in engineering work and also for those in nonengineering work, as well as annual income reported by those engineers who were unemployed at the end of 1929, 1932, and 1934. Monthly engineering earnings, while treated similarly to annual income, can only be shown for the various types of engineering employment. The earnings of those engaged in engineering work are also shown in relation to size of city.

From a consideration of certain pertinent aspects affecting the returns on income and earnings for 1929, 1932, and 1934, it is believed that these data are representative of the engineering profession as a whole. They have been shown to be representative as regards age, if allowance is made for the larger representation of engineers graduating in 1930 or later years. In analyzing the income data, as in the analysis of employment status, the samples of older and younger engineers[2] were combined on an adjusted basis to secure a cross section of the entire profession in 1932 and 1934.[3]

Without exception the several distributions of income follow a consistent pattern even when analyzed in detail.

2. Older engineers comprised 15 per cent of all those who were professionally active prior to 1930. The age composition of this group was consistently uniform with the corresponding data derived from the 1930 census on professional engineers. This was so for minor groupings of professional classes by 10 geographical regions and for the country as a whole. The younger engineers included the information furnished by all those who entered the profession in the years 1930–34 inclusive. The returns for each of these years covered the same proportions (32.0 per cent) of the total number of graduations reported by the Office of Education.

**Table III. Comparison of 5 Levels of Annual Earnings for All Professional Engineers Reporting in 1929, 1932, and 1934**

Figures derived from adjusted data as explained[3] and without regard to employment status reported or type of education

| Per Cent at Specified Income Level | Annual Earnings of More Than Specified Amount | | | Increase or Decrease | | | Per Cent of Change | | |
|---|---|---|---|---|---|---|---|---|---|
| | 1929 | 1932 | 1934 | 1929–34 | 1929–32 | 1932–34 | 1929–34 | 1929–32 | 1932–34 |
| 10 | $7,466 | $5,605 | $5,138 | −$2,328 | −$1,861 | −$467 | −31.2 | −24.9 | −8.3 |
| 25 | 5,012 | 3,827 | 3,429 | − 1,583 | − 1,185 | − 398 | −31.6 | −23.6 | −10.4 |
| 50 | 3,412 | 2,574 | 2,286 | − 1,126 | − 838 | − 288 | −33.0 | −24.6 | −11.2 |
| 75 | 2,509 | 1,698 | 1,473 | − 1,036 | − 811 | − 225 | −41.3 | −32.3 | −13.3 |
| 90 | 1,878 | 889 | 872 | − 1,006 | − 989 | − 17 | −53.6 | −52.7 | −1.9 |

Thus, the same type of distribution emerges when the data are analyzed by ages, by professional classes, or even on a regional basis. This is true of both annual income and monthly engineering income.

The averages proved to be essentially the same, whether derived from a "gross" or "net" number reporting. The "gross" number reporting income is the total number of engineers who reported income in any one year, irrespective of whether or not they reported in other years. The "net" number reporting income is the number who furnished information for all 3 years—1929, 1932, and 1934.[4] In the income tables averages are derived from the "gross" numbers reporting.

The "gross" numbers reporting earned annual income for 1934 and the "net" numbers are shown compared in table I. These numbers are the totals of those returning questionnaires before any adjustment is made in the number of the younger men.

In each case, the base for computing percentages was the number reporting in the survey, that is, those engineers who reported a type of education.[5] For all age groups, it will be noted that there were distinct differences between the "gross" and "net" percentages reporting income. The greatest divergences occurred among the 1930–32 graduate and the 1907–09 "other" engineers. For the country as a whole, these were respectively 27.1 and 11.5 per cent. On a national basis, older graduates differed by 7.3 per cent, older "other" engineers by 7.6 per cent. Despite these variations, a comparison of the corresponding measures of levels of annual income derived from the "gross" and "net" returns showed no significant differences. A similar situation was noted for the "gross" and "net" returns on monthly engineering income.

In the ensuing discussion, the middle values of income were computed for groups with at least 10 engineers reporting. For the upper and lower 25 per cent groups or levels, the measures were based on not less than 50, while the upper and lower 10 per cent groups embraced not less than 100 engineers.

3. The procedure of adjustment adopted was similar to that outlined in the discussion of the distributions of employment status. The numbers of younger engineers reporting in each income class for 1932 and 1934 were reduced in the ratio of 15 to 32, and added to the corresponding figures reported by the older engineers in 1932 and 1934.

4. In the case of the 1930–32 graduates and "other" engineers born in 1907–09, the net number reporting income is the number furnishing data for the 2 years, 1932 and 1934. In the case of the 1933–34 graduates and 1910–14 "other" engineers, income data for 1934 alone were relevant. Hence, there is no difference between "gross" and "net" data.

5. The use of type of education as a base was felt to be justified because only 104 of the 52,589 professional engineers reporting in this survey did not report their type of education. The 104 engineers however, did report their professional class; and either year of graduation or year of birth. They were, therefore, used for all purposes, except those dealing with type of education.

## Earned Annual Income

The income data for 1929 were furnished by 30,032 engineers, or slightly over 90 per cent of all reporting engineers who were professionally active prior to 1930. These data, together with the adjusted figures on earned annual income, without regard to employment status reported, for 1932 and 1934, are shown in table III.

In 1929 the range in earned annual incomes among professional engineers was great. Some 60 reported incomes less than $800 per year, while 162 earned more than $19,000 a year. In 1929, without regard to their age distribution, half of the engineers had annual incomes greater than $3,412, while half earned less than that figure. However, 25 per cent earned more than $5,012 per annum. Only 10 per cent of the 30,032 reporting engineers had incomes in excess of $7,466 per annum. On the contrary, one-quarter of all engineers reporting earned less than $2,509 per year, and one-tenth earned less than $1,878 per year.

From 1929 to 1934, marked decreases took place in the

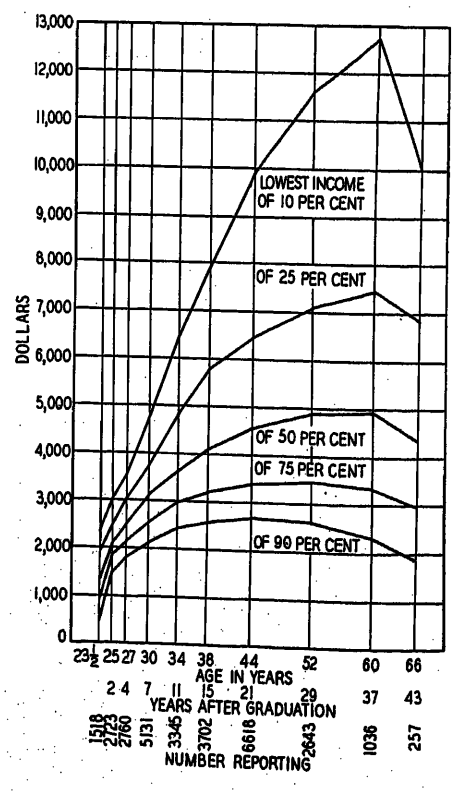

**Figure 1. Earned annual income of engineers according to age, 1929**

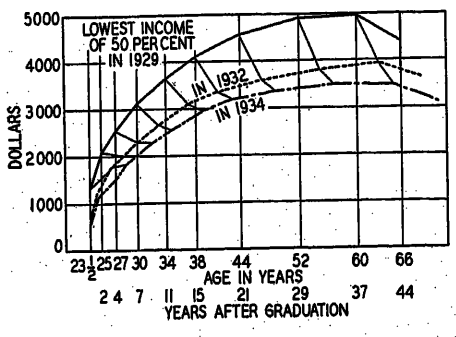
Income from engineering and non-engineering services, including full and part-time employment, all types of education



## Table IV. Comparison of 5 Levels of Annual Earnings for All Engineers Reporting in Each Professional Class in 1929, 1932, and 1934

Figures derived from adjusted data as explained[a] and without regard to employment status reported or type of education

| Per Cent of Professional Class at Specified Income Level* | Annual Earnings of More Than Specified Amount | | | Increase or Decrease | | | Per Cent of Change | | |

* Arranged in ascending order of earned annual income for 1929.

earned annual incomes of professional engineers. The sharpest absolute declines occurred in the higher income levels. Thus, in 1929, while the highest one-tenth of the engineers had earned more than $7,466, in 1934 the earnings of this highest-paid tenth ranged down to $5,138. The middle income declined from $3,412 in 1929 to $2,286 in 1934. However, the percentages of decrease for the highest 10 and 25 per cent of reporting engineers were approximately the same, namely, 31.2 and 31.6 per cent, respectively. The middle or average values of all incomes declined by 33.0 per cent. At the lower income levels, the absolute declines were almost as great as was the decline of the median earnings; but the percentage decreases were greater. This decrease at the lower levels reflects not only salary cuts, but also the low earnings of those with long periods of unemployment. In 1929, while the yearly earnings reported by the lowest 25 and 10 per cent of the engineers were less than $2,509 and $1,878, respectively, by 1934 the former had decreased to $1,473, the latter to $872. The relative percentage decreases were greatest for these 2 lower income levels, namely, 41.3 and 53.6.[6]

Income from engineering and non-engineering services including full and part-time employment, all types of education

**Figure 2. Medians of earned annual income according to age, 1929, 1932, and 1934**

Almost two-thirds of the decrease in earned annual incomes occurred between 1929 and 1932. This, it will be recalled, was coincident with the greatest declines in employment. There were further declines in the period 1932 to 1934. In general, the order of the absolute decreases and the percentages of change followed those which took place in the period 1929 to 1934, the one exception being that, between 1932 and 1934, there was only a 1.9 per cent decline in the lowest income levels. The corresponding absolute decrease was $17.

When these adjusted data on annual income were compared for all engineers reporting in the 5 professional classes, marked divergences in their respective earning capacities were revealed.

These differences in earning capacity within the several professional classes were greatest at the higher income levels. Thus, in 1929, nine-tenths of all electrical engineers earned $1,662 or more, while a similar proportion of the mining and metallurgical engineers earned $1,985. The range was $323. For the middle values of income, a difference of $733 was noted between the extremes of

6. It must be noted that errors of reporting account for part of the decline, at least in the lowest brackets for which comparison is made. The questionnaire called for earnings during the calendar years 1929 and 1934. An engineer graduating from college in either year would usually have had only a half year in which he earned. In both years, there is some evidence that annual rates were occasionally reported. Such overreporting was more common for 1929 than 1934.

$4,010 for mining and metallurgical and $3,277 for electrical engineers. However, at the highest level, one-tenth of the mining and metallurgical engineers earned $9,912 or more, whereas a corresponding proportion of civil engineers earned only $6,507 or more. Clearly, it was in the higher income levels that the earning capacities of the several professional classes diverged the most, even in terms of percentages. Furthermore, this characteristic of greater variability among the professional classes at higher levels persisted in 1929, 1932, and 1934.

However, when the question is asked as to which professional class offers the greatest earnings, or which the lowest, the answer must be carefully qualified. In the first place, the averages shown in table IV relate to the total number in the professional class. For example, 1,319 mining and metallurgical engineers reported incomes for 1929, and of these one-tenth, or 132, had incomes of $10,000 or more. There were 13,424 civil, agricultural, and architectural engineers, of whom one-tenth, or 1,342, had incomes in excess of $6,507. Therefore, it may be concluded that of every 1,000 engineers in either professional class, a larger proportion will earn $10,000 in mining and metallurgical engineering than in civil engineering. But the total number of opportunities to earn $10,000 were greater in civil engineering, much the larger of the 2 professional classes. Among the civil engineers reporting to the Bureau for 1929, there were 469 who indicated incomes of $10,000 or more in 1929.

Again, the ranking of the profession on the basis of earnings opportunity relative to the number of engineers in the professional class was not the same at all levels and in all 3 periods. As regards the relative level of income for the highest 10 per cent, and also the highest 25 per cent, in each professional class, there was a constant relationship. Thus, in 1929, 10 per cent of the mining and metallurgical engineers earned more than $9,912. Chemical and ceramic engineers ranked second with 10 per cent earning more than $9,103, and were followed in order by mechanical and industrial engineers ($8,508), electrical engineers ($7,185), and civil engineers ($6,507). Relative to the mining and metallurgical engineers, the divergence was 8, 14, 27, and 33 per cent. A similar divergence was noted between the lower limit of $6,301 reported by the upper fourth of the mining and metallurgical engineers and those of the other professional classes. In 1929, these ranged from 4 per cent in the case of chemical and ceramic

**Table V. Comparison of 5 Levels of Annual Earnings on Age Basis for All Engineers Reporting in 1929, 1932, and 1934**

Without regard to employment status reported or type of education

| Age (Years) | Year of Graduation | Years After Graduation | Proportion With Annual Earnings of More Than Specified Amount (Per Cent) | | | | |
|---|---|---|---|---|---|---|---|
| | | | 10 | 25 | 50 | 75 | 90 |
| | | | 1929 | | | | |
| 64 and over | Prior to 1889 | 41 and over | $ 9,999 | $6,942 | $4,427 | $3,005 | $1,904 |
| 56—63 | 1889–96 | 33–40 | 12,749 | 7,493 | 4,968 | 3,378 | 2,328 |
| 48–55 | 1897–1904 | 25–32 | 11,701 | 7,129 | 4,918 | 3,471 | 2,621 |
| 40–47 | 1905–12 | 17–24 | 9,913 | 6,473 | 4,588 | 3,403 | 2,683 |
| 36–39 | 1913–16 | 13–16 | 7,936 | 5,802 | 4,121 | 3,210 | 2,563 |
| 32–35 | 1917–20 | 9–12 | 6,520 | 4,850 | 3,674 | 3,004 | 2,448 |

* Includes those engineers who were professionally active prior to 1930.

engineers ($6,034) to 28 per cent for the civil engineers ($4,508). This order of professional classes was also maintained in 1932 and 1934.

In 1929, the relative order of the median professional incomes was the same as that just described, as regards mining, chemical, and mechanical engineers. But whereas the upper limit of the earnings of the lowest 25 per cent of the electrical engineers exceeded that of a similar proportion of the civil engineers by 6.6 per cent, at the median level the situation was reversed—half the civil engineers earned $3,291 or more, whereas half the electrical engineers earned $3,277 or more. This change in order persisted in 1932 and 1934.

In 1932 and 1934, the median earnings of mining and mechanical engineers led all the others. Chemical engineers were below mechanical engineers in 1932. The median earnings of chemical engineers were lower than the median of every other professional class in 1934.

At the lower levels the most marked shift in rank was that of civil engineers and chemical engineers. In 1929, one-quarter of the civil engineers earned less than $2,499, exceeding only the comparable earnings of electrical engineers. But in 1932, civil engineers were in second place as regards the level of earnings of the lowest quarter of the profession, and in 1934 they were in first place. Even in 1929, the lowest 10 per cent of the civil engineers had earned almost as much as the lowest 10 per cent of the mining and mechanical engineers, and substantially exceeded the level of the lowest 10 per cent of the chemical and electrical engineers. With reference to both the lowest 25 and 10 per cent groups, chemical engineers' earnings came in last place in 1932 and 1934.

Further examination of the adjusted data in table IV, given without regard to age, demonstrates not only differences in earning capacity but also variations in the decreases in earned annual income over the period 1929 to 1934. Without exception, the greater part of all contractions in income reported occurred between 1929 and 1932, though there were further declines in the period 1932 and 1934.

## Annual Income Related to Age

The effects of age upon earned annual incomes, for all professional engineers combined are presented in table V.

This table makes it plain that the engineers' earnings advanced with age. In 1929, the income level of half of the engineers who had graduated in 1927 or 1928, or were from 24 to 25 years of age, exceeded $2,098, whereas that of half of the engineers in the age group 56–63 exceeded $4,968. Similarly, in 1932 and 1934, there was a continuous advance. But apparently age 60 represented a turning point in the average earnings of professional engineers. Furthermore, the increase in earnings with age comprised 3 distinct phases: Initial periods of exceptionally rapid rise which contain the maximum average yearly increase, followed by 2 others in which the rates of increase were progressively slower up to the respective maxima of the 5 income groups or levels. The age spans of these phases differed with the income level. Thus, for the middle and 2 lower levels of income in 1929, the maximum yearly increase of $450 was reached at the age of 25. On the other hand, the initial periods of rapid rise for the upper 25 and 10 per cent levels were not reached until the ages of 27 and 34, respectively. The subsequent periods of increase for

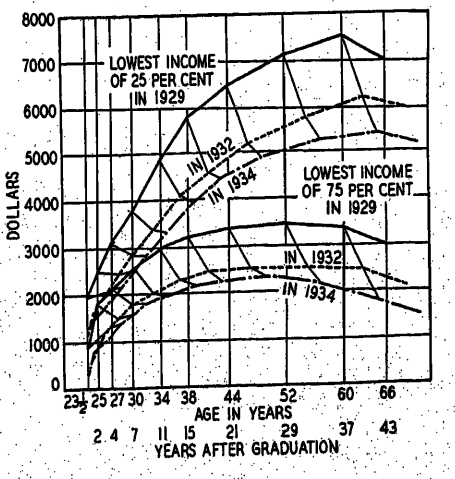

**Figure 3. Upper and lower quartiles of earned annual income according to age, 1929, 1932, and 1934**

Income from engineering and non-engineering services including full and part-time employment, all types of education

the upper 10 per cent embraced the age spans of 34 to 44, and 44 to 60, whereas those for the next highest income level extended from 27 to 38, and 38 to 60 years of age. The 3 remaining income levels increased at practically the same rate between 25 and 34 years. But while the age span for the third phase of increase was from 34 to 52 for the middle level, it only extended from 34 to 44 in the case of the 2 lower levels of income.

There was also an increased spread of earnings with advancing age. Even in the early ages there was a fairly considerable range. Thus, in 1929, among those who graduated in 1927 or 1928, the lowest quarter earned less than $1,822, whereas the earnings of the highest quarter were about 1/3 higher than this amount, or $2,497 per annum. It is also true that the highest 10 per cent of these ages earned at least twice as much as the lowest 10 per cent. But among engineers who were about 52 in 1929, the highest-paid quarter earned at least twice as much as the lowest-paid quarter, and the highest 10 per cent earned more than 4 times as much as the lowest 10 per cent. Similar relationships existed in 1932 and 1934, although the range of increases was due in large part to the influence of unemployment on the earnings in the lower levels of income.

The spread in earnings was accentuated beyond the age of 38. At that point, the income curve of the upper 10 per cent diverged upward and continued thus to the age of 60. On the other hand, the remaining curves ran consistently parallel up to their respective maxima. For example, at the ages of 25, 44, 52, and 60 the incomes of the upper 25 per cent differed from the median by 19, 41, 45, and 51 per cent, while the order of differences for the lower 25 per cent was 13, 26, 29, and 32 per cent. By contrast, the corresponding incomes of the upper 10 per cent at these ages were greater than the median by 45, 116, 138, and 157 per cent. Clearly, beyond the age of 44, the earned annual incomes reported in 1929 by the upper 10 per cent of all engineers differed very greatly from those in the other income levels, and this advantage in earning capacity was maintained in the years 1932 and 1934 also.

The earnings of engineers in the lower income brackets ceased to increase at a relatively early age. It is only approximately correct to assume that ability and income are in direct proportion. By and large, however, it is perhaps safe to assume that the engineers at any age in the lowest 10 per cent income group are less able than the average at that age; and that the highest 10 per cent are substantially more able than the average. The Bureau's data reveal that the maximum earnings of the lowest 10 and 25 per cent were reached in 1929 at about 44 years of age, and the average engineer reached his maximum earnings at about 52. The same relationship held in 1932 and 1934.

In the 2 later years the maximum for the average engineer occurred at about 60, but it is evident that earning power for engineers above the average continued to rise beyond this age. Thus, the average earnings of engineers 53 to 60 years of age in 1934 exceeded $3,502, whereas the average earnings of those 61 to 68 years were more than $3,497. But the highest 10 per cent of the first group earned over $7,720, whereas the same class of the second group earned more than $8,280.

Table V discloses differences in the age-income cycles beyond the points of maximum earnings, that is, at the end of the third phases of increase. In any case of the 2 higher income levels, the fourth and last phase in 1929 was one of decrease. This was not so for the 3 lower income levels. For them, there was a fourth phase of no change in income which covered a span of approximately 8 years: 52 to 60 for the middle group, and from 44 to 52 in the case of the 2 lower levels. The fifth phases were ones of decrease. Relatively, however, the steepest declines occurred in the 2 higher income levels.

Changes in income brought about by the depression in various years may be considered from the point of view of particular individuals whose age and experience was increasing, or from the point of view of the expectations of men with comparable periods of experience. For example, the average earnings of engineers who graduated in

**Table VII. Comparison of 5 Levels of Annual Earnings for Corresponding Years After Graduation in 1929, 1932, and 1934**

Without regard to employment status reported or type of education

| Age of Engineers (Years) | Years After Graduation | Proportion With Annual Earnings of More Than Specified Amount (Per Cent) | | | | | | | | | | | | | | |

* Includes all engineers who were professionally active prior to 1930. ** Graduate engineers embrace all postgraduates, nonengineering graduates, and first degree engineering graduates. † "Other" engineers embrace all engineers with college course incomplete, noncollegiate technical school course, and secondary school education. ‡ Arranged in ascension of graduate earned annual income for 1929.

1927–28 declined only from $2,098 in 1929 to $2,020 in 1932, and increased slightly to $2,023 in 1934. On the other hand, those who graduated in 1897–1904 averaged $4,918 in 1929, $3,832 in 1932, and $3,502 in 1934. Such comparisons for each group of engineers over the period 1929–34 may be made from table V. They are, more conveniently arranged for direct comparison in table VI.

This table shows a rise in earnings for the youngest engineers in the profession in 1929, who were near to 30 years of age in 1934. The advance in earning capacity in the first 5 years of engineering experience was so great that it offset the influence of the depression in the case of the youngest engineers. At higher ages, when an added year's experience influenced income less, the incomes of particular engineers declined by as much as 30 per cent for the average graduate of the classes of 1889–96.

In order to trace the influence of the depression on professional opportunity and on the normal expectations of members of the profession, table VII compares the earnings for identical ages in each of the 3 years.[7]

For each level of experience, incomes declined from 1929 to 1934, and two-thirds to three-quarters of this decline occurred from 1929 to 1932. Over the entire period the average income of those who had been out of college for 2 years declined 43 per cent. Those who had been out 5 years had, on the average, 35 per cent less income in 1934 than the corresponding group in 1929. For older engineers the decline approximated 30 per cent, being slightly more than this for those with 10 years' experience, and slightly less for those with 20 years' experience.

The most significant differences brought about by the depression were in the spread of incomes at various ages.

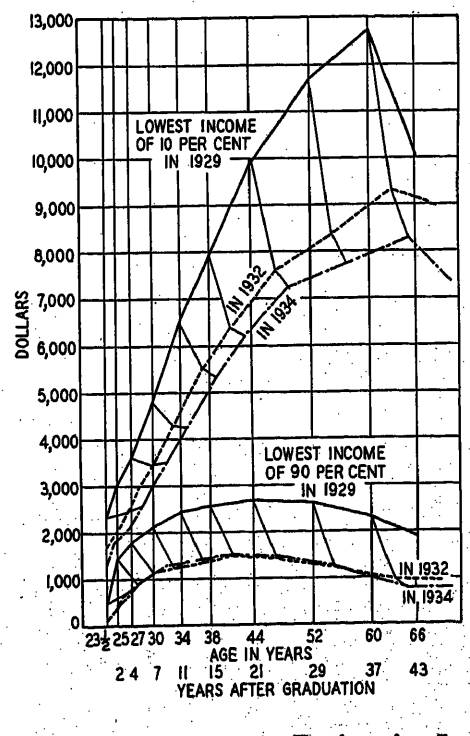

**Figure 4. Upper and lower deciles of earned annual income according to age, 1929, 1932, and 1934**

Income from engineering and nonengineering services including full and part-time employment, all types of education

7. The figures are not derived from direct tabulations which were made on the basis of the same combinations of years of birth or graduation in each of the 3 years, but the movements of earnings proved to be sufficiently regular to justify reading the values for particular ages from the chart.

In all cases, primarily because of the influence of unemployment, annual income for the lowest 25 per cent and the lowest 10 per cent declined more than the average income at a given age. Thus, 2 years after graduation, 10 per cent of the engineers earned less than $1,462 in 1929 as compared with a corresponding group earning less than $410 in 1934. This was a decline of 72 per cent as compared with a 43 per cent decline for the average of this age. Similarly, the average for engineers 30 years after graduation declined 30 per cent from 1929 to 1934, while the level below which the earnings of 10 per cent of such engineers were found fell by 50 per cent.

There was comparatively little difference for the various ages in the decline of the median income or in the decline of the level of income above which only 25 per cent of the engineers of corresponding ages were found. The highest level of income (that achieved by only 10 per cent at each age) declined more than the average in the case of all groups of engineers with 5 years' or more experience. Thus this select group among engineers 60 years of age lost 38 per cent from 1929 to 1934, whereas the average decline at that age was 30 per cent.

## Annual Income and Education

The foregoing analysis of annual incomes reported by professional engineers for 1929, 1932, and 1934 took no account of differences in educational background. In 1929, some 22,386, or 86 per cent, of the 24,837 older graduates in engineering courses in the sample reported income and 7,646, or 90 per cent, of the 8,440 older "other" engineers who were in the profession in 1929 reported. The 5 income levels for these 2 groups are shown in table VIII.

Consideration of the ratios derived from the 1929 earnings reported by the "other" and graduate engineers clearly indicates that those with a formal engineering education had higher incomes. Thus, in the highest 10 and 25 per cent income groups, the earnings of the graduates in each professional class exceeded those of the "other" engineers. It will, however, be noted that there were wide variations in the ratios in the earnings of the 2 groups, indicating that the differentials in earnings do not accrue in equal measure for all 5 professional classes. In the upper 25 per cent level, the order of yearly differences in favor of the graduates was $901, $696, $389, $324, and $67, the 3 smallest of these being in the electrical, mining and metallurgical, and mechanical and industrial classes. In the highest income level, differences of $647 and $554 per year were reported by the graduate electrical and mechanical and industrial engineers; in the 3 remaining professional classes none of the graduate groups reported differentials of less than $1,000 per year. In general, from 1929 to 1934, the earnings of the upper 25 per cent of the older graduates and of the "other" engineers declined by similar amounts.

The advantage enjoyed by engineers with college degrees is less marked at the lower levels. The average income of mechanical engineers in the profession in 1929 reporting income for 1929 was actually higher for noncollege graduates than for graduates. This was the only professional class of which this was true for the average, but, in general, the lowest 25 per cent and the lowest 10 per cent among the "other" engineers had higher incomes than among the graduates. But even at these levels, it will be seen that an advantage accrued over the period 1929 to 1934 to the college graduates. The income of the lowest 25 per cent of those graduating prior to 1929 declined less than the income of the lowest 25 per cent of the corresponding group of "other" engineers and by 1934, college graduates had the higher incomes even at this level.

The apparent advantage enjoyed in 1929 by the "other" engineers at the lower levels of income may best be explained in conjunction with the data in tables IX and X. The data for the median values[8] only of earned annual income of all engineers classified by age in the 3 years, 1929, 1932, and 1934 are presented in table IX.[9]

The first observation to be made has regard to the fact that the "other" engineers, at a very early age, lose the advantage in earning capacity, arising from practical experience gained, while the college graduate is in school. This loss of advantage is best exemplified by considering the ranking order of the 12 groups of engineers at corresponding years after graduation (table X).

At the end of 2 years after graduation[10] in 1929, the "other" engineers held ranks 1, 2, 4, 5, and 6, the first-degree civil graduates were third, and the remaining graduate groups occupied positions 7 to 12, inclusive. Five years after graduation, however, there was a complete reversal of this situation, which placed all graduates ahead of the "other" engineers.

Relatively, the greatest shifts in position occurred between the second and fifth years after graduation. Secondary-school engineers dropped from sixth to twelfth place. The noncollegiate civil engineers declined from second to eleventh place, while the civil engineers whose college course was incomplete declined from fifth to tenth place. Positions 8 and 9, respectively, were occupied by the mechanical engineers whose college course was incomplete and those who were graduates of noncollegiate technical schools; 2 years after graduation they had held first and fourth places. Among the engineering graduates, the greatest shift in position occurred among the first-degree chemical and ceramic engineers, who moved from tenth to first place at 5 years after graduation, and maintained that position throughout the 1929 age cycle. It will also be noted that the 1929 earnings reported by the first-degree civil engineers were greater at 5 years after graduation than those of both postgraduates and first-degree electrical engineers. On the other hand, the earnings of these 3 groups were less than those reported by first-degree mining and metallurgical, and mechanical and industrial engineers, and nonengineering graduates.

Thus, it follows that the greater decline from 1929 to 1934 in the incomes of the lower 10 and 25 per cent of the "other" engineers reflects in part the greater advantage of

8. I.e., the middle value of earned annual income—50 per cent earning more and 50 per cent earning less than the figure shown.
9. Insufficient data were furnished for the 2 lower and higher income levels to enable a complete comparison for all age groups and all types of education.
10. The incomes reported just after graduation are not compared. These are invalidated by the fact that, while the graduates could have reported incomes for 6 months only, it was possible for the "other" engineers to have reported an income for a full year or more.

## Table IX. Median Annual Earnings in 1929, 1932, and 1934, for All Engineers Reporting by Age and Type of Education

Without regard to employment status reported

* Prior to 1889. ** Less than 10 persons reported.

5 years additional experience among the younger college graduates.

Between 5 and 10 years after graduation, there were but slight changes in relative position. At the latter period, however, all first-degree and nonengineering graduates were ahead of the postgraduate engineers. The secondary-school engineers reported earnings greater than either of the 2 groups of "other" civil engineers. The "other" mechanical engineers trained in noncollegiate technical schools followed ninth in order, after the postgraduates.

At 20 years after graduation, the first-degree civil engineers ranked below both the "other" mechanical engineers whose college course was incomplete and the postgraduate engineers; between 20 and 37 years after graduation, the relative standing of the several groups remained comparatively stable. It will also be noted that even in 1934 the order of the groups shows no marked departure from the situation which prevailed in 1929.

A further explanation may be given of the apparent advantage of "other" engineers in the lower income levels, as shown in table VIII. There are too few cases to warrant showing text tables of income for the lowest 10 and 25 per cent of the engineers classified simultaneously by professional classifications, age, and type of education.

## Table X. Rank of Engineers of Specified Education According to Median Annual Earnings in 1929 and 1934, for Corresponding Years After Graduation

Without regard to employment status reported

| Type of Education | Years After Graduation | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|

** Less than 10 engineers reported.

But such values have been computed for every such classification embracing more than 100 reports and the results may be summarized. In 1929, at every age the lowest 10 per cent of the civil engineers with incomplete college courses had lower incomes than the lowest 10 per cent of those with completed college courses. This continued to be true in 1934 for engineers who graduated prior to 1928, the last year with an adequate number of reports to warrant this particular comparison. For the 5 age groups from 28 to 47, for which comparisons can be made, the lowest 10 per cent of civil engineers with noncollegiate technical school courses had lower incomes than those with incomplete college courses. These statements hold, not only for the lowest 10 per cent of the civil engineers but also for the lowest 25 per cent. There are not enough cases of engineers in the professional classes, other than civil engineers, to warrant a detailed analysis of nongraduates on an age basis for the separate classes. But the income of the lowest 10 and 25 per cent of the nongraduates of the 4 classes combined is less than the corresponding level of income for graduates in any of the professional classes at almost all ages for which comparisons can be made. It seems highly probable, in the light of these facts, that part of the advantage shown by "other" engineers in table VIII is due to a higher age among the nongraduates in the groups compared.

Table X also shows that, although the earnings reported in 1929 by the "other" engineers at 2 years after graduation were higher than those of the graduates, the differentials were not great. For the former, the 1929 median earnings ranged from $2,100 in the case of secondary-school engineers to $2,232 for mechanical engineers who had not completed their college course, while the range for the latter was from $1,977 for electrical to $2,099 for mechanical and industrial engineers. At 5 years after graduation, when the positions were reversed, the differentials were still slight. The earnings of the graduates ranged from $2,725 to $3,000 per year and those of the "other" engineers from $2,430 to $2,650. With advancing age, however, the spreads in earnings in favor of the graduates became very marked. In the case of mechanical engineers, for instance, the difference in earnings between the first-degree engineers and those who did not complete their college course was $175, $295, $925, $700, and $1,322 per year, and between first-degree and noncollegiate mechanical engineers it was $225, $575, $1,160 $1,150, and $1,815 per annum. Similarly, for the civil engineers, the difference in earnings between those with first-degrees and whose college course was incomplete was $275, $590, $800, $1,050, and $1,248 per year, while between first-degree civil and noncollegiate technical school engineers, the order was $300, $540, $875, $1,250, and $1,324 per annum.

Even among the graduate groups there was variation in earning capacity. Thus, while the earnings of first-degree civil engineers ranged from $2,750 to $4,800 per year between 5 and 30 years after graduation, the range for the first-degree chemical and ceramic engineers was from

$3,000 to $6,600 per year. In other words, over a period of 25 years, the civil engineers' earnings increased by only $2,050, whereas those of engineers in the chemical and ceramic field increased by $3,600. The ranges in earnings of the remaining graduate groups fell between those reported by the civil and the chemical and ceramic engineers.

Earnings of the "other" engineers cease to increase several years before those of the graduates. Their earnings began to decline after 55 years of age in 1929, whereas the earnings of the graduates continued to increase even at 64 years of age and over (table IX).

When consideration is given to the changes in income status between 1929 and 1934 of selected age groups of engineers in each type of education, it appears, again, that the depression bore hardest upon the older engineers.

As indicated in table XI, over the period 1929–34 the decreases in earnings of engineers who were 60 years of age in 1929 and 65 in 1934 ranged from 20 to 45 per cent. The smallest range, however, occurred among the graduate engineers. This is explained by the fact that for the "other" engineers, the earnings reported at the age of 60 in 1929 were those for the period of decline, since they were less than those reported for engineers who were 52 in 1929. When, however, comparison is made of the earnings for the 2 age groups of engineers who were 52 and 44, respectively, in 1929 and 5 years older in 1934, it will be noted that the decreases in their earnings over the period 1929–34 show little variation. The important thing to note is that the effect of the depression was approximately the same on both graduates and "other" engineers. On the other hand, for the 2 younger groups shown in table XI, the graduate engineers who were 25 in 1929, practically all showed increases in their earnings by 1934, whereas the "other" engineers showed further decreases. This situation was even more pronounced in favor of the graduate engineers who were 23½ years of age in 1929.

Throughout the whole of this analysis of differences in earnings by type of education, there have only been incidental references to the changes which occurred over the period 1929–34 and in the intervening periods, 1929–32 and 1932–34. It will be recalled, however, that the percentage decreases in the incomes for all engineers at corresponding years after graduation were practically the same. This was also the case for the 12 groups of engineers when segregated by type of education, as is evidenced by a consideration of the data shown in table XII.

**Table XI. Comparison of Median Annual Earnings in 1929, 1932, and 1934 of Selected Age Groups of Engineers Reporting by Type of Education**

Without regard to employment status reported

| Type of Education | Engineers Whose Age Was— 60 in 1929 | 63 in 1932 | 65 in 1934 | 52 in 1929 | 55 in 1932 | 57 in 1934 | 44 in 1929 | 47 in 1932 | 49 in 1934 | 25 in 1929 | 28 in 1932 | 30 in 1934 | 23½ in 1929 | 26½ in 1932 | 28½ in 1934 |

* Includes chemical, ceramic, electrical, industrial, mining, and metallurgical engineers. ** Less than 10 engineers reported.

At 5 years after graduation the range of decreases of earnings over the period 1929–34 was from 25 to 43 per cent. At 10 years after graduation, the range was from 25 to 39 per cent, while even at 30 years after graduation the percentage decreases ranged only from 22 to 35 per cent. It will, however, be noted that the extremes of the ranges are the exception, indicating that regardless of type of education, the incomes of engineers of identical ages in 1929 and 1934 suffered about the same from the depression.

It cannot be too strongly emphasized that these data relate only to what engineers of various ages were earning in 1929, 1932, and 1934. Since there are no better data available it is almost inevitable that the figures will be used to predict what young engineers may expect to earn 10 or 15 years hence. For that reason, it is important to emphasize the severe limitations which attach to the data in this connection.

The first point—that the general level of engineering income fluctuates from year to year—needs merely to be mentioned in passing. Therefore, the absolute level of incomes for engineers with any given amount of experience cannot be forecast for any future year.

The chief danger to be guarded against is the assumption that the income relationships for 1934 will hold in some future year. A cautious use of such information may add to the value of the advice of those who are directing young men into the various fields of specialization. A careless assumption that this same relationship will hold 20 years hence for future graduates will make the resulting advice dangerous.

The tabulations show merely the facts of the income distribution in 1934 or some other particular year. For example, chemical and ceramic engineers 20 years after graduation averaged $4,100 and one-quarter of such engineers earned more than $6,000. On the contrary, civil engineers 20 years after graduation averaged $3,100 and the best-paid quarter averaged only $4,100 or more. It is evident, therefore, that men graduating from college in 1914 advanced on the whole to higher levels of income if their college work had been in the field of chemical or ceramic engineering rather than if it had been in the field of civil engineering. This much is fact.

But it must not be concluded from these data on income alone that it is wise to encourage men entering college in 1937 to specialize in chemical and ceramic engineering and to discourage their entering the field of civil engineering. Such advice will be sound only if the conditions surrounding the two fields of engineering and their prospects for the next 20 years are similar to the conditions of 1914 to 1934. Years of experience are themselves a factor in determining what kind of engineers are available. It is quite possible that there may be a relative scarcity of engineers with a given type of academic background and with 20 years of experience, while at the same time the supply of younger engineers with that same type of formal education may have become excessive. It is quite easy to see that a special scarcity value may have attached in 1934 to chemical engineers that did not accrue to civil engineers graduating in 1914. There was a tremendous expansion of the chemical industry in the United States during and following the war. It is a matter of common knowledge that such enterprises had the greatest difficulty in finding sufficient men with the requisite education and experience. On the other hand, while there are more civil engineers and more jobs for civil engineers than in 1914, a decrease in certain types of civil engineering work—as, for example, the construction of new railroads—has acted to restrain the development of relative scarcity values such as may have attached to chemical engineers.

At the same time it is impossible to make a comparison of the earnings of the younger engineers in the several professional classes and to conclude that the relationship between the professional groups will hold when they have had 20 years' experience. Thus in 1934 we find that chemical and ceramic engineers who graduated in 1932 averaged $1,286, whereas civil and mechanical engineers averaged $1,384. The statistics do not preclude the possibility that there is a longer period of apprenticeship for some types of engineering work than for others and that, following such a period of apprenticeship, there may be a more rapid advancement in the one line than in the other, ultimately to a higher level of income.

Conclusions as to the relative desirability of entering one type of engineering rather than another should be drawn only by those with an intimate acquaintance with all fields of engineering. Available statistics are probably a less satisfactory basis for advice than would be the pooled nonstatistical judgments of a number of people

**Table XII. Percentage Decreases in Median Annual Earnings Over Period 1929–34, for Corresponding Years After Graduation Among Engineers Reporting by Type of Education**

** Less than 10 engineers reported in 1934.

with a wide knowledge of the engineering profession and its opportunities. The statistical materials of this study can be used safely in projection only to fortify the judgments and forecasts of such individuals. To those who know not only the present situation of the various professional groups, but also the changing background of those professions over the past few decades, the income data will have particular significance. One who knows how the supply of and demand for particular types of engineering training has changed can make allowances and may attempt to estimate the most probable changes in future relationships. He will be helped to appraise the state of the current market for engineering services by earlier articles in which has been indicated the extent to which recent engineering graduates have been able to find engineering jobs.

The statistics which are presented here have a value that varies with the richness of the background of the user. Educational advisers and directors are performing specialized work and by the very nature of their work must guess what the future holds in store for various professions. Their prognosis becomes better if it is based on an extensive and accurate knowledge of existing conditions. This basis of knowledge the Bureau supplies on a hitherto unprecedented scale. The Bureau has attempted as comprehensive an analysis of recently existing relationships as its resources permit, and will welcome further critical analysis from any source of the detailed materials.

The Bureau has carefully refrained in this article from describing differences in the average incomes of graduate and nongraduate engineers as a measure of the value of a completed college course in engineering. From the data in hand, it is impossible to determine whether the differences are due to the fact that given individuals have received a college education or to other factors. It is possible that the differences in income arise from an initial process of selection. It is also possible that a prejudice in favor of the college graduate affords him better opportunities to acquire valuable experience than are given to the noncollege graduate. In such case, the advantages would arise not from formal education which the man had received but from his status as a college graduate.

It is a matter of common belief that college training has economic value for the prospective engineer. The figures in this study support this belief but cannot be taken as conclusive proof. Rather more conclusively they prove the great importance of other factors in addition to formal education. If formal education is an asset, the young graduate engineer should advance more rapidly than the nongraduate of corresponding age. This does happen. The data thus furnish supporting evidence as to the value of a formal education. But were formal education an all-important element in determining income in these early years, there should come a point at which no further relative spread developed between the average earnings of college graduates and nongraduates.

The facts show that the spread does increase. The difference is greater both in absolute terms and in relative terms after 30 or 40 years of experience than it is after 10 or 15 years of experience. This increased spread is noted

not only with reference to the average of the 2 classes but applies at the 5 levels that have been studied. It was found not only in 1929 but also in 1932 and 1934.

It can hardly be argued that the scholastic background of engineers who entered the profession in 1900 is a controlling factor with reference to their earnings in 1929 and 1934. Certainly, the value of their services is no longer primarily dependent upon the odds and ends of information which they acquired in college, although it is possible that habits of thinking and study which the engineer received in his college days constitute a permanent legacy. By and large the factors controlling the value of a man's engineering services after 30 years or more of experience must be primarily his native capacity and the training which he has received on the various jobs that he has performed.

As regards native capacity, there is reason to believe that, on the average, better material will be found among college graduates than among those who failed to complete a college course. There are, of course, many individuals who are unable to complete an engineering course for financial reasons. There are also many individuals of limited capacity who receive degrees. But there is also a wholesale process of weeding out that goes on in the engineering schools. Thus even the differences in income shown in

the earliest years of experience may reflect differences in capacity rather than differences arising from the value of the formal training.

Whether ability is more important than the differences in the kinds of experience that are open to the college graduate and the nongraduate, it is impossible to tell. It is a matter of common knowledge that for a number of years college education has been thought of as a normal prerequisite to engineering work. Some large employers of engineers deliberately differentiate between the college graduate and the nongraduate, offering the young engineer with a college education opportunities for training on the job which either are not available to the nongraduate or which are open to him after special consideration rather than as a matter of routine.

It must be noted that this latter type of advantage will tend increasingly to accrue to the status of the graduate as opposed to the nongraduate. In this sense status is gained by graduation, to some extent no longer with regard to the value of the formal education as such. The more common a college education becomes, the more widespread the assumption of a difference in capacity between the college graduate and the nongraduate becomes, the more certain it is that employers will discriminate in favor of the college graduate. Such discrimination means that the college graduate will generally be given more favorable opportunites for training on the job than the nongraduate of equal capacity.

It is known, however, that many large employers of young engineers have already developed a highly selective process of employment in interviewing candidates from engineering colleges. They may assume that in general college graduates are more promising material than nongraduates. They no longer recognize the mere fact of graduation as evidence of employability and give special status only to those who graduate with a standing substantially better than the average of the class. Thus the advantage of status which may have accrued a number of years ago through the fact of college graduation alone now accrues in equal measure only to graduation with exceptional standing.

The candidate for a position in the engineering profession should study carefully the tables which will be presented in the final bulletin[1] not only for average earnings (as in table IX) but also for the upper and lower 10 and 25 per cent of the engineers. Table IX showed clearly enough that a young man is well advised to enter the profession after successfully completing a period of formal education beyond the high-school level. An earlier chapter on education indicated that college training was coming to be a prerequisite for entrance to the profession. But it is unwise to rely heavily on the value of a college education per se.

The present study gives conclusive demonstration of differences of income which generally reflect different degrees of capacity. The lot of the college graduate may be somewhat easier than that of the nongraduate. But even in 1929 the lowest 10 per cent of the college graduates in civil engineering were earning less than $2,500 after 10 years of experience and $2,700 after 20 years of experience. These figures are to be compared with the average earnings of $3,600 and $4,400 for these respective groups. On the other hand, the upper 10 per cent of the civil engineers whose college course was incomplete earned $5,200 or more after 10 years of experience and $7,600 or more after 20 years of experience. The upper 10 per cent of the engineers with only a secondary-school education similarly show earnings substantially above those of the average college graduate. In other words, graduation from an engineering school is no guaranty of a satisfactory income, while there is still apparently an opportunity for a man of outstanding capacity to secure far better than an average engineering income even though he has not attended college.

The most significant differences in income revealed by the present survey are not the differences in the average income received by individuals who have received a college degree and those who have not. Nor are they the differences as between individuals who have entered one professional class rather than another. These differences on the whole are moderate, though they are large enough to prove the desirability of choosing well both the field of endeavor and the type of training best adapted to advancement in that field. The most striking differences are those which exist within each profession and within each group classified on the basis of its educational background. One out of 10 of the engineers in each such group secures an income several times as great as the average for the group as a whole. At least one out of 10 at the bottom of each such group, whether a college graduate or not, whether a chemical engineer or a civil engineer, whether a man with many years of service or freshly out of college, is hardly to be distinguished as regards income from a skilled wage earner.

We [of the Bureau] do not feel ourselves competent to project from these data what the future holds in store for the high-school boy who must be advised as to what type of training will be most advantageous. We hope he may be fortunate enough to encounter wise advice. We dare do no more than point out that in 1929 the average income of graduate engineers with 10 years' experience ranged from $3,600 to $4,600 in the various professional classes. In 1929 only 6.4 per cent of the incomes in the United States exceeded $4,000. Furthermore, engineering is a profession in which earning capacity advances and is sustained until late in life. But if in these respects the profession appears attractive on the average, its rewards are not particularly attractive to the poorer or less fortunate engineers. Even in 1929 the lowest-paid 10 per cent of the engineers could hope for no more than $2,500 to $3,000, though they might stay in the profession for 40 years. In 1934, exposed as the profession was to the risks of unemployment, the lowest-paid 10 per cent of the engineers with less than 5 years' experience after graduation earned less than $1,000. Even with 10 to 30 years' experience they earned no more than $1,000 to $1,500. Judged from the basis of money income, there can be no question but that the best of a group of skilled wage earners are in better economic position than those who struggle to maintain a position on the fringes of the engineering profession.

# Electrical Applications in Bethlehem's 72-Inch Strip Mill

By F. D. EGAN
MEMBER AIEE

THE RAPIDLY increasing demand for flat-rolled sheet steel and strip products has made necessary the application of electrical apparatus to modern developments in rolling-mill machinery and caused the rapid construction of many wide continuous hot- and cold-strip mills in every section of the country. A comprehensive picture of a strip mill, and the application of electricity to the production of sheet steel can be seen in Bethlehem Steel Company's hot- and cold-strip mill.

This mill is built on a plot of 67 acres adjacent to, and across the highway from the main plant, acquired for the purpose of providing ample space for the best arrangement of buildings, in order that the most economic routing of materials and product through its 22 acres of floor space could be obtained.

This mill, which has an annual hot-rolled capacity of strip, sheet, and light plate of 800,000 tons, of which 360,000 tons can be converted into cold-rolled finished product, is capable of producing wide strip up to 60 inches in width by 0.0625 inch in thickness, and 72 inches in width by 0.078 inch in thickness, with a minimum width of 18 inches by 0.05 inch thick; as well as light plates up to $1/2$ inch in thickness. Cold-rolled strip is produced ranging from $18 1/2$ inches to 72 inches wide and from 0.0125 inch in thickness up to 0.109 inch in thickness, and by cross rolling in a 93-inch 4-high skin pass mill, sheets may be rolled up to 84 inches in width.

All possible refinements for hot-rolled products, as well as for cold-rolled sheet and strip for which there is a commercial demand, are provided in the finishing departments.

The mill's location gives it a nearby source of its basic material; namely, the slab, the steel made at the open hearth furnaces, and the ingots rolled to required sizes in the main plant. Its location enables it to use electricity, water, and gas from the main plant; also permits service, controlled to meet its needs by the South Buffalo Railroad, connecting with 13 trunk line railroads entering Buffalo, provides the advantages of shipping facilities on the Great Lakes for raw and finished materials, as well as the advantage of a location, central in relation to the consumers of sheet product.

The slab storage building (figure 1) comes first in the sequence of rolling operation; this building is 925 feet long and 85 feet wide, and has a capacity of approximately 10,000 tons of slabs. The stock of slabs varies in widths from 20 inches to 48 inches, in thicknesses from 3 inches to 6 inches, and in lengths from 5 feet to 15 feet. These slabs, of various chemical composition, are ready for heating and rolling as needed.

The slabs are removed from storage by an overhead traveling crane and piled on a magazine pusher, which is driven by a 35-horsepower motor through a rack and pinion arrangement. Each operation of the machine lifts the magazine so that a chain drive can carry but one slab at a time, onto the furnace charging table. This 3-section roller table carries the slab to a position in front of one of 3 heating furnaces, from where a pusher forces it into the furnace. These furnaces are of the recuperative type, 3 zone and triple fired. They have an effective heating length of 80 feet and can be either gas or oil fired. Each is capable of heating 55 gross tons of slabs per hour, giving a total furnace hourly capacity of 165 gross tons. At a signal from the head roller, the pulpit *A* operator, located in the slab yard, opens the furnace door, and then pushes a slab into the rear of the furnace; this causes one of the heated slabs to drop out of the furnace at the other end onto the 3-section furnace delivery table. These tables are duplicates of the charging tables.

The slab leaves the furnaces at approximately 2,250 degrees Fahrenheit and proceeds down the roller table to number 1 scale breaker, which precedes a series of 4 mill stands in the roughing train. The scale breaker is a 2-high mill, having 24-inch diameter by 76-inch long rolls, through which the slab passes and is given a slight reduction in thickness to break up any scale that may have formed on the surface of the slab as it is leaving the furnace. As the slab leaves the scale breaker, water at 1,000 pounds pressure is sprayed upon it to remove the loosened scale.

The slab now enters a 4-high broadside mill, which has 2 36-inch diameter working rolls, and 2 49-inch diameter backup rolls, all 96 inches long. Slabs which are to be finished as strip less than 48 inches, pass straight through this broadside mill; but, for a strip width of greater than 48 inches, the slab is turned crosswise on the turntable and is cross rolled to the desired strip width, after which it is turned back 90 degrees for rolling lengthwise in the remaining mill stands. On cross roll passes, a 150-horsepower motor-driven pusher is provided to force the slab into the stand.

Before the slab enters the remaining mills of the roughing group, a slab squeezer, driven by a 275-horsepower motor, squeezes the slab sideways to true and square its edges. The remaining 3 roughing stands are 4-high universal mills, each has $24 1/2$-inch diameter working rolls and 49-inch diameter backup rolls 79 inches long, as well as 2 vertical edging rolls, the latter driven by a 150-horsepower motor. These rolls are used to maintain the required slab width.

After leaving the last universal mill, the slab emerges onto a long, 2-section approach table. Each section is

A paper presented at the AIEE North Eastern District meeting, Buffalo, N. Y., May 6, 1937, and recommended for publication by the AIEE committee on applications to iron and steel production. Manuscript submitted May 19, 1937; released for publication July 12, 1937.

F. D. EGAN is superintendent of the electric department, Bethlehem Steel Company, Lackawanna, N. Y.

Figure 1. Slab storage building

driven by 2 35-horsepower motors operated in either series or parallel, to give 2 table speeds. Since the finishing temperature of the hot strip is a prime factor in the quality of the product produced, this roller line serves as a special cooling place between the roughing and finishing stands. When the thin slab has reached the proper temperature, which is automatically indicated by a photoelectric pyrometer, it enters the second scale breaker, which breaks up the secondary scale, formed on the cooling table. As the slab leaves the scale breaker, water at 1,000 pounds pressure removes the scale.

The cleaned slab now enters the 6-stand finishing train (figure 2). However, unlike the roughing mill, the strip is in all of these stands at the same time; thus, the speed of successive mill stands must be increased to compensate for the elongation in the preceding stand. This, together with the loopers, provide a means of keeping the slack out of the sheet throughout the finishing mill.

As in the roughing mills, so in the finishing mill, every precaution is taken during the rolling to eliminate scale and dirt. Here, steam instead of water is sprayed on the rapidly thinning strip just after it passes through each set of rolls. As it leaves the last finishing stand, the rapidly moving strip may be cut to any predetermined length from 11 to 22 feet, by a flying shear, synchronized with the speed of the strip, or the shear may be used to cut off the front and rear crop of the strip to be coiled.

On the front of each mill, there is a screwdown dial resembling a clock face, the hands of which indicate the movement of each end of the top roll. The rolls are roughly set up with a feeler gauge to produce a definite gauge of product. Then, to obtain perfectly accurate adjustments, either one or both ends of the top roll can be moved as small as $^{1}/_{1,000}$ of an inch by the screwdown motors, these movements being indicated by the hands on the screwdown dial. These screws are driven by 70-horsepower motors, which are coupled by a magnetic clutch when the screws are moved together.

Throughout the whole series of mill stands, grease is automatically pumped into the roll neck bearings at intervals of a few seconds, and a constant flow of oil is maintained to all motor bearings, gear and pinion housings, and backup roll bearings. These automatic lubrication systems help to insure a smooth operating mill.

In the production of hot-rolled strip it is important to secure the desired grain structure, which is controlled by the temperature of the strip as it leaves the finishing mill train. The finishing temperature is regulated by the length of time that the plate is held on the cooling tables ahead of the finishing stands. To indicate the finishing temperature, a recording Speedomax has been installed and placed within view of the finishing mill operator.

The finishing end of the hot-strip mill, designed to dispose of the various products rolled by the hot mill proper, consists of runout tables, cooling beds, trimming line, and other processing equipment. The runout table equipment serves to transport the steel from the mill to the coilers in a continuous strip, and to transport sheets, cut to length, by the flying shear, to the pilers.

That part of the runout table *A* between number 10 stand of the mill and the coilers is made up of 125 16-inch-diameter rollers, direct connected to gear head motors through flexible couplings. The motors are 2.25/7.5-horsepower 600/1,800-rpm 147/440-volt 20/60-cycle squirrel-cage induction motors, with a 5 to 1 gear ratio output shaft. The remainder of *A* table run, from the coilers to the piler, is made up of 216 rollers, 12 inches in diameter, arranged for flange-mounted motors with one motor driving 2 rollers. These motors are 1.37/5-horsepower 560/1,770-rpm 147/440-volt 3-phase 20/60-cycle induction motors.

As the continuous strip approaches the coiler, a door is opened in the table roller line, to direct the strip down into the coiler, where it is wound around a mandrel to a compact coil by individual-motor-driven revolving rolls. The finished coil is deposited on a chain conveyor and

either carried through an underground tunnel to storage space in the continuous-pickler building of the cold mill, or taken from the conveyor in the hot-mill shipping building to be delivered as hot-rolled coils, or further processed in shearing, trimming, and leveling lines.

These continuous trimming lines consist of a coil box, a trimmer, a leveler, and a shear with interconnecting roller lines. The strip passes through these machines and emerges as cut-to-length flat sheets, ready for shipment or storage. The cut-to-length strip from the flying shear is collected by automatic pilers and transported to temporary storage for self-annealing. Part of these sheets are delivered as self-annealed black sheets; however, if deep drawing qualities are required by the customer, the sheets are normalized in a 150-foot-long gas-fired furnace.

The normalized sheets may be further processed by passing through a roller leveler and a skin pass mill. However, other finished product specifications may require that the normalized sheets be first taken through a sheet pickling process. This pickling process consists primarily of dipping the sheets into a sulphuric-acid bath and a hot-water rinse and then a cold-water rinse. The sheet next passes through a scrubber and dryer for final cleaning.

For handling and processing plates, 3 additional roller tables, designated as *B*, *C*, and *D* lines, have been provided south of, and parallel to, *A* table line. When plate is being rolled it is routed from *A* to *B* table line by a chain transfer, driven by 3 70-horsepower motors. The *B* table run is made up of 434 12-inch-diameter rollers, arranged for flange-mounted 0.66/2-horsepower 147/440-volt 3-phase 20/60-cycle motors, with each motor driving 2 rollers. For flexibility of control, this *B* table run is divided into 3 major divisions. The first section, consisting of 174 rollers, delivers the plate to a leveler. The second section of 172 rollers carries the plate from the leveler and feeds it into a shear, which cuts it to desired lengths. The third section of 88 rollers carries the plate from the shear to the *B* to *C* table transfer.

*C* table, used entirely as a transfer and cooling table, is made up of 436 12-inch-diameter rollers, arranged for flange-mounted 0.5/1.5-horsepower 240/720-rpm 147/440-volt 3-phase 20/60-cycle motors, with each motor driving 2 rollers.

For convenience in plate handling, this *C* table is divided into 5 separately controlled sections. The last section of this table delivers plate to the *C* to *D* table transfer. The *D* table run, utilized as a $^1/_2$-inch-plate processing line, consists of 480 12-inch-diameter rollers, geared to flange-mounted motors duplicate of those driving *C* table. This table is divided into 7 sections. The first 2 sections are used either to spot material already processed on *B* table for removal by plate handling equipment, or to deliver material requiring further processing to the third section of this line which serves as an approach to a rotary side-trimming shear. Section number 4 is used to convey the material from this shear to a leveler from where it is

**Figure 2. Side view of number 9 and number 10 stands rolling wide strip**

delivered by section number 5 to an up-cut shear. The sheared plate is carried by sections number 6 and number 7 to piling skids, for transfer to storage and shipment or transferred to the $^5/_{16}$-inch trimmer line, or $^1/_2$-inch re-squaring shears for further processing.

All of the motors (figure 3), driving *A* table rollers and both coilers, the motors driving the second section of *B* table, and the motors driving the fourth and fifth sections of *D* table, receive their power from 6 166/500-kva 147/-440-volt 3-phase 20/60-cycle synchronous generators, each driven by 2 125/250-horsepower 300-volt 400/1,200-rpm shunt-wound, separately excited at 250 volts, adjustable-speed d-c motors connected in series to operate from the 600-volt d-c hot-mill bus. The table sections and coilers are arranged to be driven from the 6 alternator sets as follows:

Number 1 motor-alternator drives section number 1 of *A* table.
Number 2 motor-alternator drives section number 2 of *A* table.
Number 3 motor-alternator drives either number 1 coiler or section number 3 of *A* table.
Number 4 motor-alternator drives either number 2 coiler or section number 4 of *A* table.
Number 5 motor-alternator drives section number 2 of *B* table.
Number 6 motor-alternator drives section number 4 and number 5 of *D* table.

The motors driven from these alternators are started at base speed, 20 cycles at 147 volts on the line and increased to full speed, 60 cycles at 440 volts by field weakening of the d-c motors driving the alternators. In reverse manner the table drives are decelerated to base frequency and voltage by field strengthening of the driving motors, which pump regenerated energy into the 600-volt system. At base speed the motors are cut free from the alternators and brought to rest by d-c dynamic braking. This direct current is supplied by a 200-kw 75-volt separately excited shunt-wound generator driven by a 300-horsepower 440-volt motor. Excitation for this dynamic braking machine and the motor-alternator sets is supplied by a 100-kw self-excited 250-volt generator driven by a 150-horsepower 440-volt motor.

The motors driving the remaining sections of *B*, *C*, and *D* tables are operated at a fixed frequency of 25 cycles at about 187 volts, supplied by 2 banks of 3 100-kva single-phase, 440-volt primary, 170/200-volt secondary, transformers.

Coils of strip rolled in the hot mill are carried underground by 3 motor-driven coil conveyors to coil storage in the continuous pickler building. From here the hot-rolled coils definitely start on their journey through the cold mill for the process of becoming full-finished cold-rolled sheets.

The coils are taken from storage with a lifting magnet suspended from a traveling crane, to one of the continuous pickling lines, in vertical position. An up-ender tilts this coil to a horizontal position, from where it is rolled down an incline to the feed reel. The coil is lifted into position in this feed reel by an electric hoist, where motor-adjusted heads clamp it into place. The strip is threaded into a combination processor and straightener, which unwinds the coil and levels the sheet. The end of the strip continues to a shear where it is cropped square, so that it can be fastened to the squared end of the preceding strip by a stitcher to form a continuous ribbon of steel.

A looping pit is provided between the stitcher and the acid tanks, where sufficient slack can be kept in the strip to allow time for the stitching and shearing processes and still maintain a continuous passage of steel through the pickle tanks. The strip is then pulled by pinch rolls, out of the looping pit and through 4 60-foot acid tanks, a 25-foot cold-water-rinse tank, and a 25-foot hot-water-rinse tank, which helps to dry it. Emerging from the latter it moves over a roller table, under which is a hot-air dryer, designed to remove all traces of moisture. The pickling solution normally consists of a sulphuric-acid bath, kept at a temperature of 180 degrees Fahrenheit by pyrometrically controlled steam heat.

As the sheet is pulled from the drying table by the third pinch roll, it is recut to original coil lengths by a double-cut shear which removes the stitch. A recoiler located at the end of the line, coils the strip, from which it is discharged to a gravity conveyor, weighed, and delivered to the storage space adjacent to the tandem cold-rolling mills.

The next step after pickling is to reduce the strips' thickness to such gauges as may have been ordered by customers. This is accomplished by rolling the metal cold in the 3-stand 4-high tandem mills, there being 2 sets. One set of mills is designed to roll coils up to 48 inches maximum width, while the other will roll them up to a width of 72 inches.

The tandem arrangement of 3 mills in series makes possible 3 cumulative reductions at one pass of the strip through the mill train. Synchronizing the series of mills to the proper speed and reduction is accomplished by an elaborate electrical control system. The gauge or thickness of the strip on its passage through the mill stands is indicated to the operator by a flying micrometer which automatically indicates on a dial any variations in the thickness in increments of 0.0002 of an inch. The dial is located within view of the operator, and enables him quickly to adjust the pressure on the rolls to maintain uniform gauge.

Each mill stand is driven by a 1,250-horsepower motor, sufficient power being available to give a delivery speed at the last stand of 660 feet per minute. From the stand (figure 4), the strip is wound by a reel with a collapsible core, which maintains a predetermined strip tension during recoiling. After the strip is coiled the reel is stopped, then a pneumatic pusher discharges the coil from the reel, and the coil is either sent to storage for shipment, or subsequent treatment.

Preparatory to annealing, the coils from the tandem cold mills are cut into sheets, or especially processed in coil form. If the steel is to be annealed in sheet form, the coils are taken to a group of 3 cutting up lines. Each of these lines consists of a feed reel, a side trimming shear, roller leveler, and flying shear, arranged in tandem. From these lines the strip, now flattened sheets, are delivered in packs by gravity conveyors to the annealing department. Strip, to be annealed in coil form, is taken to a loose

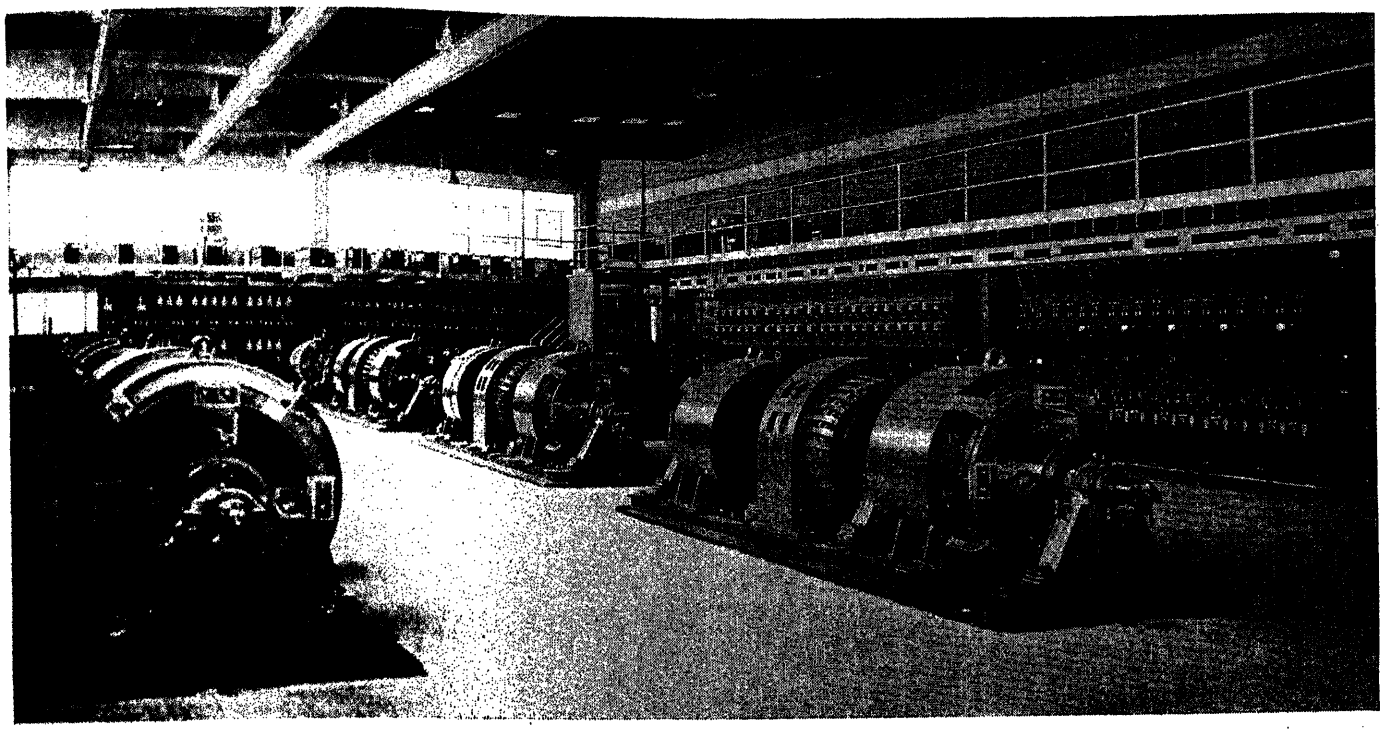

**Figure 3. Variable-frequency-motor room**

winding machine, which rewinds the tightly coiled strip as it comes from the tension reel of the tandem mills. This is done to permit a more thorough annealing and to eliminate the possibility of the smooth surface of the coils adhering to each other under the high annealing temperature.

The annealing equipment consists of 44 gas-fired radiant-tube furnaces. Thirty-one of these furnaces, provided with 91 bases and inner covers, will handle sheets up to 75 inches in width by 220 inches in length or coils up to 59 inches in width; 5 furnaces, provided with 14 bases and inner covers, are capable of taking sheets up to 84 inches by 186 inches, or coils up to 72 inches in width; and 8 furnaces, provided with 28 bases and inner covers, size 90 inches by 250 inches, are now being installed. The use of several bases to one furnace has secured maximum efficiency of furnace capacity.

In the sequence of the annealing operation, sheets are piled on a base, the inner cover placed over the pile, and the furnace lowered over this cover. The lower edges of both the inner cover and the furnace are sand sealed. During the annealing operation, an atmosphere of deoxidized gas is introduced under the inside of the inner cover at a slight positive pressure. The temperature in the furnace is slowly brought up, until it is a little above the predetermined annealing point. To reach this temperature requires from 30 to 40 hours on sheets, and about 20 hours on coils. The furnace temperature is maintained at this level by automatic control, while the pack of sheets is soaked for about 22 hours, or in the case of coils, 6 hours. The furnace is then removed by an overhead crane to another base that has been charged in a manner similar to the first. The annealed pile, enclosed in its inner cover, is allowed to cool to about 200 degrees Fahrenheit. The inner cover is then removed and after the pile has cooled to atmospheric temperature, it is removed. The base is now ready for another cycle of annealing operations.

Strip steel, when annealed in coils, is placed upright on the bases and covered by the inner cover, and furnace. The same method of annealing processes pertains to coils as to sheets, except that, due to the separation between coil turns, the soaking period can be reduced, making possible a shorter annealing cycle.

Four individual mills have been provided to skin pass the annealed sheets, namely: 2 4-high 76-inch mills; one 4-high 90-inch mill; and one 2-high 54-inch mill. In addition to skin rolling single sheets, one of the 76-inch 4-high mills and the 2-high 54-inch mill are equipped with feed and tension reels for skin passing strip in coil form. The slight reduction of one to 3 per cent, not only smoothens and polishes the sheet but also affects the hardness and ductility of the sheet. These qualities can be modified by varying the amount of reduction, depending upon the draw required in the sheet.

Strip, in coil form, can be delivered in widths, ranging from one inch to 72 inches, and in varying thicknesses from 0.0125 inch to 0.125 inch. To supply the narrow widths of 18 inches and under, the hot- and cold-rolled coils are slit to required widths by especially designed slitting units. One of these machines is capable of handling strip up to 36 inches in width and the other up to 72 inches in width. The machines may also be used to trim wide strip in coil or sheet form to accurate widths.

Typical uses of sheet and strip products, rolled by this mill, are as follows:

Hot-rolled sheets are used in the manufacture of tacks, large steel tanks, concrete forms, brick pallets, perforated screens, range boilers, and similar articles.

Hot-rolled annealed sheets are used in the manufacture of steel drums, barrels, metal flasks, coiling stock, stove parts, low price cabinets, lockers, and shelving, and other products, which do not have very rigid forming or surface requirements.

Blued sheets are used for the manufacture of stove pipe, stove parts, and other articles that are finished with a smooth unpainted surface.

Extra-smooth hot-rolled annealed sheets, also called japanning steel, are used principally for steel cabinets, shelving, stove parts, and various metal novelties that require a smooth surface suitable for lacquer or enamel finish and which do not have severe forming requirements.

Hot-rolled annealed sheets-pickled, have a clean, porous surface and are suitable for products that have drawing or electric welding requirements, but they are not recommended for articles on which a smooth finished surface is required. They are used by the automobile industry for inside body and chassis parts, such as: inside door panels, seat backs and bottoms, floor pans, and pillar posts.

Cold-rolled sheets are used in the automobile industry for turret tops, doors, panels, hoods, fenders, radiator shells, and side aprons; in the container industry for milk, paint, ink, grease, and oil cans; in the refrigerator industry for panels and doors; in the radio industry for chassis parts; and in the furniture industry for filing cabinets, desks, chairs, partitions, hot-air registor and radiator covers; in the electrical industry, cold-rolled stretcher-leveled sheets are used for control panels, metal-clad switchgear, instrument panels, breaker panels, and for other products which require perfectly flat, non-resilient steel.

Due to the distance between the main plant and the strip mill, it became necessary to erect an independent boiler plant to provide steam for processing and heating. This station is equipped with 4 500-horsepower boilers, 150 pounds pressure, 200 degrees superheat, capable of operating at 200 per cent rating. The units are designed to use coke breeze for fuel; this fuel is handled from cars to bunkers over the boilers by an automatic skip hoist and belt conveyor. The fuel is fed into the boilers by chain-grate stokers, and the ash removed by dumping directly into hopper cars. Three of the 4 boilers are equipped with steam-driven auxiliaries, the fourth being equipped with motor-driven auxiliaries. The boiler feed pumps, water-softening plant, and 3 2,000-cubic-feet-per-minute air compressors for general plant service, are located in a room adjoining the boiler house proper.

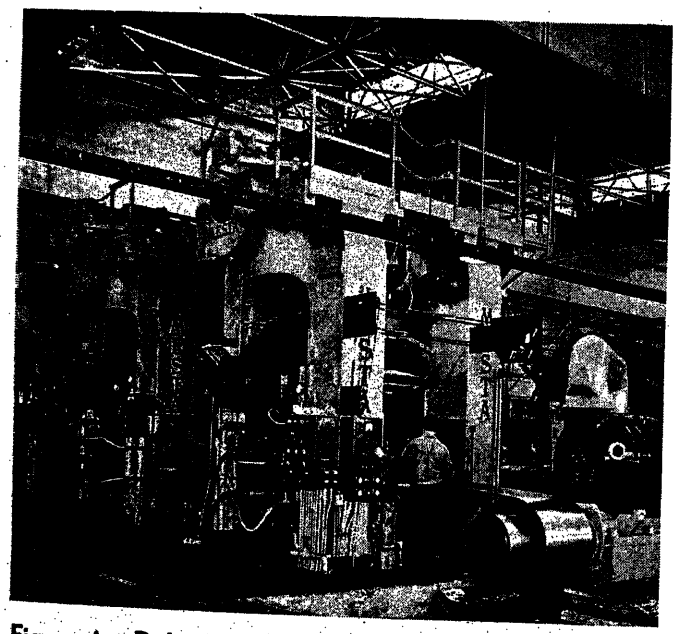

**Figure 4. Delivery side of 54-inch tandem mill, showing tension reel**

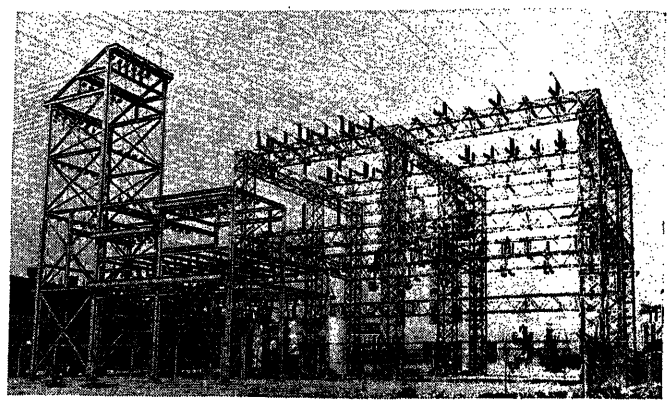

**Figure 5. Number 5 substation**

A roll shop is provided as a continuation of the cold-mill building, for grinding both the hot- and cold-mill rolls. This shop is equipped with 2 53-inch by 20-foot and 2 36-inch by 18-foot grinders, together with bearing changing blocks, roll racks, and sandblasting equipment for surfacing the cold-mill rolls.

A service building located central to the hot and cold mill, contains an electric shop, machine shop, and storehouse for small machines and tools required for general plant maintenance.

For the convenience of the large number of workmen a welfare building was built between the hot and cold mills to provide shower baths, washing basins, and individual lockers for the workmen. This building is steel brick construction, with glazed tile interior; covered walkways have been provided between this building and the various departments for the convenience of the workmen.

As the steel industry has developed, electricity has played an increasingly important part in the production of steel. Thus, with the large investment in the modern strip mill, it becomes most important that provision be made to supply adequate power with minimum interruption to service.

The power for this strip mill is supplied from 3 different sources over 6 lines from 2 different directions. The main source of supply is number 5 substation (figure 5). This station is located approximately 600 feet east of the hot-mill motor room, and consists of a 2-bay outdoor high-voltage switching structure, 56 feet by 80 feet. This station is fed from the power company over 2 3-phase 25-cycle 60,000-volt lines, each rated at 40,000 kva. These lines pass through this structure and continue to another substation feeding the main plant.

Each of the power company's lines occupy one bay of the high-voltage structure and with the use of a cross bus and tie switch, it is possible to feed this station from either or both of these lines. The structure is designed to accommodate 2 15,000-kva 60,000/6,600-volt 25-cycle 3-

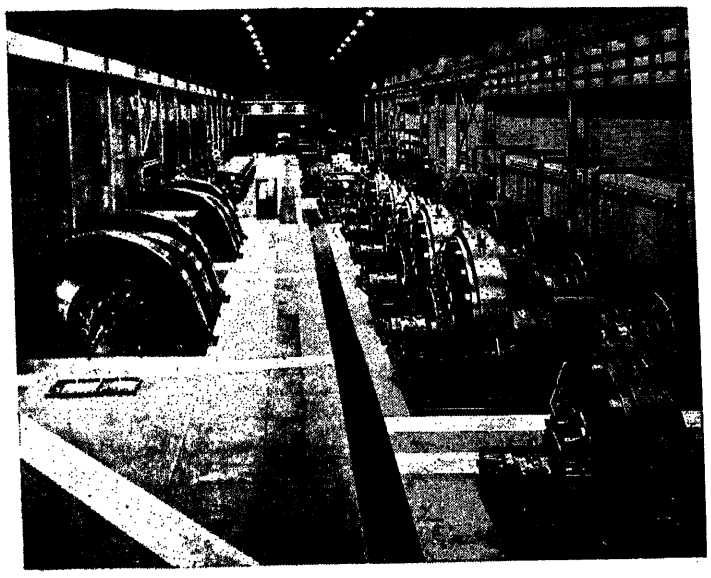

**Figure 6. General view of motor room**

phase water-cooled banks of transformers, one of which is installed at present.

A secondary bus structure, 20 feet deep by 40 feet long, is provided to accommodate the bus work, oil switch on the secondary side of the transformer, and the disconnect switches on the outgoing lines. Provision is made to add a duplicate secondary structure for the future bank of transformers.

The secondary bus structure and the towers between the substation and the motor room are designed for 6 500,000-circular-mil circuits, 4 of which are installed at present. These lines are tied to the secondary bus of the transformers through 1,200-ampere high-pressure-contact outdoor disconnect switches and 2 circuits are paralleled on the other end to feed the motor-room bus through a 1,200-ampere 500,000-kva metal-clad oil circuit breaker.

The 2 power company lines that pass through station number 5, continue to the main plant to feed station number 3 through 2 400-ampere 1,000,000-kva oil circuit breakers. This station is very similar in design to station number 5, including the cross bus and transformer layout for 2 15,000-kva 60,000/6,600-volt 3-phase 25-cycle air-cooled banks of transformers, both of which are installed and operating. Space is available at this station for the installation of a third 15,000-kva bank, duplicate of above. This station is located about one mile north of the strip mill, with a 6,600-volt tower line connecting the substation with the mill, designed for 4 500,000-circular-mil circuits, 2 of which are installed at the present time. Each line is tied to the substation bus through a 1,200-ampere 25,000-volt outdoor-type oil circuit breaker and each is tied to the motor-room bus through a 1,200-ampere 500,000-kva metal-clad oil circuit breaker.

(Figure 6) this is a general view of the motor room with the d-c motors driving the finishing mill in the right foreground, the 2 1,500-kw auxiliary motor-generator sets in the right center, and the 6,600-volt a-c roughing-mill induction motors in the right background. The 2 6,000-kw motor-generator sets driving the finishing-mill motors are shown in the left foreground and the 6,600-volt metal-clad bus structure in the left center.

This metal-clad bus structure consists of 22 high-speed 1,200-ampere 500,000-kva oil switches, complete with sealed-in bus compartment. A 250-volt storage battery is located in the basement to provide closing and tripping power for these switches.

The main bus in this metal-clad structure is separated into 2 parts which are tied together through a 2,000-ampere nonautomatic 500,000-kva oil circuit breaker. The incoming lines from number 3 substation feed into the west end of this bus and the incoming lines from number 5 substation feed into the east end of this bus. The roughing-mill induction motors, the 3 cold-mill motor-generator sets, and one of the auxiliary motor-generator sets feed off the west bus and the finishing-mill motor-generator sets, auxiliary transformers, spray pumps, and one of the auxiliary motor-generator sets feed off the east bus. The normal operation of the power system is to have the east and west busses tied together with the lines from both number 3 and number 5 substations operating in parallel.

The bus at number 3 substation that feeds the 2 500,000-circular-mil lines to the strip mill is tied in with a 25,000-kva generating station through the plant network.

The roughing-mill motors driving number 1 scale breaker and stands numbers 1 to 4, inclusive, are 6,600-volt 3-phase 25-cycle induction motors equipped with automatic liquid slip regulators for starting and regulating the load, with the exception of the 1,000-horsepower squirrel-cage motor driving number 1 scale breaker, which starts across the line. Each motor has 6 leads brought out of the stator, with current transformers ahead of the motor and in the neutral for differential protection.

These motors are stopped by applying direct current to the motor windings, which results in a modified form of

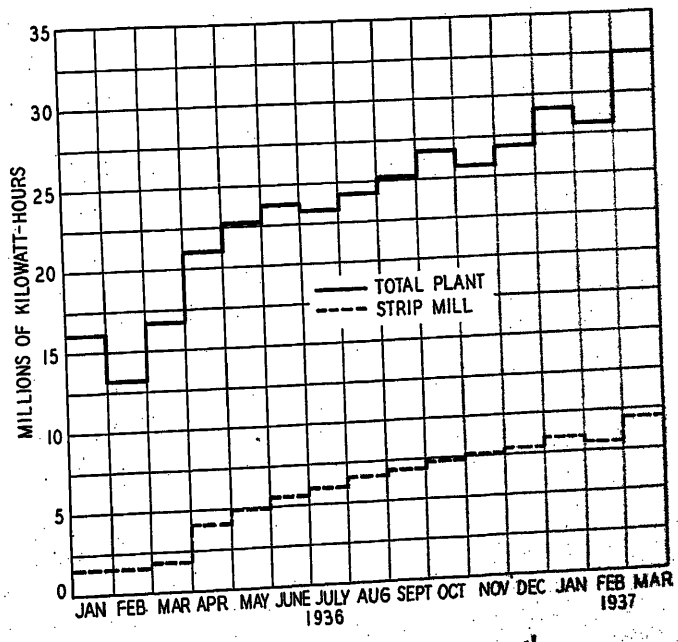

**Figure 7. Kilowatt-hours per month**

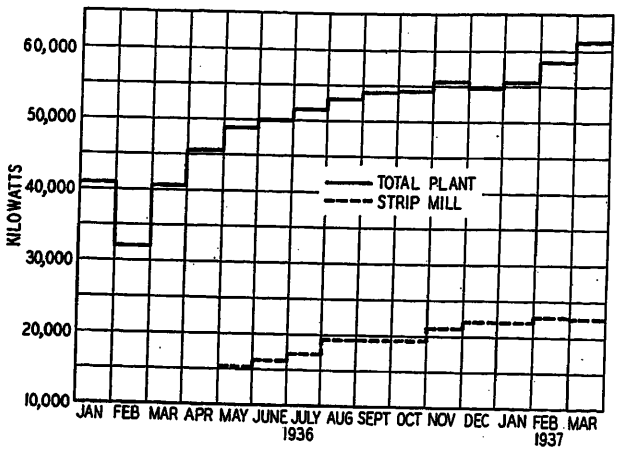

**Figure 8. Maximum 15-minute demands**

dynamic braking. The ratings of these motors are as follows:

| | | | |
|---|---|---|---|
| Number 1 scale breaker | 1,000 horsepower | Squirrel cage | 375 rpm |
| Number 1 stand | 3,000 horsepower | Wound rotor | 150 rpm |
| Number 2 stand | 3,000 horsepower | Wound rotor | 500 rpm |
| Number 3 stand | 3,000 horsepower | Wound rotor | 500 rpm |
| Number 4 stand | 3,000 horsepower | Wound rotor | 500 rpm |

Number 1 stand has a flywheel mounted on the motor shaft and numbers 2, 3, and 4 stands have 2 flywheels mounted on the pinion shaft of the gear unit.

The 600-volt direct current, to operate the finishing-mill motors, is supplied by 2 6,000-kw motor-generator sets, each set consisting of one motor and 2 generators. The motor driving these sets is a 7,200-kva 6,600-volt 3-phase 25-cycle 375-rpm synchronous motor, connected for differential protection, the same as roughing-mill induction motors. The motors are started through the 1,200-ampere metal-clad switchgear and are brought up to speed as an induction motor, the current being limited by the starting reactor to 165 per cent in terms of normal rating. At approximately 90 per cent speed, a light field is applied to the motor to pull the machine in step with proper polarity on field poles. After the machine pulls into step, the reactor is shorted out of the circuit, placing the machine across the line, and at the same time full field is applied. The d-c generators are rated 3,000-kw 600-volt d-c continuous rated, open, compensated, shunt wound, separately excited with 250 volts, direct current.

The 4 generators feed into a common bus, from which, the 7 d-c finishing-mill motors and the variable-frequency motor-generator sets obtain their power. The ratings of these motors are as follows:

| | | | |
|---|---|---|---|
| Number 2 scale breaker | 1 | 500 horsepower | 150/600 rpm |
| Numbers 5, 6, 7 stands | 3 | 3,500 horsepower | 175/300 rpm |
| Numbers 8, 9 stands | 2 | 4,500 horsepower | 125/250 rpm |
| Number 10 stand | 1 | 2,500 horsepower | 175/350 rpm |

making a total connected load of 22,500 horsepower for finishing stands.

These 22,500 horsepower of d-c motors, together with the 4 3,000-kw generators, form an extremely heavy concentration of d-c power on the 600-volt d-c bus. In the case of a short circuit on this bus, there would be developed a current in the nature of 300,000 amperes, which would produce an estimated separating force of several tons per running foot for ordinary bus spacing. Since the force is inversely proportional to the distance between the busses, this installation was made with busses placed at several times normal spacing. The positive and negative busses were placed on opposite sides of the bus room, to give this wide spacing. Aluminum channel, placed back to back, was used to increase the lateral stiffness and in addition, the bus was firmly braced against the walls of the room. Each motor and generator and the 600-volt bus to the variable-frequency room are tied to the main bus through 2 single-pole high-speed d-c circuit breakers, incorporating the "rate of rise" feature of instantaneous trip on direct short circuits. These breakers are located in both the positive and negative legs of each machine and spaced on opposite sides of the room each being firmly braced to the back walls. This entire construction of bus, circuit

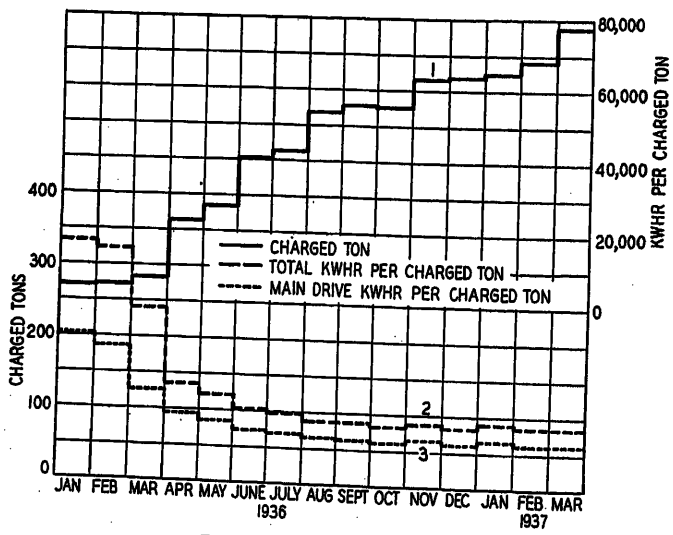

**Figure 9. Hot-strip mill**

breakers, and feeder bus was designed to withstand heavy short-circuit stresses.

The d-c motors and generators are connected to the bus at zero voltage and motors brought up to speed by building up the generator voltage by the use of a motor-operated potentiometer rheostat. Each individual motor is adjusted to the required speed by weakening or strengthening the field of the motor with the use of a motor-operated coarse rheostat and a hand-operated vernier rheostat, both located in the mill pulpit *C*, from which point the finishing-mill motors are controlled. Six meters, calibrated in horsepower, are located in the face of *C* pulpit, in view of the roller, to indicate load on the 6 finishing stands.

A great deal of heat is generated through the heavy loads imposed on the main drive equipment. To dissipate this heat a recirculating system of ventilation is provided. The finishing-mill motor foundations are so arranged that all 6 motor pits are connected with each other forming a tunnel, closed on each side and open at the ends. The 2 6,000-kw motor-generator sets, located

directly across the room have a similar layout in the foundation arrangement. The rotating motors and generators pick up cool, clean air in the motor room by their natural fan action, which ventilates the machines and is then discharged into the foundation tunnel. At each end of these 2 foundation tunnels is a surface cooler through which the heated air from the machines must pass, to be recooled to normal temperature. A blower is located near the discharge of each of these coolers, the sucking action of which draws the air through the coolers and discharges it into the motor room for recirculation. As the 4 blowers are not connected direct to the coolers, any one of the units can be shut down without affecting the coolers. Under normal operation the blowers operating depends upon the temperature in the motor room. To offset air losses, as well as to maintain a slight positive pressure in the motor room, makeup fans are provided at each end of the room. These fans draw fresh air from the outside, through a filter cleaning equipment and discharge it into the motor-room basement.

The 2 hydraulic spray pumps are driven by 2 1,000-horsepower 6,600-volt wound-rotor induction motors, the pumps deliver 1,000 gallons per minute at 1,000 pounds pressure to the spray nozzles.

The cold-mill substation contains the motor-generator sets and auxiliary units for driving the tandem and skin pass mills. A 3-unit 6,000-kw motor-generator set, duplicate of the hot-mill main drive sets, is provided to furnish 600-volt direct current to the 76-inch tandem mill from one generator to the 54-inch tandem mill from the other generator. A 2,500-kw motor-generator set driven by a 3,750-horsepower 6,600-volt synchronous motor, direct connected to 2 1,250-kw 600-volt generators, furnishes power to the 2 76-inch skin pass mills. A 1,300-kw motor-generator set driven by a 2,000-horsepower 6,600-volt synchronous motor, is direct connected to 3 generators. Two of these generators are 500-kw 300-volt capacity and one generator is 300-kw 250-volt capacity. The 2 500-kw generators are normally connected in series to provide 600 volts to drive the 90-inch skin pass mill. However, they can be connected in parallel to provide emergency 250-volt direct current for plant auxiliaries at reduced capacity. The 300-kw generator furnishes power to drive the 54-inch skin pass mill. The ventilating scheme of the substation is duplicate of the hot-mill motor room, described earlier in this paper.

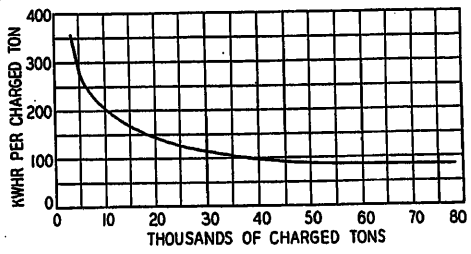

**Figure 10. Hot-strip mill**

A bus tunnel is provided to connect the cold mill substation with the various cold-mill control rooms, which are located in the basement. The top of this tunnel houses the bus runs between the generators and the tandem and skin pass mill motors and the tunnel proper is used to provide makeup air for the ventilation of the cold-mill drive motors. The makeup air equipment consists of an air washer and blower located at the end of the tunnel, the blower discharging into the tunnel to maintain a slight positive pressure in the tunnel and control rooms. Each of the cold-mill drive motors has its own recirculating ventilation system, taking air from the tunnel, circulating it through the motors and coolers to discharge into the tunnel again. In this manner, each motor is cooled with fresh clean air.

The d-c auxiliary power for both hot and cold mill is supplied by 2 1,500-kw motor-generator sets, each driven by a 2,100-kva 6,600-volt 500-rpm 80-per-cent-power-factor synchronous motor with 250-volt d-c field excitation from the d-c end. The motor is designed for full-voltage starting, requiring 500 per cent kilovolt-ampere inrush, in terms of normal rating. The generator is rated 1,500 kw at 250 volts, and is self-excited and flat compound wound. The 2 generators are arranged to operate in parallel, but only one set is required to furnish both hot- and cold-mill power.

The 2 1,500-kw generators tie into the 250-volt bus through 2 8,000-ampere single-pole 600-volt air circuit breakers, each equipped with overload, under voltage, and reverse-current features. The d-c power is fed into the various sections of both hot and cold mill over 6 feeder circuits, each connected to the bus with a 4,000-ampere single-pole 600-volt air circuit breaker with inverse time overload protection.

The a-c auxiliary power is supplied by 3 1,000-kva 6,600/440-volts ingle-phase 25-cycle air-cooled transformers connected delta-delta. The power is distributed to the mill over 3 3-phase circuits, each protected with a 1,600-ampere 3-pole 600-volt air circuit breaker.

The entire lighting for the mill is supplied by a bank of 3 500-kva 6,600/440-volt single-phase 25-cycle air-cooled transformers, connected delta-delta. The primary side of this bank is connected in parallel with the primary side of the power transformers, and both are fed through a common oil circuit breaker from the station bus. The

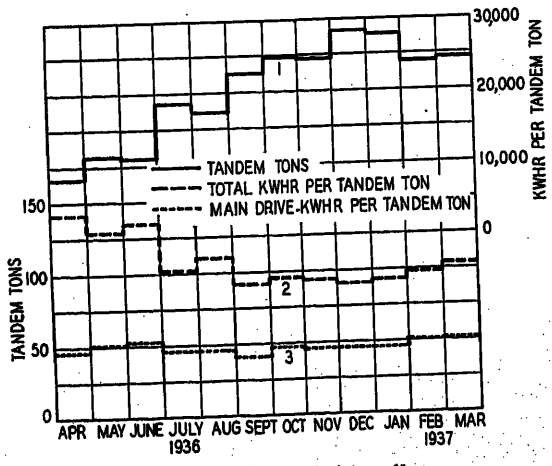

**Figure 11. Cold mill**

secondary side of this bank feeds through a 4,000-ampere 3-pole 600-volt air circuit breaker, to the various distribution points throughout the mill. At these points, the 440-volt power is stepped down to 3 phase, 110-volts, through $7\frac{1}{2}$- and 10-kva single-phase oil-insulated air-cooled transformer banks, to sectionalized 110-volt feeder circuits.

The overhead lighting consists of 300 porcelain-enamel reflectors, 225 silver-backed glass reflectors with steel covers, and 450 prismatic glass reflectors with spun-on steel covers. All of these units are of the high-bay type of 750 watts capacity. The low-bay lighting, control house and pulpit lighting, and various scattered units, consists of over 700 units, varying in capacity from 50 to 500 watts. The tunnel lighting consists of 220 units, built into the side walls, each of 200 watt capacity.

### Summary of 6,600-Volt Connected Load

| | Kilovolt-Amperes |
|---|---|
| Number 1 scale breaker | 860 |
| Number 1 stand | 2,650 |
| Numbers 2, 3, 4 stands | 7,260 |
| Finishing mill—motor-generator sets | 14,400 |
| Spray pumps | 1,640 |
| Auxiliary motor-generator sets | 4,200 |
| Cold-mill motor-generator sets (1) | 7,200 |
| (2) | 3,110 |
| (3) | 1,660 |
| Power transformers | 3,000 |
| Lightning transformers | 1,500 |
| Total | 47,480 |

### Summary of Total Connected Horsepower

| | Number | Horsepower |
|---|---|---|
| Motors—hot mill | 1,407 | 81,550 |
| Generators—hot mill | 24 | 23,850 |
| Total—hot mill | 1,431 | 105,401 |
| Motors—cold mill | 514 | 35,050 |
| Generators—cold mill | 18 | 13,675 |
| Total—cold mill | 532 | 48,725 |
| Total installed units | 1,963 | 154,126 |

All of the above units are controlled by 350 2-pole 60-ampere 110-volt circuit breakers with overload protection, enclosed in cast iron case. These breakers are fed from the sectionalized 110-volt lighting busses.

To give a more comprehensive picture of the power requirements of this hot- and cold-strip mill, the following curves have been plotted to graphically show the relation between the kilowatt-hours, the kilowatt demand, and tons charged.

(Figure 7) top curve shows the kilowatt-hours consumed by the total Lackawanna plant for 1936 and the first quarter of 1937, including the strip mill, while the bottom curve shows kilowatt-hour consumption of the strip mill alone for the same period. The top curve shows the gradual increase in kilowatt-hours for the total plant from 13,200,000 kilowatt-hours in February 1936 to 32,578,000 kilowatt-hours in March 1937 and corresponding to this increase in total energy consumed, the strip mill, starting in January 1936, used 1,600,000 kilowatt-hours, gradually increasing to 9,256,000 kilowatt-hours in March 1937, or approximately 28.4 per cent of the total plant power, which averages 1,050,000 kilowatt-hours per day.

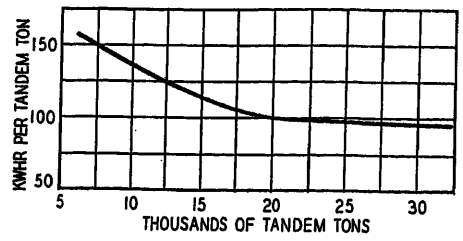

**Figure 12. Cold mill**

Figure 8 shows the maximum 15-minute monthly demand for the total plant and the maximum 15-minute monthly demand for the hot- and cold-strip mill. The total plant demand has increased from 32,000 kw in February 1936 to 61,140 kw in March 1937. The maximum demand for the strip mill has gradually increased from 15,000 kw in May 1936, the first month that the demand meter was installed, to 22,680 kw in March 1937. This demand has gradually increased with the increase in tonnage rolled.

(Figure 9) curve 1 on this graph represents the charged tons which have gradually increased from 4,000 tons, the first month of rolling, to 77,800 tons in March 1937. Curve 2, showing total kilowatt-hours per charged ton, has gradually decreased from 333 to 85 kilowatt-hours per ton. Curve 3 shows the kilowatt-hours per charged ton for the main drive, and represents that part of the total power used by the main drive motors, and the difference between curves 2 and 3 represent that part of the total power used by the auxiliary equipment. The main drive equipment uses approximately 75 per cent of the total power and the auxiliary equipment uses approximately 25 per cent.

Figure 9 shows that the total kilowatt-hours per ton remains approximately constant above 55,000 tons. However, below 55,000 tons, the curve begins to rise at an increasingly rapid rate. Figure 10 shows a curve plotted between charged tons and kilowatt-hours per charged ton and confirms the above statement.

In analyzing the tandem tons rolled in the cold mill, (figure 11), it will be noted that the total kilowatt-hours per ton, curve 2, has decreased from 143 to 92, as the tandem tons, curve 1, increased from 8,000 to 28,000 tons. Further, it will be noted that the kilowatt-hours per ton for the main drive equipment remained almost constant at 49 kilowatt-hours per ton, while the variation in total kilowatt-hours per ton to the mill occurred in the auxiliary drive equipment. The cold-mill main drive equipment uses approximately 53 per cent of the total energy and the auxiliaries, approximately 47 per cent, and the kilowatt-hours per ton for the cold mill remain almost constant above 22,000 tons, but rises sharply as the tonnage decreases. Also, the curve in figure 12, plotted between tandem tons and kilowatt-hours per tandem ton, flattens out at 22,000 tons, indicating approximately a constant value of kilowatt-hours per ton above this tonnage.

# Some High Lights in the Use of Electricity in Steel Mills

By GORDON FOX
MEMBER AIEE

## Synopsis

Approximately one tenth of the investment in the American steel industry is in electrical plant. The power consumption of steel mills is increasing. About two thirds of the power used is generated within the plants but there is a trend toward increased purchase of power.

Electricity is gaining a foothold in the field of transportation through the Diesel-electric locomotive.

D-c motors are being used more for main-roll drives. Synchronous motors are also gaining favor. Reversing drives have developed interesting ramifications.

There is a trend toward subdivision of main roll drives. The combination of reduction gears and mill pinions into a single unit is of interest. The use of new types of bearings affects power requirements.

The concentration of d-c power associated with the main-roll drives of wide strip mills has introduced problems concerning interrupting capacity of circuit breakers and strength of bus installations.

In the field of auxiliary drives, the increased application of small individual induction motors is notable.

Electrical precipitation finds greater acceptance in the field of gas cleaning.

Electric melting furnaces supply a small but growing increment of total steel production. High-frequency heating is finding some uses. New types of electric furnaces are being installed for heat treating and annealing operations.

NOT SO MANY years ago electricity played but a minor part in the steel industry. It has gained rapidly and steadily in importance. Today, in a total investment on the order of $5,000,000,000 represented by the American steel industry, more than $500,000,000 is involved in electrical plant. Considering a typical steel plant as a whole, about 10 per cent of the total investment is electrical.

The relationships between electrical plant and total investment are indicated by the approximate figures shown in table I.

The cost of materials is the major element in the cost of producing steel. The cost of electric power is a minor element. In the iron- and steel-producing departments, the cost of electric power is generally not more than 5 per cent of the total conversion cost. In the rolling mills, the cost of electric power commonly amounts to about 10 to 15 per cent of the conversion cost. Although relatively a minor item, in an absolute sense the amount of electric power consumed and the cost thereof are substantial figures.

The installed capacity in main-drive motors in American steel mills is nearly 3,000,000 horsepower. The capacity of main and auxiliary drives combined approaches 8,000,000 horsepower. The installed generating capacity driven by prime movers amounts to about 1,250,000 kw. The present annual power consumption of the industry is about 7,000,000,000 kilowatt-hours. All American public utilities combined generated in 1934 about 95,000,000,000 killowatt-hours.

The rate of power consumption of American steel mills is increasing for several reasons:

1. Mills are becoming more fully electrified.
2. New applications of electricity are being developed.
3. The character of product is changing.

In 1926, about 20 per cent of the rolled product was represented by heavy sections such as rails and structurals, which involve only a moderate amount of work per ton due to moderate elongation in rolling. The total power represented in a ton of rails is about 100 kilowatt-hours. Today less than 15 per cent of the finished product leaves the mills in these heavy shapes.

Such products as sheets, strip, tin plate, and wire rod require relatively large amounts of power for rolling. A ton of sheets or rods may represent an accumulated expenditure of more than 200 kilowatt-hours of power. In 1926, about one third of the product took these forms. Today about two thirds is so rolled.

Approximately two thirds of the power consumed in our steel plants is generated in their own power plants. About one third is purchased from utilities.

The figures for 1929 are approximately as follows:

| | |
|---|---|
| Electric power purchased from public utilities | 3,500,000,000 kilowatt-hours |
| Electric power generated by prime movers in steel plants | 6,000,000,000 kilowatt-hours |
| Total use of electric power | 9,500,000,000 kilowatt-hours |

Table I

| Unit or Department | Per Cent Investment Represented by Electrical Plant |
|---|---|
| Coke ovens, blast furnaces, and steel making (open hearths) | 5 |
| Mills, average | 15 |
| Power and blowing plant | 25 |
| Total plant average | 10 |
| Modern wide strip mill (hot) | 25 |
| (cold) | 10 |
| (total) | 20 |

A paper recommended for publication by the AIEE committee on applications to iron and steel production. Manuscript submitted November 25, 1936; released for publication July 19, 1937.

GORDON FOX is vice-president of the Freyn Engineering Company, Chicago, Ill.

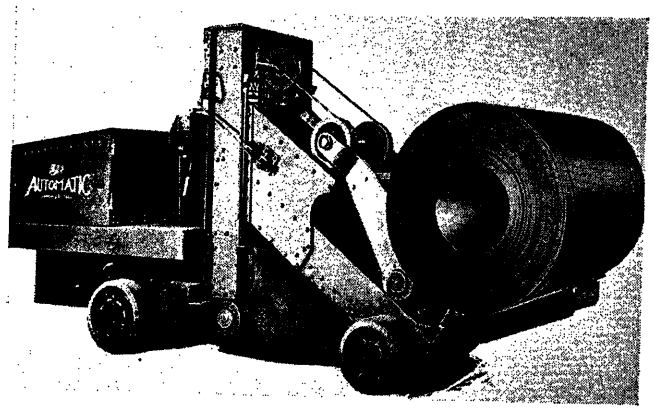

**Figure 1. Industrial truck handling 8-ton coil of strip**

The steel industry is probably the largest industrial consumer of electric power. However, because of the large amount of power generated in its own plants, it is only on an approximate par with 3 other industries as a purchaser of electric power from utilities. The big four are the steel industry, chemical industry, food products, and printing.

The trend, in the steel industry, is toward purchase of a greater amount of power, both in absolute and in relative sense. Three factors which encourage this trend may be mentioned:

1. Large increases in power demand are generally associated with installation of heavy mill equipment involving large expenditures. Additional simultaneous investment for power generating plant may be undesirable.

2. The increase in power consumption per ton of rolled product results in a decrease in the amount of available by-product fuels relative to the power load. Moreover, by-product fuels are being diverted to process uses where they are more valuable. The availability of by-product fuels for power generation is decreasing both in relative and in absolute sense. Hence, power generation must be based, in increasing degree, upon purchased fuel.

3. The utilities are encouraging power purchase through more reliable supply and through development of contracts suited to the special requirements of the steel mills.

4. The applications of electricity in steel mills are so varied in character and have so many ramifications that it is possible, in a brief discussion, to touch upon only a few features, selected somewhat at random, but with a view to developments of recent years.

## Modernization of Generating Stations

A number of steel plants have taken steps toward modernization of their existing power plants, involving the installation of new high-pressure boilers and topping turbine generators exhausting into the existing steam mains. This practice has permitted modernization of boiler plants, increase in generating capacity, and improvement in economy to be accomplished at minimum expense. The resulting plants compare favorably in performance with those of the public utilities.

## Steam Drives

Although electrification in steel plants is very general, steam drive is still retained for a few classes of equipment. Most notable are coke-oven exhausters and gas boosters and blast-furnace blowers. Exhausters are steam driven because of the nicety of speed regulation required, and because the exhaust steam is needed for process uses. Gas boosters are quite large units, well suited in speed requirement to turbine drive. Centrifugal blast-furnace blowers continue to be driven by steam turbines because of ease and perfection of speed control and also because they excel, both in over-all economy and in first cost, any method of electric drive yet proposed. Moreover, involving less steps of transformation, they are more reliable than would be motor-driven units supplied by turbine generators.

In the Buffalo district, where power is exceptionally cheap, a motor-driven centrifugal blast furnace blower has been installed. The drive is a 2-pole synchronous motor. Control of pressure and volume is by a device, termed a power wheel, which throttles the inlet pressure by means of a set of adjustable vanes somewhat akin to the vanes of a water wheel. The velocity imparted to the intake air in throttling is partially converted into power in the first stage of the compressor intead of being dissipated in eddies, as by an ordinary damper. Good regulation of volume is obtained. The equipment is quite simple. The efficiency is comparable with that which might be obtained with a wound-rotor motor drive using secondary resistance control.

## Transportation

Another field in which electricity has not made great inroads is that of transportation. There are a few individual runs in steel plants where electric locomotives or cars are employed. Both overhead and third-rail systems are represented. But there is, I believe, no steel plant in this country which has a completely electrified transport system. The principal deterrent rests in the

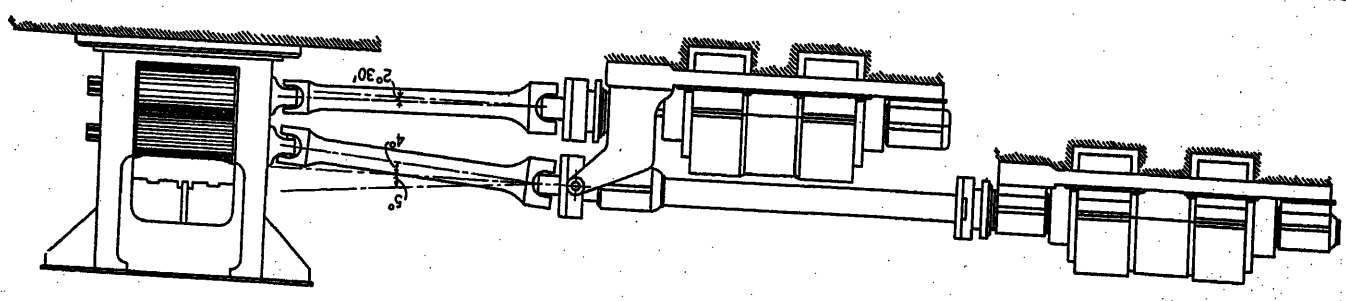

**Figure 2. Twin-motor reversing drive**

ections to either overhead or third-rail systems of ply.

The Diesel-electric locomotive has made its debut in the l plant, where it is used for switching purposes. It is tively high in first cost but it is faster in operation and operating costs and maintenance costs are substanly lower. For some classes of service its use appears to well warranted.

There has recently been put into service at one of the nts in the Chicago district a gas-electric locomotive ton, 500 horsepower) using butane as fuel. This unit broadly comparable in first cost with the gasolinetric unit and comparable in operating cost with the esel-electric type.

Another field of transportation in which electricity is ying an important part is the industrial truck. These cks are finding considerable use in the finishing departnts of strip mills and wire mills, for instance. Storagettery units and so-called "ready power" units employing gasoline-engine-driven generator as the power source are th popular. Figure 1 shows a truck handling one 8-ton il of strip.

## onnected Load and Power Consumption

In a typical steel plant the large main-drive motors at e rolling mills represent less than half of the total inalled motor capacity. They have a higher load factor an the auxiliary drive motors, however, and are therere responsible for a greater relative share of the power nsumption. Table II shows typical relationships.

D-c auxiliary drives are used mostly on cranes, roller bles, and manipulating devices which are subject to

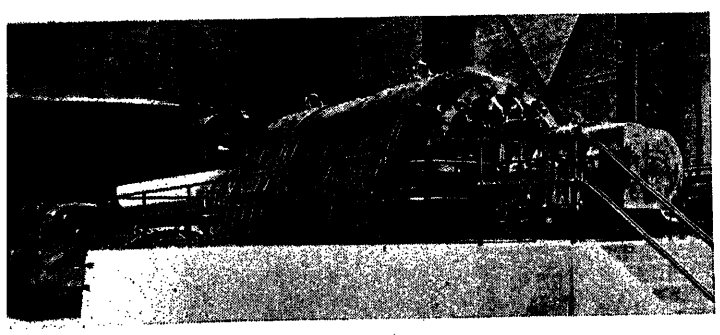

**Figure 3. Twin-motor reversing drive**

much starting and stopping, but which have substantial dle periods. Their load factor is very low. A-c auxiliries include many pumps, fans, conveyors, and similar ontinuously running drives. Their load factor is quite igh.

## The Trend in Main-Roll Drives

Over a period of years, the application of motors to main-roll drives has changed in a number of respects. The changes are more or less interrelated but may be discussed separately.

Formerly the a-c motor prevailed. Today the d-c motor holds foremost place. In 1928, about 40 per cent of the main roll drive motors sold were for alternating current, 60 per cent were for direct current. In 1936, only 13 per cent were a-c motors and 87 per cent were d-c motors.

D-c main-drive motors are being so generally adopted because of their controllability, as for reversing drives, and because of their ability to meet adjustable-speed requirements. Adjustable speed is more and more commonly

**Table II. Motor Capacity and Motor Load—Typical Steel Plant**

| Class of Motors | Per Cent of Total Installed Capacity | Per Cent of Total Motor Load |
|---|---|---|
| Main-roll drives | 37 | 55 |
| D-c auxiliaries | 50 | 20 |
| A-c auxiliaries | 13 | 25 |

demanded, partly for reasons of flexibility and greater precision of rolling, partly because of higher rolling speeds, and partly because more modern continuous and semicontinuous types of mills, with stands in tandem, introduce requirements which were not met in the earlier layouts using Belgian roll trains.

There has been a trend toward individually driven roll stands or subdivision into small groups as contrasted with the older practice in which one or two large motors drove a whole mill. Some of the reasons have been higher speeds, greater capacities, greater operating flexibility, greater flexibility of layout, mechanical simplification.

In a-c drives, there has been a trend away from the induction motor and toward the synchronous motor as will be discussed at greater length a little later.

In general, the trend has been in such direction as to increase greatly the cost of main roll drive equipment.

## Reversing Drives

Reversing motors have been used for many years to drive blooming mills, roughing mills, plate mills. Somewhat more recent is their application in tandem on slabbing mills and beam mills. In a slabbing mill, for instance, 2 sets of rolls work on the piece simultaneously. The horizontal rolls reduce its thickness; the vertical rolls restrict or reduce its width. These 2 sets of rolls are driven by separate reversing motors. These motors must accelerate, run, decelerate, and reverse in unison. The relative speeds must be different in the forward and in the reverse direction of travel. This is accomplished by feeding both motors from the same generator or generators, using variable-voltage control. The relative speed of the vertical roll motor is changed, for the 2 directions of travel, through change of the field strength of that motor.

There are installed in one plant in the Chicago district 2 very interesting reversing motor drives designated as double motor drives. Each roll in the 2-high reversing

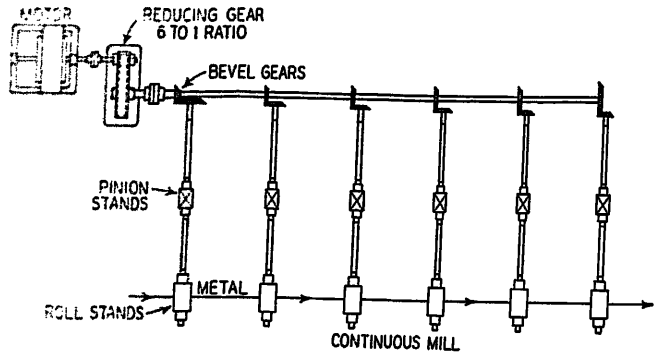

**Figure 4. Group drive through lay shaft and bevel gears**

mill is driven by a separate 5,000-horsepower motor. The driving spindle for the upper roll passes over the motor which drives the lower roll. The use of the twin motor is dictated, in a large measure, by mechanical considerations. The construction of a 10,000-horsepower motor at 40 rpm base speed within limits of size feasible for transport and erection, would be difficult. The manufacture of suitable mill pinions would also be difficult. The twin motor affords substantial advantage due to its relatively low inertia, resulting in a "lively" mill. It eliminates the necessity of matching roll diameters. Omission of the pinions reduces friction losses and eliminates a source of back-lash and noise.

It has long been customary to employ Ilgner-type motor generator sets for supplying direct current to reversing motors. Flywheels were provided. To drive these sets, wound-rotor induction motors were used, in conjunction with liquid slip regulators. This is still the accepted practice for blooming mills, slabbing mills, sheared plate mills, etc., where the load is heavy and passes are short and of brief duration and the load is consequently very peaked. In a few recent instances a synchronous motor has been substituted for the wound-rotor motor of the set and the flywheel has been omitted. This practice is only feasible for mills having relatively long passes. Even then the power fluctuations are so severe that they can be permitted only on a large power system. Where applicable, the synchronous motor drive has advantage in first cost, efficiency, power factor, and sustained speed as well as in greater simplicity.

A relatively new field for reversing drives is found in both hot and cold strip mills. These mills involve not alone the main reversing motor, but also the drives for the coiling reels upon which the strip is alternately wound and unwound as the mill reverses its direction of rolling. The reel motors must reverse and the speed must increase and decrease in unison with speed changes of the main reversing motor; in addition, they must compensate automatically for the varying diameter of the coil as it builds up or runs off the reel.

## Synchronous Motors

Ten years ago there were very few synchronous motors in use in the steel industry. They were applied only to drive motor-generator sets and for occasional pumps or blowers. Today they are widely used for main roll drives. Perhaps more commonly they are applied to groups of stands. In many instances, however, they drive single stands. In very few instances are the starting requirements of main roll drives difficult for synchronous motors to meet. More exacting, perhaps, are the severe peak loads of brief duration sometimes experienced. The synchronous motor is now the normal selection for constant-speed main roll drives except where flywheels are required. Incidentally it may be remarked that flywheels are not now used as generally as they once were.

An interesting application of synchronous motors is that in which stands or pairs of stands in tandem, in continuous relationship, are driven by separate motors. The synchronizing power of the motors causes the rolls in the several stands to retain their speed relationship as effectively as if they were driven from a common line shaft. Figure 4 shows the former prevalent practice, employing a single drive motor with line shaft and bevel gears.

Figure 5 shows the newer practice employing subdivided drive and herringbone gearing.

The number of synchronous motors connected to steel-plant systems is increasing, not alone because of their more frequent use for main roll drives and for driving accessory equipment but also because of the great increase in motor-

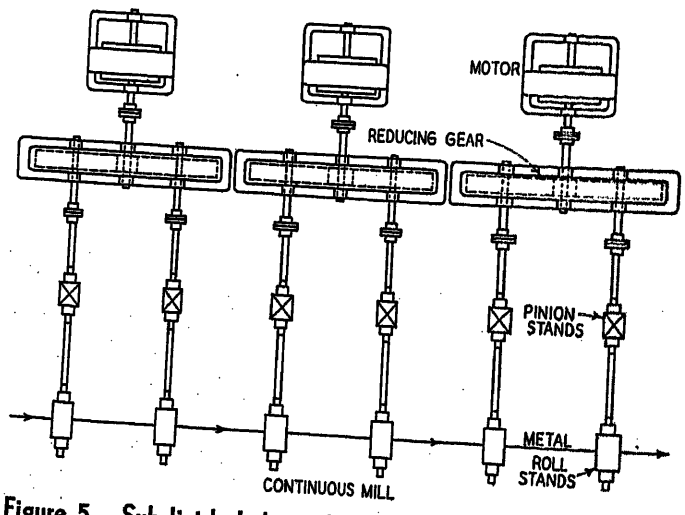

**Figure 5. Subdivided drive through helical or herringbone gears**

generator capacity occasioned by the increased adoption of adjustable-speed d-c drives.

Most of the synchronous motors initially used in steel mills were rated on 80-per-cent-power-factor basis. They were overexcited and were utilized for power-factor correction. Due to the substantial increase in synchronous equipment in use, the need for power-factor correction has diminished. It is not desirable to operate 80-per-cent-power-factor motors with much less than their full excitation lest they be deficient in pull-out torque. Hence, more motors rated on 90- to 100-per-cent-power-factor basis are being selected.

## D-C Drives

Adjustable speed is being provided to an ever-increasing extent for main roll stands. The d-c motor at 600 volts is practically standard for this service. Figure 6 shows a 4,500-horsepower 125/250-rpm motor of this type such as is applied to the finishing stands of a hot wide strip mill. This is representative of the maximum size attained by motors of this type. These motors are usually started by connecting them at standstill to the supplying generator or generators at zero voltage, then building up the voltage as the motors accelerate. Because of the large motor capacities involved, it is usually necessary to operate several generators in parallel to supply the direct current. Several schemes have been tried to obtain satisfactory parallel operation of these generators and, at the same time, to secure a closely maintained operating voltage. One of these schemes involved interconnected cumulative and differential series windings. It is now prevailing practice to use simple shunt-wound generators or to provide a slight differential winding to give a drooping voltage characteristic, thereby insuring satisfactory parallel operation. Generators of this type may be paralleled at zero voltage. The voltage of all units may then be built up in unison, thereby starting all the driven motors at once. When the motors attain full speed, all is in readiness for rolling. It is no longer necessary to start the motors by building up the voltage of one generator and then to parallel with the other generators before the load is applied.

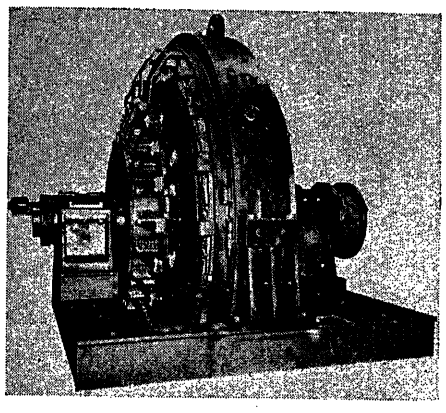

**Figure 6. Adjustable-speed d-c motor**

When generators with drooping voltage characteristics are employed, a voltage regulator is provided to maintain constant operating voltage. This functions in connection with an exciter which is common to the fields of all of the generators operating in parallel; see figure 7.

D-c reversing motor drives are an exception to this practice. When 2 or 3 generators are paralleled to supply a single reversing motor or combination of motors, interconnected differential and cumulative field windings are generally used to insure division of load among the generators, even under severe load changes; see figure 8.

## Cold-Rolling Mills

In final cold rolling of coils of annealed strip in a so-called skin pass, it is advantageous to maintain tension upon the piece while it is being compressed between the main rolls. It is also desirable that different amounts of tension be independently maintained in the process of unwinding the coil from one reel and in winding it upon another reel. In a recent design of skin pass mills, pinch rolls are installed between the unwinding reel and the mill stand being entered; a similar pair of pinch rolls is located on the delivery side of the mill ahead of the reel upon which the coil is wound. These pinch rolls are controlled to maintain the most advantageous drag and pull tensions in the strip on the entering and delivery sides of the main rolls. The unwinding and winding reels, in turn, are controlled to maintain suitable values of drag and pull tension in the strip between these respective reels and the adjacent pinch rolls.

These tensions are governed by field control responsive to current, which determines the tension. The speed of the mill as a whole can be varied, without disturbing the relationships of the individual elements, by variation of the voltage of the generator which supplies all drives in common.

The ability to control the tension as well as the rolling pressure appears to be an important contribution to the art of cold rolling steel.

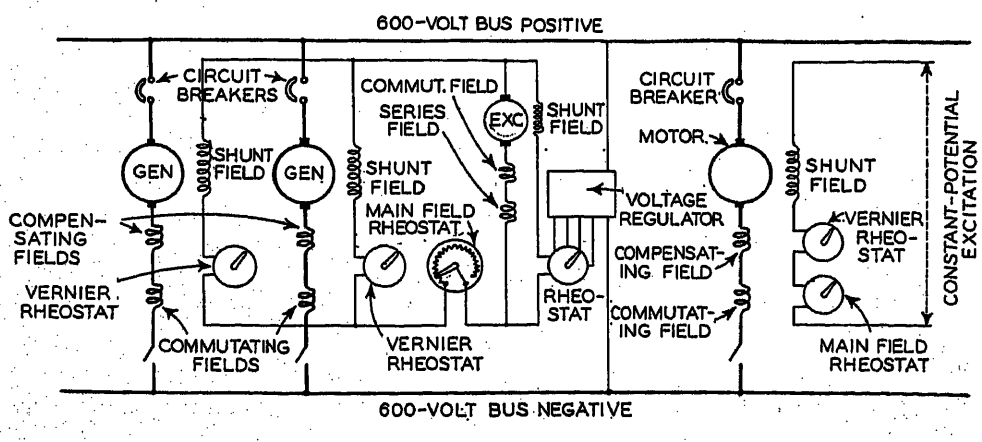

**Figure 7. Parallel operation of shunt generators supplying adjustable-speed motors**

## Combination Gear and Pinion Stands

While discussing main roll drives, mention should be made of recent practice in which the motor speed reducing gear or the train of helical or herringbone gears, through which the motor drives, is combined with the mill pinions in a single unit. Such an arrangement results in compactness and rigidity.

## Bearings

As a development affecting motor drive practice, we should mention the increasing use of roller bearings, composition bearings, and precision type oil-lubricated bearings in connection with mill rolls. These bearing types have resulted in reductions of rolling power in amounts ranging from 10 to 50 per cent, depending upon the type of mill, the product being rolled, and the particular conditions of the case.

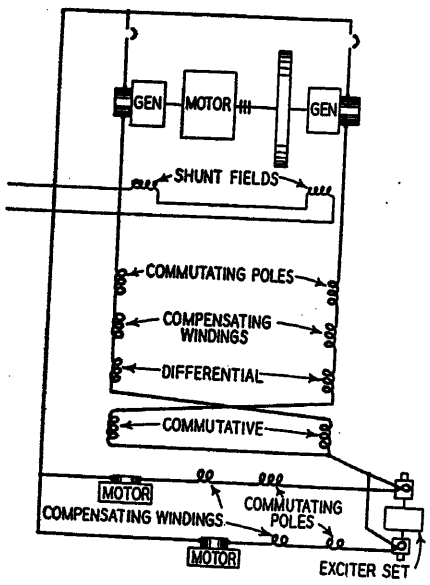

**Figure 8. Parallel operation of cumulative - differential compound-wound generators**

## Concentrations of D-C Power

Wide strip mills usually have about 6 finishing stands, each individually driven by a motor of 2,000- to 4,000-horsepower capacity. This is a substantial aggregation of motors. See figure 9. The combined full-load rated current on a common bus connecting such a group of generators and motors may be on the order of 30,000 to 40,000 amperes. Perhaps 15,000 kw of d-c generators will be connected to such a bus. The motors may total the equivalent of 20,000 kw. Due to their flat regulation characteristics, these motors can and will act as generators almost instantly. In the event of a short circuit on such a system, the amount of fault current which can flow is tremendous. It amounts to several hundred thousand amperes, and experience, in the matter of damage done, indicates that it has plenty of wrecking ability. Very substantial bus construction using structural shapes is essential. The positive and negative busses are well separated to minimize magnetic stresses. Circuit breakers must be reinforced to prevent being bent out of shape by magnetic forces. Circuit breakers have been recently developed for this work which, under test, have ruptured successfully 70,000 amperes of direct current (as much as it is possible to provide for test purposes). These circuit breakers have ruptured successfully under test as much as 400,000 amperes at 60 cycles. The time of interruption is about 3 cycles.

An interesting development in connection with these large circuit breakers is a feature which causes them to trip particularly quickly in case the rate of increase of current is rapid, as when a severe short circuit occurs. This is accomplished in the following manner: The section of bus connecting to the circuit breaker is divided into 2 parallel paths. One path is surrounded by a laminated steel yoke. The series trip coil of the circuit breaker is interlinked with the other path. Normally the current flows equally or proportionally through the 2 paths. Only a portion of the current through the breaker passes through and acts upon its trip coil. However, when a short circuit occurs and the current rises quickly, most of the current flows through the low reactance path which is not surrounded by the steel yoke. As a consequence of this action, most of the current flowing through the breaker passes through and acts on its trip coil and causes it to trip more quickly than it would in the case of gradually applied load of equal value.

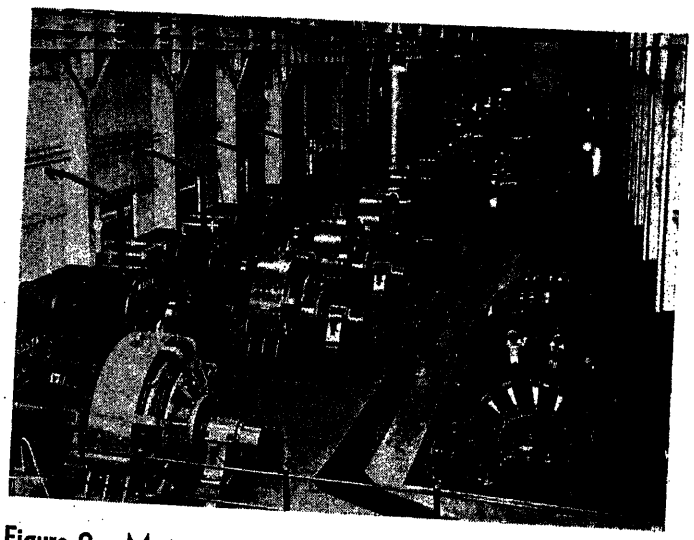

**Figure 9. Motor room, wide strip mill, Youngstown Sheet and Tube Company**

## Auxiliary Drives

It has long been the practice to equip the main tables, side guards, manipulator and screw-down mechanisms of blooming mills with mill-type motors and magnetic controllers supplied from a 230-volt d-c system. In a recent installation, individual generators are provided to supply

the respective drives and Ward-Leonard variable voltage control is employed. This arrangement results in somewhat faster action together with closer speed control over a wider range. Since approximately half of the total rolling time of such a mill is consumed in reversing and manipulating the ingot between passes, expedition of these functions may have an appreciable influence upon output. This is increasingly true in view of the higher percentage of slabs now being rolled in many such mills.

A notable recent development in auxiliary drives is the extensive application of individual small squirrel-cage induction motors to table rollers, coilers, sheet mill lifting tables. In a single mill recently constructed there are some 900 of these motors; see figure 11.

For individual table-roller drives, the adjustable-frequency system of speed control is commonly employed. The table drive motors are supplied from a-c generators which, in turn, are driven by adjustable speed d-c motors. A speed range of 3 or 4 to 1 is common.

In some cases it is necessary that these tables reverse frequently. If the table drive motors were plugged from full speed, they would draw very heavy currents from the generators supplying them and they would also overheat due to the large rotor losses incident to plugging. To avoid these difficulties, the table-drive motors are first

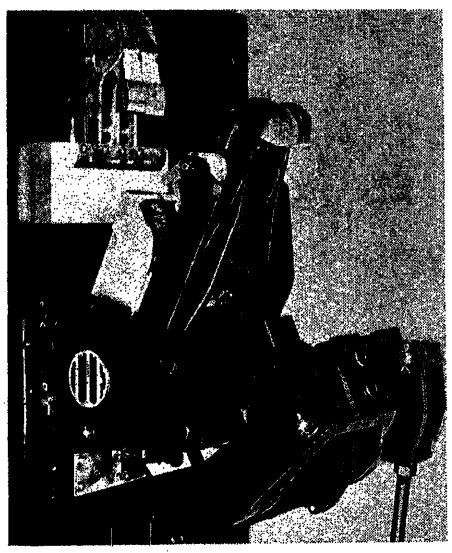

**Figure 10. D-c circuit breaker**

slowed down by reducing the frequency to a low value. They are then plugged, from low speed in one direction to low speed in the other direction. They are then accelerated by increasing the frequency. By this means most of the deceleration and acceleration of the table drive motors takes place with the motors operating with running characteristics, that is, with small values of slip. Only during a small part of the reversing cycle do the motors operate with starting characteristics, that is, with large values of slip.

In the operation of the coilers, the mechanisms which coil the flat product emanating from a wide strip mill, frequent starting and stopping is involved. The coilers are not reversed but it is desirable to stop them quickly and accurately. The simplest possible mechanism involves the use of several separate motors of small horsepower; see figure 12. The most successful control to meet these requirements employs dynamic braking. The motors are of squirrel-cage induction type. They are supplied with power at adjustable frequency in the general manner previously described. To stop them, the frequency is first reduced, then the primary windings are disconnected from the a-c supply, and direct current at low voltage is applied to these windings. This direct current is obtained from a small motor-generator set.

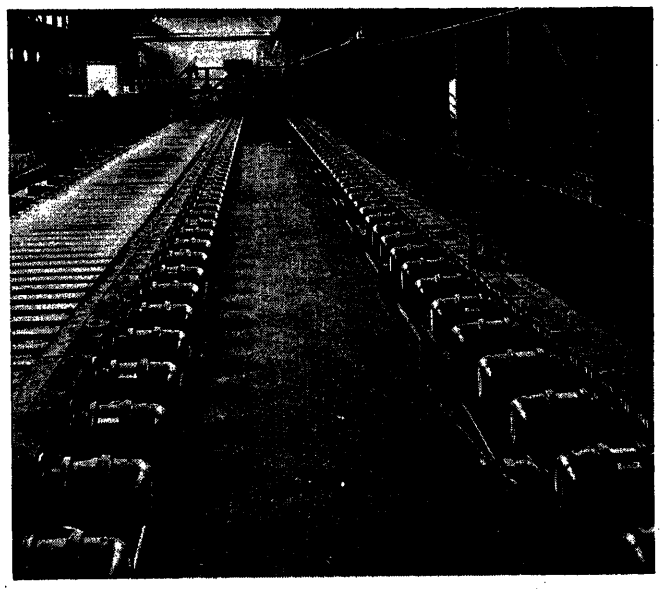

**Figure 11. Individual roller-table drives**

## Water-Cooled Motor

Small induction motors have been applied to a number of drives which involve very frequent starting, stopping, and reversing. The load is comprised largely of inertia. Squirrel-cage motors can be made with very light rotors. When 40 starts per minute, or perhaps more, are involved, it becomes quite a problem to dissipate the heat generated in the motor. To use a larger motor does not help much since the rotor inertia increases and the load increases likewise. For such cases a water-cooled motor has been developed and tried with considerable success; see figure 13.

## A-C Switching

Many steel plants have been confronted with problems in distribution and in switching, due to the rapid growth of their a-c systems. In some cases the increased use of synchronous motors has been a factor in increasing the current to be handled in case of short circuit.

In some cases the difficulties have been accentuated by the advent of purchased power from utilities. Because of

the substantial amounts of purchased power involved and the desire for economy and reliability of supply, the connection between the utility generating capacity and the steel plant consuming system is usually a fairly direct one. Consequently the flow of power in case of a fault may be great. It then becomes necessary to employ generally switching equipment of high rupturing capacity, or to devise compromises using group breakers or reactors in order that existing equipment may be safely continued in service.

In general, it may be said that the switching now being installed is of much higher rupturing capacity and substantially higher cost than in the past. The scheme of distribution and switching to be adopted is therefore deserving of increased consideration.

The advent of deionizing and oil-expulsion types of circuit breakers has been timely in permitting higher rupturing capacities to be attained within existing limitations of space and reasonable limitations of cost. In this connection, it may be mentioned that the high cost of switching has stimulated the use of fewer relatively larger

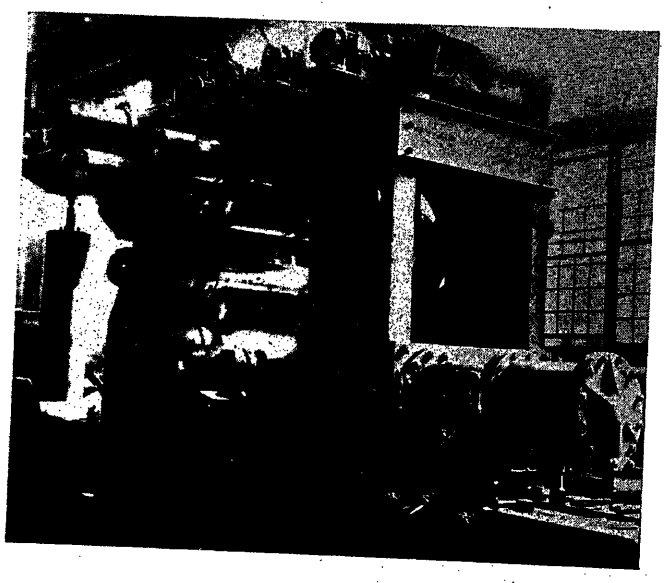

Figure 12. Individual drives for coilers

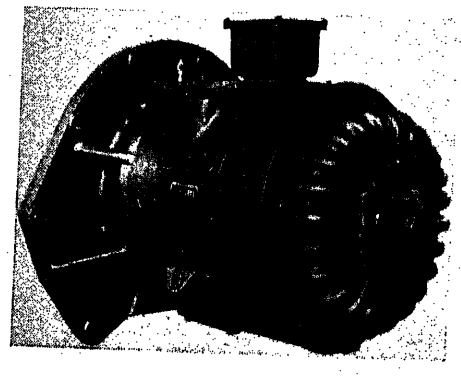
motor-generator sets and the use of 3-unit sets in which one synchronous motor drives 2 d-c generators.

## Mercury-Vapor Rectification

The first installation of a 250-volt rectifier with grid-control of voltage has recently been made in a steel mill in the Chicago district. The output is used for general d-c supply to wire drawing machinery and auxiliaries.



## Electrical Precipitation

Among the newer uses of electricity in the steel mill, electrical precipitation deserves mention. This method has been successfully applied to the removal of tar from coke oven gas. There are now a number of precipitators applied to cleaning blast furnace gas. Attempts to clean this gas in the hot, dry state, preserving its sensible heat, have indicated this method to be too expensive and too sensitive to be generally acceptable. Precipitation has proved to be moderately successful as a method of fine cleaning following wet scrubbing. One deterrent to its more general adoption is the rather high cost of necessary plant.

## Electric Furnaces

Electric melting furnaces and electric heating furnaces are both gaining in popularity. The amount of steel produced in electric furnaces for ingot production is a small percentage of total production. Nevertheless the percentage tends to show steady growth, as indicated by the following figures showing the relationship of the tonnage of ingots produced by electric furnaces as a per cent of total ingot tonnage:

Figure 13. Water-cooled motor

| | |
|---|---|
| 1922 | 0.55 per cent |
| 1924 | 0.61 per cent |
| 1926 | 0.70 per cent |
| 1928 | 0.90 per cent |
| 1930 | 0.78 per cent |
| 1932 | 1.05 per cent |
| 1934 | 1.35 per cent |

Sizeable installations are now being made of electric arc furnaces of the top-charged type for the melting of scrap for production of carbon steels in small ingot sizes. These furnaces involve a substantial increase over previous practice in the ratio of transformer capacity to furnace volume.

The application of high-voltage air-break (deionizing) circuit breakers for electric arc furnace service, involving frequent circuit interruption, is deserving of mention.

The coreless induction furnace is earning recognition as one of the tools of the industry. This furnace comprises essentially an insulated crucible surrounded by a cylindrical coil of copper tubing. Through this coil, current at high frequency is passed, inducing currents in the charge in the crucible. The primary or inducing coil is water-cooled.

This type of furnace is essentially a single-phase load. The frequencies used range up to 5,000 cycles per second,

but 960 cycles is a typical value. The voltage is usually about 1,000 volts. The power factor is inherently very low but is largely corrected by use of capacitors. Due to the high frequency, the cost of these capacitors is not excessive. Power of these characteristics is supplied by special motor-generator sets. The consumption ranges between 600 and 1,000 kilowatt-hours per ton of metal, being comparable with arc furnaces of similar size.

As yet the coreless induction furnace has been built only in small sizes, having capacity of one ton or less. It

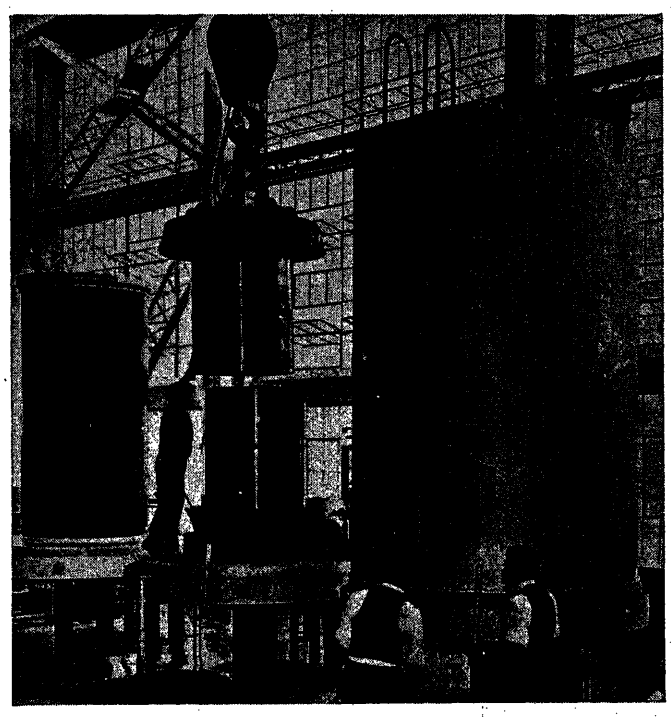


**Figure 14. Bell-type cylindrical annealing furnace**

is probable that larger units will be developed. The principal advantages of this type of furnace are:

1. Freedom of contamination of the charge (absence of electrodes).
2. Very high temperatures attainable since heat is internally generated.
3. Uniformity of analysis and rapid refining due in part to electromagnetic circulation of the charge which brings it into contact with the slag.
4. Ability to melt scraps containing alloys without oxidizing and losing these alloys in the melting process.

The coreless induction furnace is applied principally to production of steels of very low carbon content (such as some magnetic steels); highly refractory alloy melts; tool steels and heat-resisting alloys such as iron, nickel, chromium alloys.

High-frequency heating is being applied to a few lower temperature heating operations, such, for instance, as local annealing at circumferential pipe welds. Development of this field of electrical heating lies ahead of us.

Electric heating for annealing and heat treating operations gains steadily in prominence. Although bulk heat in electrical form is relatively expensive, advantages leading to better product often more than compensate. Better control, better furnace insulation, more advantageous and uniform heat application, less weight of auxiliary equipment heated—these are principal advantages.

Electric heating furnaces take a great variety of forms. Figure 14 shows a recent application of cylindrical bell-shaped furnaces for annealing coiled strip.

Electric heating is being adopted for some controlled-atmosphere furnaces. It is desirable that neither free air nor products of combustion be permitted to contact the metal being heated. The electric resistance furnace is inherently well suited since it is easily made externally gas tight. The direct, unmuffled heat tends to be most uniform and may be distributed to afford favorable temperature gradients for heat flow.

## Electronic Control

While the amount of power used in electronic devices is negligible, they are being adapted and adopted for steel-mill use, and are performing some important control functions. One of the most general applications involves the use of photoelectric tubes for the determination of temperatures of steel during the rolling process, and for such indications as the temperatures of furnace walls or roofs.

There are other interesting electrical devices which, though small in size, are important in function. Among these should be mentioned the so-called selsyn devices for remote indication or for synchronized angular movements. The "thrustor," which utilizes a centifugal oil-pump to translate the rotary motion of a small motor into linear motion with considerable force, is finding numerous applications in the steel mill. Lifting magnets have been modified to dispose the poles and the flux more advantageously for special applications, such as handling coiled strip.

Electricity is being applied in the field of measuring and regulating devices. Sensitive electromagnet gauges are being utilized for determining with extreme accuracy the thickness of strip by continuous gauging while rolling. Strain gauges are being inserted in mill housings to measure minutely their stretch, and thereby to indicate rolling pressures. Tension rolls are being installed between the stands of tandem cold-rolling mills to indicate the tension on the piece between stands and to control the drive motors of the respective stands to maintain advantageous tension. Small winches driven by torque motors are being applied to the continuous measurement of the depth of burden in blast furnaces. These are but a few examples.

I hope that this incomplete and abbreviated résumé of high lights in the use of electricity in the steel industry will give to those of you who are not familiar with the steel mills, a glimpse of the wide range of problems which confront the steel mill electrical engineer. To those of you within the industry, I trust that this review may have suggested some new and useful slant at your every-day tasks. Of one thing we may be sure, namely: there is much that is new yet ahead.

# Two-Reaction Theory of Synchronous Machines With Any Balanced Terminal Impedance

By C. CONCORDIA
MEMBER AIEE

## Introduction

R. H. PARK[1,2,3] has presented a general analysis of salient-pole synchronous machines* in terms of direct, quadrature, and zero axis quantities. This analysis is very well adapted to the case of a machine with balanced series inductance and resistance in the armature circuit, but requires modification for any other terminal impedance. S. B. Crary[4] has recently extended the method of Park to include the effects of balanced armature circuit capacitance. In the present paper the same method of analysis is further extended to include the effects of *any* balanced impedance network connected to the armature terminals. Every concept (impedance operators, per-unit quantities, $d$ and $q$ axis quantities, etc.) of the previous synchronous machine theory is preserved unchanged in this extended theory, and every problem solvable by the previous theory is now susceptible to an exactly similar solution in the extended case. Such problems are, e.g.: 3-phase short circuit, sudden application or change of load, self-excitation, asynchronous operation, hunting, pulling into step, any prescribed change of field or armature voltage, torque under any of the conditions given above.

Application of the present theory has been made to the determination of the regions of self-excitation occurring in induction and synchronous machine circuits containing series capacitors. This is described in a related paper.[6]

## Results

The results of the analysis may be stated as follows: First let

$$\begin{aligned} e_d - p\psi_d + ri_d + \psi_q(p\theta) &= D \\ e_q - p\psi_q + ri_q - \psi_d(p\theta) &= Q \\ e_0 - p\psi_0 + ri_0 &= N \end{aligned} \tag{1}$$

where $D = 0$, $Q = 0$, $N = 0$ are recognized as the 3 equations 8, 9, 10 of reference 2.

Next let the voltage of phase $a$ due to the external network be

$$z_{11}i_a + z_{12}i_b + z_{13}i_c \tag{2}$$

with similar expressions for the voltages of phases $b$ and $c$. For any balanced, 6-terminal network containing inductances, resistances, and capacitances connected in any arbitrary way there is, by ordinary circuit theory,

$$\begin{aligned} z_{ii} &= w(p)/y(p) \\ z_{ij} &= v(p)/y(p) \end{aligned} \tag{3}$$

for $i, j = 1, 2, 3$; $i \neq j$ where $w(p)$, $v(p)$, $y(p)$ are polynomials in the operator $p$. For example, let

$$\begin{aligned} w(p) &= d_0 + d_1p + d_2p^2 + \dots \\ v(p) &= c_0 + c_1p + c_2p^2 + \dots \\ y(p) &= b_0 + b_1p + b_2p^2 + \dots \end{aligned} \tag{4}$$

Further, let

$$\begin{aligned} u(p) &= w(p) - v(p) = a_0 + a_1p + a_2p^2 + \dots \\ n(p) &= w(p) + 2v(p) = e_0 + e_1p + e_2p^2 + \dots \end{aligned}$$

Then it may be shown that the general equations of a machine, to the terminals of which the balanced impedance has been connected, are

$$\begin{aligned} &b_0D + a_0i_d + p(b_1D + a_1i_d) - (p\theta)(b_1Q + a_1i_q) + \\ &\quad [p^2 - (p\theta)^2](b_2D + a_2i_d) - [2(p\theta)p + (p^2\theta)](b_2Q + a_2i_q) + \\ &\quad [p^3 - 3(p\theta)^2p - 3(p\theta)(p^2\theta)](b_3D + a_3i_d) - \\ &\quad [3(p\theta)p^2 + 3(p^2\theta)p - (p\theta)^3 + (p^3\theta)](b_3Q + a_3i_q) + \\ &\quad [p^4 - 6(p\theta)^2p^2 - 12(p\theta)(p^2\theta)p + (p\theta)^4 - 3(p^2\theta)^2 - 4(p\theta)(p^3\theta)] \times \\ &\quad (b_4D + a_4i_d) - \\ &\quad [4(p\theta)p^3 + 6(p^2\theta)p^2 - 4(p\theta)^3p + 4(p^3\theta)p - 6(p\theta)^2(p^2\theta) + (p^4\theta)] \times \\ &\quad (b_4Q + a_4i_q) + \dots = 0 \end{aligned} \tag{5a}$$

$$\begin{aligned} &b_0Q + a_0i_q + p(b_1Q + a_1i_q) + (p\theta)(b_1D + a_1i_d) + \\ &\quad [p^2 - (p\theta)^2](b_2Q + a_2i_q) + [2(p\theta)p + (p^2\theta)](b_2D + a_2i_d) + \\ &\quad [p^3 - 3(p\theta)^2p - 3(p\theta)(p^2\theta)](b_3Q + a_3iq) + \\ &\quad [3(p\theta)p^2 + 3(p^2\theta)p - (p\theta)^3 + (p^3\theta)](b_3D + a_3i_d) + \\ &\quad [p^4 - 6(p\theta)^2p^2 - 12(p\theta)(p^2\theta)p + (p\theta)^4 - 3(p^2\theta)^2 - 4(p\theta)(p^3\theta)] \times \\ &\quad (b_4Q + a_4i_q) + \\ &\quad [4(p\theta)p^3 + 6(p^2\theta)p^2 - 4(p\theta)^3p + 4(p^3\theta)p - 6(p\theta)^2(p^2\theta) + (p^4\theta)] \times \\ &\quad (b_4D + a_4i_d) + \dots = 0 \end{aligned} \tag{5b}$$

$$b_0N + e_0i_0 + p(b_1N + e_1i_0) + p^2(b_2N + e_2i_0) + \dots = 0 \tag{5c}$$

or the zero-sequence equation may be written as

$$y(p)N + n(p)i_0 = 0 \tag{5d}$$

The derivation of these general equations is given in the appendix. Equations 5 may be used directly in place of equations 8, 9, 10 of reference 2 to determine the transient performance of a synchronous or induction machine with any connected balanced network.

## Discussion

It may be shown that equations 5 yield all the previous results as special cases. For example, if there is no external impedance, all the constants $a$, $c$, $d$, $e$ are zero, while

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted March 13, 1937; released for publication July 22, 1937.

C. CONCORDIA is in the engineering division of the central station department, General Electric Company, Schenectady, N. Y.

* It is assumed that the reader is completely familiar with the first 4 of the references given at the end of the paper.

1. For all numbered references, see list at end of paper.

$b_0$ may be any constant number. Then equations 5 reduce to

$$\begin{aligned} D &= 0 \\ Q &= 0 \\ N &= 0 \end{aligned} \tag{6}$$

which are exactly Park's equations.[2] Similarly, if there is series capacitance in the armature circuit,

$$\frac{w(p)}{y(p)} = \frac{x_c}{p}, \frac{v(p)}{y(p)} = 0$$

so $d_0 = a_0 = e_0 = x_c$, $b_1 = 1$, while all other constants vanish. Then equations 5 reduce to

$$\begin{aligned} x_c i_d + pD - (p\theta)Q &= 0 \\ x_c i_q + pQ + (p\theta)D &= 0 \\ x_c i_0 + pN &= 0 \end{aligned} \tag{7}$$

which are exactly Crary's[4] equations.

The present analysis has been restricted to the case of balanced circuits. This is because the balanced case is the only one for which the use of $d$, $q$, 0 axis quantities offers any simplification in the actual solution of problems. In all cases of operation with unbalanced impedances in the armature circuit, e.g., unbalanced faults, the phase quantities should be used directly. The phase voltage equations are given in the appendix and the expressions for phase flux linkages in terms of phase currents are given in equations 10, 11, 12 of reference 1 or equations 2 of reference 2. From the point of view of the practical engineer one reason for the use of $d$, $q$, 0 axis quantities is that such use results in the formulation of his problem as a set of linear differential equations with constant coefficients. These equations may be simply solved by the ordinary operational methods with which he is familiar. However, when the armature impedances are not balanced the machine voltage equations have variable coefficients regardless of the co-ordinate system used. Thus, it is usually simpler in such cases to use phase quantities for voltage, flux, and current; on the other hand the machine impedances should *always* be expressed along the $d$ and $q$ axes.

For a large class of problems the armature and its connected circuits may be treated as operating in the steady state and only the rotor circuit transients need be considered. This form of treatment is the basis of the practical utility of the definitions of transient and subtransient reactances and is analytically equivalent to the neglect of the $p\psi$ terms of the voltage equations. It is obvious that when the armature circuits are in steady state operation the presence of any connected impedance does not complicate the fundamental equations, and equations 6, with $p\psi = 0$, will apply to any case of balanced armature impedance. From this point of view the exact equations derived here are seen as a refinement and need be used only for exceptional cases. However, in these exceptional cases the refinement is all-important, as entirely misleading and useless results may be obtained without it. Such, e.g., was the case in the calculation of the regions of self-excitation in references 4 and 6.

## Examples

1. Suppose the external impedance is simply a balanced series self- and mutual inductance and resistance, the phase $a$ voltage being

$$(r_s + pl_s)i_a - pm_s(i_b + i_c) \tag{8}$$

then

$$\begin{aligned} w(p) &= r_s + l_s p \\ v(p) &= -m_s p \\ y(p) &= 1 \end{aligned}$$

Therefore,

$$\begin{aligned} a_0 &= r_s, & a_1 &= (l - m), & a_2 &= 0, & \ldots \\ e_0 &= r_s, & e_1 &= (l + 2m), & e_2 &= 0, & \ldots \\ b_0 &= 1, & b_1 &= 0, & \ldots & & \end{aligned}$$

and by equations 5,

$$\begin{aligned} D + r_s i_d + p(l - m)i_d - (p\theta)(l - m)i_q &= 0 \\ Q + r_s i_q + p(l - m)i_q + (p\theta)(l - m)i_d &= 0 \\ N + r_s i_0 + p(l + 2m)i_0 &= 0 \end{aligned} \tag{9}$$

It is evident that these equations may be reduced at once to the elementary form

$$\begin{aligned} D' &= e_d - p\psi_d' + r' i_d + \psi_q'(p\theta) = 0 \\ Q' &= e_q - p\psi_q' + r' i_q - \psi_d'(p\theta) = 0 \\ N' &= e_0 - p\psi_0' + r' i_0 = 0 \end{aligned} \tag{10}$$

where the primed quantities are of the same nature as the unprimed quantities, and

$$\begin{aligned} r' &= r + r_s \\ \psi_d' &= \psi_d - (l - m)i_d \\ \psi_q' &= \psi_q - (l - m)i_q \\ \psi_0' &= \psi_0 - (l + 2m)i_0 \end{aligned} \tag{11}$$

2. Suppose the external circuit consists of an inductance coil (having also resistance) in parallel with a capacitor in each phase. Then

$$\frac{w(p)}{y(p)} = \frac{1}{\frac{1}{r_l + x_l p} + \frac{p}{x_c}} = \frac{x_c r_l + x_c x_l p}{x_c + r_l p + x_l p^2} \tag{12}$$

and

$$\frac{v(p)}{y(p)} = 0$$

Therefore

$$\begin{aligned} a_0 &= x_c r_l, & a_1 &= x_c x_l, & a_2 &= 0, & \ldots \\ e_0 &= x_c r_l, & e_1 &= x_c x_l, & e_2 &= 0, & \ldots \\ b_0 &= x_c, & b_1 &= r_l, & b_2 &= x_l, & b_3 = 0, \quad \ldots \end{aligned}$$

and by equations 5

$$\begin{aligned} &x_c D + x_c r_l i_d + p(r_l D + x_c x_l i_d) - (p\theta)(r_l Q + x_c x_l i_q) + \\ &\quad [p^2 - (p\theta)^2]x_l D - [2(p\theta)p + (p^2\theta)]x_l Q = 0 \\ &x_c Q + x_c r_l i_q + p(r_l Q + x_c x_l i_q) + (p\theta)(r_l D + x_c x_l i_d) + \\ &\quad [p^2 - (p\theta)^2]x_l Q + [2(p\theta)p + (p^2\theta)]x_l D = 0 \\ &(x_c + r_l p + x_l p^2)N + (x_c r_l + x_c x_l p)i_0 = 0 \end{aligned} \tag{13}$$

These equations may be used to determine the transient performance of, e.g., a synchronous machine supplying an open-circuited transformer and shunt capacitor. In many

cases it will be possible to neglect the transformer resistance, thus effecting a considerable simplification.

3. Let the external *inductance* be zero in the previous case. Then

$$\begin{aligned} x_c D + x_c r i_d + p r_l D - (p\theta) r_l Q &= 0 \\ x_c Q + x_c r i_q + p r_l Q + (p\theta) r_l D &= 0 \\ (x_c + r_l p) N + x_c r i_0 &= 0 \end{aligned} \tag{14}$$

These equations, when put in the form

$$\begin{aligned} \left(p + \frac{x_c}{r_l}\right) D + x_c i_d - (p\theta) Q &= 0 \\ \left(p + \frac{x_c}{r_l}\right) Q + x_c i_q + (p\theta) D &= 0 \\ \left(p + \frac{x_c}{r_l}\right) N + x_c i_0 &= 0 \end{aligned} \tag{15}$$

are seen to be of exactly the same form as Crary's[4] equations but with $p$ replaced by $(p+x_c/r_l)$ wherever it operates on the elementary functions $D$, $Q$, $N$. Putting the resistor in shunt with the capacitor thus does not complicate the problem but only introduces the ratio $x_c/r_l$ where $r_l/x_c$ may be interpreted as the time constant of the resistor-capacitor circuit considered by itself.

## Appendix I

1. We first derive Park's equations in their original form from the phase equations.

We have

$$e_a - p\psi_a + r i_a = 0 \tag{16}$$

with 2 similar equations for phases $b$ and $c$. There are also the 9 transformation equations (equations 14, 15, 16 of reference 2).

$$a = i_d \cos\theta - i_q \sin\theta + i_0, \text{ etc.} \tag{17}$$

Substitute 17 in 16 and obtain

$$\begin{aligned} &e_d \cos\theta - e_q \sin\theta + e_0 - \\ &\quad p(\psi_d \cos\theta - \psi_q \sin\theta + \psi_0) + r(i_d \cos\theta - i_q \sin\theta + i_0) = 0 \end{aligned}$$

Perform the indicated differentiations and segregate the coefficients of the trigonometric functions.

$$\begin{aligned} &[e_d - p\psi_d + r i_d + \psi_q(p\theta)] \cos\theta - \\ &\quad [e_q - p\psi_q + r i_q - \psi_d(p\theta)] \sin\theta + \\ &\quad [e_0 - p\psi_0 + r i_0] = 0 \end{aligned} \tag{18}$$

By combining equation 18 with the 2 similar equations for phases $b$ and $c$ it may be shown that the coefficients of 18 must be separately equal to zero. Then,

$$\begin{aligned} e_d - p\psi_d + r i_d + \psi_q(p\theta) &= 0 \\ e_q - p\psi_q + r i_q - \psi_d(p\theta) &= 0 \\ e_0 - p\psi_0 + r i_0 &= 0 \end{aligned} \tag{19}$$

which are the familiar stationary axis equations.

2. Now suppose there is connected to the terminals of the machine a balanced impedance network containing inductances, resistances, and capacitances connected in any manner. The network may be represented by the operational expression $w(p)/y(p)$ where $w(p)$, $y(p)$ are polynomials in $p$ as shown in equations 4. Equations 16 are now replaced by

$$e_a - p\psi_a + r i_a + \frac{w(p)}{y(p)} i_a = 0 \tag{20}$$

If the impedance network has, in addition, mutual effects which cannot be eliminated by the use of an equivalent circuit there is also a mutual impedance $v(p)/y(p)$ where $v(p)$ is a polynomial as shown in equation 4. Since the circuit is balanced all the mutual coefficients are the same. The phase $a$ voltage equation now becomes

$$e_a - p\psi_a + r i_a + \frac{w(p)}{y(p)} i_a + \frac{v(p)}{y(p)} (i_b + i_c) = 0 \tag{21}$$

By the substitution

$$i_b + i_c = 3i_0 - i_a \tag{22}$$

we obtain after clearing of fractions,

$$y(p)(e_a - p\psi_a + r i_a) + [w(p) - v(p)] i_a + 3v(p) i_0 = 0 \tag{23}$$

The result of the previous section for the special case of no external impedance can still be used now, i.e., expression 18 can be substituted directly for $(e_a - p\psi_a + r i_a)$ in 23. Then

$$\begin{aligned} &y(p)\{[e_d - p\psi_d + r i_d + \psi_q(p\theta)] \cos\theta - [e_q - p\psi_q + r i_q - \psi_d(p\theta)] \times \\ &\quad \sin\theta + [e_0 - p\psi_0 + r i_0]\} + [w(p) - v(p)](i_d \cos\theta - i_q \sin\theta + \\ &\quad i_0) + 3v(p) i_0 = 0 \end{aligned} \tag{24}$$

By equations 1

$$\begin{aligned} &y(p)(D \cos\theta - Q \sin\theta + N) + [w(p) - v(p)] \times \\ &\quad (i_d \cos\theta - i_q \sin\theta + i_0) + 3v(p) i_0 = 0 \end{aligned} \tag{25}$$

and by (4)

$$\begin{aligned} &(b_0 + b_1 p + b_2 p^2 + \ldots)(D \cos\theta - Q \sin\theta + N) + \\ &\quad (a_0 + a_1 p + a_2 p^2 + \ldots)(i_d \cos\theta - i_q \sin\theta + i_0) + \\ &\quad 3v(p) i_0 = 0 \end{aligned} \tag{26}$$

As before, perform the differentiations required to segregate the trigonometric coefficients.

$$\begin{aligned} &b_0(D \cos\theta - Q \sin\theta + N) + b_1[(pD) \cos\theta - D \sin\theta(p\theta) - (pQ) \sin\theta - \\ &\quad Q \cos\theta(p\theta) + pN] + \ldots + a_0(i_d \cos\theta - i_q \sin\theta + i_0) + \\ &\quad a_1[(pi_d) \cos\theta - i_d \sin\theta(p\theta) - (pi_q) \sin\theta - i_q \cos\theta(p\theta) + pi_0] + \\ &\quad \ldots + 3v(p) i_0 = 0 \end{aligned} \tag{27}$$

Again utilizing the result of the previous section, the coefficients of $\cos\theta$, $\sin\theta$, and the constant term are equated separately to zero. The result is the set of equations 5. These equations have been given explicitly for polynomials of up to the fourth degree in $p$, but further terms may be formed as indicated in equation 27. It is probable, however, that the mathematical complexity encountered will preclude the solution of the equations for polynomials of any higher degree and perhaps even for the fourth degree. It is therefore believed that the equations given are as complete as will be necessary for any practical case.

## Appendix II

### Nomenclature

The notation is in general the same as that of Park[1,2,3] and Crary.[4]

| | |
|---|---|
| $e$ | = armature voltage |
| $i$ | = armature current |
| $\psi$ | = armature flux linkage |
| $d, q, 0$ | = subscripts denoting direct-axis, quadrature-axis, and zero-sequence quantities, respectively |
| $p$ | = $d/dt$ |
| $r$ | = armature phase resistance |
| $\theta$ | = rotor angular displacement |
| $a, b, c$ | = subscripts denoting the 3 armature phases |
| $x_c$ | = capacitive reactance |

## Appendix III

In the last few years considerable interest has been shown in the application of tensor analysis to electrical engineering problems.[5] A derivation of the general equations of this paper in tensor symbolism is therefore appended below. It is believed that this form of derivation has the great virtue that, to one familiar with the notation, the principal and necessary steps of the derivation stand out clearly. That is, the main line of reasoning is not obscured by lengthy algebraic manipulations.

The voltage equations 21 in terms of phase quantities may be written as:

$$e + R \cdot i - p\psi + Z \cdot i = 0 \tag{28}$$

where $Z$ is the impedance tensor of the outside network having components specified by equation 3.

Now if voltage and current are expressed along the $d$, $q$, 0 axes by transforming $e$, $i$, $\psi$ by Park's transformation $C$, where $C$ is the tensor whose components are the coefficients of equations 14, 15, or 16 of reference 2, equation 28 becomes:

$$C \cdot e' + R \cdot C \cdot i' - pC \cdot \psi' + Z \cdot C \cdot i' = 0 \tag{29}$$

where the primed quantities are measured along the $d$, $q$, 0 axes.

By multiplying the first 3 terms of 29 by $C \cdot C^{-1}$, where $C^{-1}$ is the inverse of $C$, equation 29 becomes:

$$C \cdot P + Z \cdot C \cdot i' = 0 \tag{30}$$

where

$$P = e' + R \cdot i' - p\psi' - J \cdot \psi' p\theta \tag{30a}$$

$P$ is seen to be the expression which in Park's analysis is equal to zero. The tensor $J$ is

$$J = C^{-1} \cdot \frac{dC}{d\theta} = \begin{array}{|c|c|c|}\hline 0 & -1 & 0 \\ \hline 1 & 0 & 0 \\ \hline 0 & 0 & 0 \\ \hline \end{array} \tag{31}$$

The external impedance $Z$ may be expressed as

$$Z = \frac{1}{y(p)} A \tag{32}$$

where $A$ is the tensor whose elements are $a_{ii} = w(p)$, $a_{ij} = v(p)$ $i \neq j$. Then 30 becomes

$$y(p) C \cdot P + A \cdot C \cdot i' = 0 \tag{33}$$

But this may be expressed as

$$(b_0 + b_1 p + \ldots) C \cdot P + (A_0 + A_1 p + \ldots) \cdot C \cdot i' = 0 \tag{34}$$

where

$$A_0 = \begin{array}{|c|c|c|}\hline d_0 & c_0 & c_0 \\ \hline c_0 & d_0 & c_0 \\ \hline c_0 & c_0 & d_0 \\ \hline \end{array} \qquad A_1 = \begin{array}{|c|c|c|}\hline d_1 & c_1 & c_1 \\ \hline c_1 & d_1 & c_1 \\ \hline c_1 & c_1 & d_1 \\ \hline \end{array} \quad \text{etc.} \tag{35}$$

If in equation 34 the indicated differentiations are performed, the result is

$$b_0 C \cdot P + b_1 \left[ \frac{dC}{d\theta} \cdot P p\theta + C \cdot pP \right] + \ldots + A_0 \cdot C \cdot i' + A \cdot \frac{dC}{d\theta} \cdot i' p\theta + \ldots = 0 \tag{36}$$

It remains only to multiply the whole equation 36 by the inverse transformation tensor $C^{-1}$ to obtain the set of equations 5. The elements of $C^{-1}$ are the coefficients of the set of equations 3, 6, or 7 of reference 2. That this multiplication eliminates the $C$'s is evident since:

$$C^{-1} \cdot C = \begin{array}{|c|c|c|}\hline 1 & 0 & 0 \\ \hline 0 & 1 & 0 \\ \hline 0 & 0 & 1 \\ \hline \end{array} \tag{37}$$

$$C^{-1} \cdot \frac{dC}{d\theta} = -C^{-1} \cdot \frac{d^3C}{d\theta^3} = C^{-1} \cdot \frac{d^5C}{d\theta^5} = \text{etc.}, =$$

$$= \begin{array}{|c|c|c|}\hline 0 & -1 & 0 \\ \hline 1 & 0 & 0 \\ \hline 0 & 0 & 0 \\ \hline \end{array} = J \tag{38}$$

$$-C^{-1} \cdot \frac{d^2C}{d\theta^2} = C^{-1} \cdot \frac{d^4C}{d\theta^4} = -C^{-1} \cdot \frac{d^6C}{d\theta^6} = \text{etc.}, =$$

$$= \begin{array}{|c|c|c|}\hline 1 & 0 & 0 \\ \hline 0 & 1 & 0 \\ \hline 0 & 0 & 0 \\ \hline \end{array} \tag{39}$$

The final equation is thus:

$$b_0 P + b_1 [J \cdot P p\theta + pP] + \ldots + A_0' \cdot i' + A_1'' \cdot i' p\theta + A_1' \cdot pi' + \ldots = 0 \tag{40}$$

where

$$A_0' = C^{-1} \cdot A_0 \cdot C = \begin{array}{|c|c|c|}\hline a_0 & 0 & 0 \\ \hline 0 & a_0 & 0 \\ \hline 0 & 0 & e_0 \\ \hline \end{array}$$

$$A_1'' = C^{-1} \cdot A_1 \cdot \frac{dC}{d\theta} = \begin{array}{|c|c|c|}\hline 0 & -a_1 & 0 \\ \hline a_1 & 0 & 0 \\ \hline 0 & 0 & 0 \\ \hline \end{array}$$

$$A_1' = C^{-1} \cdot A_1 \cdot C = \begin{array}{|c|c|c|}\hline a_1 & 0 & 0 \\ \hline 0 & a_1 & 0 \\ \hline 0 & 0 & e_1 \\ \hline \end{array}$$

It will be noted that here the same transformation $C$ has been applied to both $e$ and $i$, rather than applying the transformation $C_i^{-1}$ to $e$. The latter transformation has the property of maintaining the power $e \cdot i$ as an invariant, while in the former the only requirement has been that the trigonometric functions be eliminated from the differential equation $e = Z \cdot i$, without regard to the formula for power. A transformation tensor can, of course, easily be found which will resemble as nearly as possible Park's transformation yet which has the further property of invariance of power. This transformation tensor is:

$$C = \sqrt{\frac{2}{3}} \begin{array}{|c|c|c|}\hline \cos\theta_1 & -\sin\theta_1 & \sqrt{1/2} \\ \hline \cos\theta_2 & -\sin\theta_2 & \sqrt{1/2} \\ \hline \cos\theta_3 & -\sin\theta_3 & \sqrt{1/2} \\ \hline \end{array} \tag{41}$$

where $\theta_2 = \theta_1 - 120°$, $\theta_3 = \theta_1 + 120°$. It will be found that now $C_i^{-1} = C$, so that it is immaterial which is used in the derivation of the equations.

# Resistance Characteristics of Tellurium and Silver-Tellurium Alloys

By H. T. FAUS
MEMBER AIEE

## Synopsis

The problem of correcting temperature errors in electrical instruments with copper windings is explained and the high electrical efficiency obtainable by correcting these errors with series resistors having negative temperature coefficients of resistance is noted. A method is described for making such resistors of tellurium and of silver-tellurium alloy. Tests at various loads are described as a result of which the suitability of these resistors for various applications is determined.

## General

THE WINDINGS of electrical instruments and meters must usually be made of copper or aluminum wire to obtain high conductivity. Where, as in a millivoltmeter, the resistance of the winding has an effect on the accuracy of the instrument, the high temperature coefficient of resistance of the winding causes the instrument to have a correspondingly high temperature error.

A simple method commonly used for correcting this error is to connect a resistor of some material of low temperature coefficient, such as manganin, in series with the winding. The chief disadvantage of this method is that it increases the full-scale millivolts of the instrument in nearly an inverse ratio to the decrease in the temperature error, a total increase of 19 times[1] in the full-scale millivolts being required for complete compensation.

Another method which is more efficient and also more complicated makes use of a network of manganin and copper, iron, or nickel resistors. Brooks[1] has shown that by this method it is possible to compensate accurately the temperature error of a millivoltmeter by increasing the full-scale millivolts to nearly 5 times the millivolts of the uncompensated instrument.

Compensation by means of a series resistor having a negative temperature coefficient of resistance is an efficient method which has been used in instruments for many years. To the writer's knowledge, the only materials of negative temperature coefficient which have previously been known to have the required linear temperature-resistance curves are carbon and certain carbides. These materials as used in commercial instruments have negative temperature coefficients of resistance nearly equal numerically to the positive temperature coefficient of resistance of copper. Complete compensation of the temperature error is obtained at the expense of a 100 per cent increase in the full-scale millivolts of the uncompensated instrument. (Temperature errors due to the magnet and springs are disregarded because they are much smaller than the error due to the resistance change and may be compensated by the same method.) While instruments compensated with these materials are more sensitive than are instruments compensated by the other methods, a further gain in sensitivity may be obtained by the use of materials of higher negative temperature coefficients of resistance. The materials which are to be described have temperature coefficients which are numerically about 3 times as great as the temperature coefficient of copper. This makes it possible to obtain complete compensation at the expense of only a 33 per cent increase in the full-scale millivolts of the instrument.

In a search which the writer made for information on materials of negative temperature coefficient of resistance, he noted the values given in the International Critical Tables[2] for silver-tellurium alloys slowly cooled from their melting temperatures. These data were quoted from a thesis written by Riviere at the University of Paris in 1912.

All available data on tellurium indicated that it was inconstant in resistance and that small traces of impurities affected its resistivity so greatly as to preclude the use of commercial tellurium as a resistor material.[3]

## Method of Fabricating and Testing Resistors

As the result of tests it was found that the silver-tellurium alloys could be readily formed into rods by melting the constituents in a porcelain crucible, stirring the melt thoroughly, and drawing the molten alloy into a long glass tube of which one end was plunged under the surface of the melt and the other was attached to a rubber bulb used to create a partial vacuum in the tube. The rods could sometimes be pushed out of the tubes without breaking, but it was often necessary to dissolve the tubes in hydrofluoric acid in order to obtain the rods.

The method of attaching the leads was to electroplate the ends of the resistors with nickel, cobalt, platinum, or rhodium and solder them on with ordinary lead-tin solder. No failures of any of the resistors were observed to be traceable to plated joints in which any of these four metals were used. Most of the tests were made on resistors with platinum- or rhodium-plated joints.

The temperature-resistance tests were made by connecting the resistor to a Wheatstone bridge and immersing it in a bath of water for temperatures above 0 degrees

A paper recommended for publication by the AIEE committee on instruments and measurements. Manuscript submitted January 16, 1937; released for publication July 22, 1937.

H. T. FAUS is a development engineer in the General Electric Company, Lynn, Mass.

1. For all numbered references, see list at end of paper.

centigrade and of alcohol cooled with solid carbon dioxide for temperatures below zero degrees centigrade. Check tests with several different voltages applied to the bridge were frequently taken in order to detect any variation in resistance with current density. No changes in resistance were detected in this way except those attributable to self heating.

## Improvement in Alloy to Obtain Linear Temperature-Resistance Curve

Tests on resistors made from an alloy of 15 per cent Ag with 85 per cent Te melted under illuminating gas to prevent oxidation gave temperature-resistance curves similar to that shown in figure 1. The method by which the resistors were heat treated will be explained later. It will be noted that, like those of Riviere's alloys which were all melted in a nonoxidizing atmosphere, the curve shows a sudden departure from a linear form near −15 degrees centigrade and below this temperature the slope changes rapidly. When resistors so made were suddenly cooled to any temperature between −15 and −60 degrees centigrade it was noted that their resistances did not at once assume definite values but that they slowly increased for an hour or more. The resistance corresponding to the temperature on any linear portion of the curve was attained quickly, and no subsequent variation was observed to occur while the temperature was held constant.

A melt which had not been protected from oxidation was found to have a linear temperature-resistance curve from −70 to +70 degrees centigrade and no resistance variation occurred while the temperature was held at any value in this range. As a result of tests on several melts of each type, the nonlinear and erratic resistance variation was found to be characteristic of the alloy melted in illuminating gas, and the linear temperature-resistance curve with a definite resistance for each temperature was found in every melt that had been melted in air.

All melts subsequently made were stirred in the presence of air until the formation of a scum of undissolved oxide indicated that no more would dissolve.

## Development of Heat-Treating Process

In view of recent developments in the age hardening of alloys it appeared that the results that Riviere obtained by slowly cooling the Ag-Te alloys might be due to precipitation and that they could be more effectively accomplished by annealing at a constant temperature than by slow cooling. The results of subsequent tests tend to confirm this assumption.

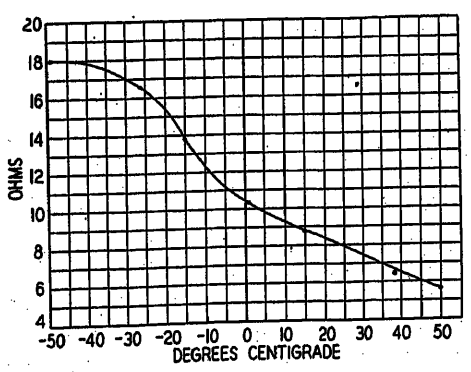

**Figure 1. Temperature - resistance curve of a 15 per cent silver-tellurium alloy resistor melted in an atmosphere of illuminating gas and annealed 15 hours at 115 degrees centigrade**

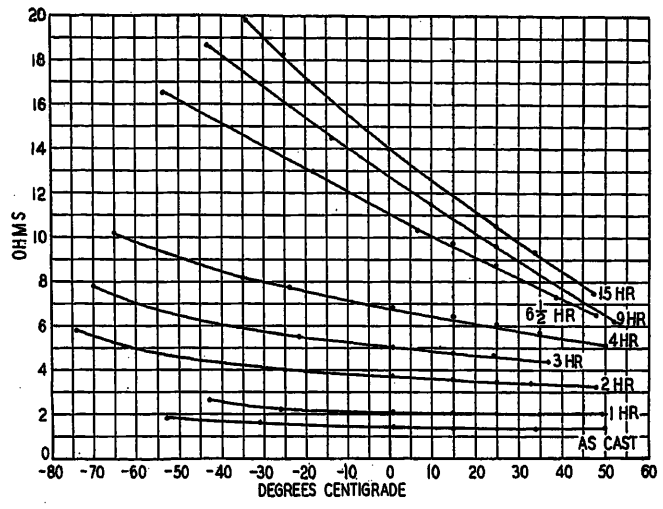

**Figure 2. Effect of annealing time at 115 degrees centigrade on the temperature-resistance curve of a resistor of 15 per cent silver with 85 per cent tellurium. Effective length of resistor, $^{9}/_{32}$ inch; diameter of resistor, 0.102 inch**

Figure 2 shows the effect of annealing at a constant temperature of 115 degrees centigrade on the temperature-resistance curve of a 15 per cent Ag, 85 per cent Te alloy. In order to get the data in this form, it was necessary to perform the annealing in a series of steps, taking a temperature-resistance curve between each of the steps. No difference has been observed between resistors annealed in in this way and resistors which were given the same total hours annealing time in a single treatment.

Groups of curves similar to those shown in figure 2 were taken for annealing temperatures from 105 degrees centigrade to 145 degrees centigrade and the results are summarized in figures 3 and 4. Some data were taken at 95 degrees centigrade, but at this temperature the rate of change was so slow that it would apparently have required a period of weeks to effect the entire change.

The increase in resistivity during the heat treatment, with a few exceptions which may be due to cracks, almost exactly parallels the increase in the negative temperature coefficient of resistance of both in 15 per cent Ag-Te alloy and of the purest grade of tellurium which we could readily obtain (Eimer and Amend *CP*). This tends to show that the same physical change is responsible for both effects.

## Effect of Direct Current on Polycrystalline Resistors of 15 Per Cent Silver-Tellurium Alloy

In the course of tests made under various conditions on resistors prepared and annealed as previously described, it was found that when a direct current of 25 milliamperes was continuously passed through a resistor of approximately 0.10 inch in diameter its resistance decreased for a period of from 2 to 4 weeks when it had decreased about

10 per cent after which time its resistance began to increase. This increase in resistance was evidently due to cracks which occurred spontaneously and gradually extended until they caused a fracture of the resistor. It was also found that the same effect could be produced by immersing the resistor in either oil or water for cooling and passing a direct current of 0.9 ampere through it for one to 2 hours.

In studying this effect it was noted that these resistors had a structure as shown in figure 5. The first visible change in the resistor previous to failure was usually a widening of the longitudinal crack, followed by the development of cracks which branched from the longitudinal crack, usually at right angles to it. These cracks appeared to develop at crystal boundaries, so it was thought that if the resistor were so made that the current did not pass through the boundaries between crystals, this effect might be eliminated.

## Effect of Direct Current on Single-Crystal Resistors of 15 Per Cent Silver-Tellurium Alloy

In order to determine whether the type of failure just described was related to the crystal structure, tests were conducted as follows: Sealed glass tubes containing the 15 per cent alloy were passed through a 480 degree-centigrade furnace at a rate of $^3/_8$ inch per minute. The alloy was molten at this temperature, and the time that it remained in the furnace after melting was not important. Where the tube emerged from the lower end of the furnace it passed into an oil bath. Rods made in this manner were found to have a single-crystal structure. Resistors made from these rods showed practically the same temperature-resistance characteristics and responded in the same manner to heat treatment as did those made by the simple casting process.

A number of these resistors were placed on a life test

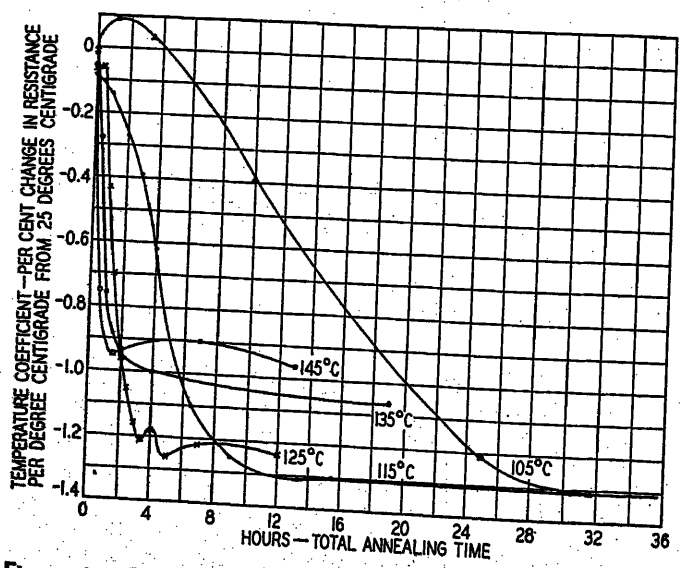

**Figure 3. Effects of time and temperature of annealing on the temperature-resistance coefficient of an alloy of 15 per cent silver with 85 per cent tellurium**

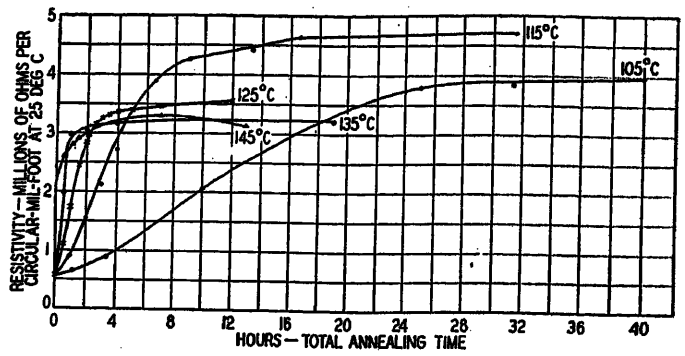

**Figure 4. Effects of time and temperature of annealing on the resistivity at 25 degrees centigrade of an alloy of 15 per cent silver with 85 per cent tellurium**

with a direct current of 25 milliamperes flowing continuously through them. Their resistances continued to decrease for a period of several weeks, the total decrease ranging from 8 per cent to 20 per cent and the length of time required to attain minimum resistance ranging from 3 weeks to 7 months, most of the change in every case taking place in the first month. After attaining the minimum resistance some of the resistors tended to remain constant in resistance for several months and others increased slowly in resistance. After a period of 257 days all of a group of 4 resistors which were tested under these conditions showed a bulge at a distance of $^1/_8$ inch from the cathode end of the resistor. Cracks appeared in these bulged sections and the resistors broke spontaneously. Figure 6 shows photographs of a resistor in which this bulge has developed, together with a similar resistor which has not been subjected to direct current long enough for this type of failure to develop.

## Effect of Alternating Current on Single-Crystal Resistors of 15 Per Cent Silver-Tellurium Alloy

Since the failures of the resistors were evidently due to an effect resembling electrolysis, tests were made similar to those just described except that 60-cycle alternating current was used instead of direct current. In the test at 0.9 ampere with the resistor immersed in a cooling liquid, the resistance increased slowly, the total increase in resistance being 12 per cent for a period of 14 days during which time the current was passed continuously through the resistor except for the brief periods during which it was removed from the circuit to have its resistance measured. At the end of this period it was put through a temperature cycle from −62 degrees centigrade to +74 degrees centigrade after which its resistance was only 7 per cent above the original value.

Since the chemical as well as the heating effect of the current is involved in the effect of direct current on the resistors, comparisons should be made on the basis of average as well as on effective values of current. However, in this case the difference in the effects of alternating and of direct current is so great that the comparison is little affected by a change in the alternating current equal

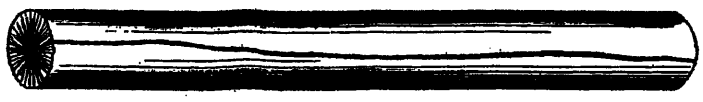

**Figure 5. Arrangement of crystals and longitudinal crack in a cast resistor of 15 per cent silver-tellurium alloy**

to the difference between the effective and the average values. Comparatively stated: a direct current of 0.9 ampere applied to a 15 per cent Ag-Te resistor which has been annealed 15 hours or more at 115 degrees centigrade caused it to decrease 40 per cent in resistance in 3 hours and to fracture spontaneously in $4^1/_2$ hours. An equivalent (root-mean-square) value of alternating current applied to a similar resistor under similar conditions for over 300 hours caused a semipermanent increase of 12 per cent in its resistance and no mechanical damage. It is reasonable to suppose that this increase in resistance may have been due to heat rather than to any other effect of the current.

## Effect of Direct Current on Resistors With Various Percentages of Silver

Annealed resistors of single-crystal tellurium of both the *CP* and the technical grades withstood direct current for a much longer period than did the alloy resistors. The tests at 0.9 ampere direct current were not continued longer than 10 hours, and at the end of this time the resistances had decreased only 2 per cent and there was no evidence of physical change in the resistors.

Tests at 0.9 ampere direct current on resistors with 5 per cent and 10 per cent of silver showed that the 5 per cent alloy resistors withstood the current longer than did the resistors with 10 per cent of silver. Failure of resistors containing 10 per cent of 15 per cent silver occurred by fracture, while with resistors containing 5 per cent silver a separation of the electroplated joints occurred at the cathode ends of the resistors. This separation was accompanied by the formation of a black coating on the separated surfaces.

For reasons to be explained later the 10 per cent alloy was the only one which appeared to have substantially as good temperature-resistance characteristics as those of the 15 per cent alloy. Hence it was the only one to be tested with a small current over a long period of time. Under these conditions it failed in a shorter time than did the 15 per cent alloy.

## Effect of Composition on the Temperature-Resistance Characteristics of Silver-Tellurium Alloys

Preliminary tests on alloys with different percentages of silver and tellurium had indicated that compositions low in silver content gave temperature-resistance curves which were concave downward below −10 degrees centigrade while compositions which were high in silver content gave curves which were concave upward over the same temperature range. Since the composition which gave the most nearly linear curve over the range from −70 degrees centigrade to +70 degrees centigrade was that containing 15 per cent silver, most of the previously described work was done with an alloy of this composition.

The temperature-resistance characteristics of compositions ranging from zero (*CP* tellurium) to 50 per cent were determined by making a series of resistors of the required compositions in the manner which had been found to give the best results with the 15 per cent alloy. This procedure comprised melting in air, casting in glass tubes, progressive solidification, and annealing for 15 hours at 115 degrees centigrade.

The temperature-resistance curves for this range of compositions are shown in figures 7 and 8. In figure 8 it will be noted that portions of the curves are indicated by dotted lines. Over the temperature ranges so indicated the resistance is not constant at any given temperature. When the temperature of the resistor is lowered to a value on the dotted curve the resistance assumes the value so indicated, but when the temperature is held constant in this region, the resistance continues to increase at a diminishing rate for a period of several hours or more. In one case a resistance increase of 70 per cent in 45 minutes was observed. In all observed instances, this increase in resistance was not permanent; that is, the original resistance at any point on the solid portion of the curve could be again obtained by bringing the temperature to the corresponding value.

This behavior resembles that of the 15 per cent alloy melted in a reducing atmosphere, although the alloys with the higher percentages of silver were melted in an oxidizing atmosphere, using the same procedure as that used in producing the 15 per cent alloy which had a linear temperature-resistance curve.

It will be noted that the resistivity of the 15 per cent alloy resistor in figure 7 is lower than that of the resistor of the same composition in figure 4. This difference may be accounted for by the fact that the former is a single crystal, while the latter is polycrystalline in structure.

When the single-crystal resistors were found to be superior to the polycrystalline resistors, sufficient tests were made to determine the fact that they responded to heat treatment in a manner similar to that of the polycrystalline

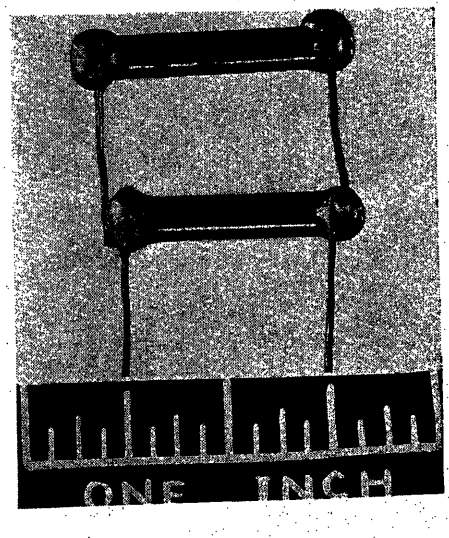

**Figure 6. At top, a silver-tellurium resistor in which bulge has formed due to passage of direct current over a long period of time; at bottom, a similar resistor which has not been subjected to current**

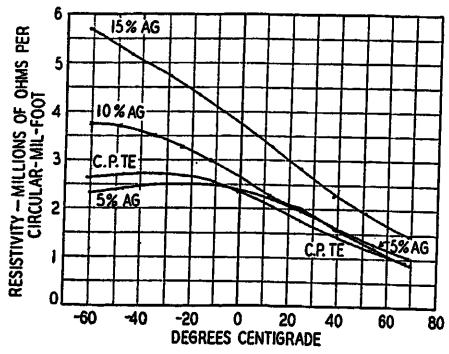

**Figure 7. Temperature - resistivity curves of Ag-Te alloys with zero to 15 per cent Ag annealed 16 hours at 115 degrees centigrade**

resistors, although the resistivities of the single-crystal resistors were the lower. The series of tests summarized in figures 1 to 4 inclusive were made with polycrystalline resistors and were not repeated with single-crystal resistors. Figures 7 and 8 were made with single-crystal resistors or at least with resistors which had been solidified progressively in a manner which had been found to produce single crystals.

Referring to figure 7, the temperature-resistivity curve of annealed chemically pure tellurium is linear between −10 degrees centigrade and +70 degrees centigrade. Tests on commercial tellurium from 4 different sources showed that unannealed single-crystal resistors of these materials had temperature coefficients within the range +0.1 to −0.1 per cent per degree at 25 degrees centigrade. Unannealed single-crystal resistors of chemically pure tellurium had temperature coefficients of approximately −0.7 per cent per degree at 25 degrees centigrade. After the annealing treatment, the temperature-resistivity curves of the commercial and of the chemically pure tellurium resistors were practically the same. Both had temperature coefficients of −1.2 per cent per degree at 25 degrees centigrade.

## Thermal Electromotive Force

The thermal electromotive force as measured on an unannealed sample of 15 per cent Ag-Te alloy was found to be 0.46 millivolts per degree with the hot junction at 50 degrees centigrade and the cold junction at 25 degrees centigrade. This is close to the value usually given for tellurium.[4]

The annealing treatment which had such a great effect on the resistivity and temperature coefficient of resistance of the alloy lowered the thermal electromotive force as measured over the above temperature range to 0.25 millivolt per degree.

## Aging Tests

The accelerated life tests which have been described were made sufficiently severe to destroy the resistors. While these tests did not represent service conditions, they were valuable guides in selecting the compositions and treatments of the resistors on which aging tests were made.

The following test results indicate the constancy that may be expected under the specified conditions of use:

1. In a group of 9 single-crystal tellurium resistors of 0.1 inch diameter, tested at 0.025 ampere direct current for 81 weeks, the maximum change was +1.2 per cent in one resistor, and the average change for the group was +0.15 per cent.

2. In a group of 3 single-crystal Ag-Te resistors of 0.1 inch diameter, tested at 0.10 ampere alternating current for 78 weeks, the maximum change was +2.1 per cent in one resistor, and the average change for the group was +1.4 per cent.

3. In a group of 4 single-crystal Ag-Te resistors of 0.1 inch diameter, tested at 0.001 ampere direct current for 80 weeks, the maximum change was +2.2 per cent in one resistor, and the average change for the group was +1.4 per cent.

In all of these groups most of the change took place during the first part of the period, indicating a tendency to stabilize at a higher value of resistance. It should be noted that in the previously described tests in which the Ag-Te resistors were broken by electrolytic action, a considerable decrease in resistance always preceded failure. The tests at one milliampere direct current indicate that this effect is not occurring at this low current density, since the resistance is increasing.

Aging tests on polycrystalline Ag-Te resistors of the type shown in figure 5 showed resistance changes several times as great as those in the single-crystal resistors.

## Applications

The heat-treated tellurium resistors of single-crystal structure are more constant than are the similarly treated Ag-Te alloy resistors, their temperature coefficient is practically the same from −10 degrees centigrade to +70 degrees centigrade, and they are not subject to electrolytic effects. Therefore, they are to be preferred to the Ag-Te alloy resistors for all applications in which compensation is not required at temperatures below −10 degrees centigrade. Since the resistance of these resistors should not be more than 25 per cent of the resistances of the instrument circuits in which they are used, the maximum change of 1.2 per cent which was noted in one resistor during the aging test would have caused a maximum instrument error of 0.3 per cent. From these data it appears that this material may be used in instruments with rated accuracies of one per cent to 2 per cent, provided that other sources of error are kept sufficiently low.

The 15 per cent Ag-Te alloy is suitable for long-range

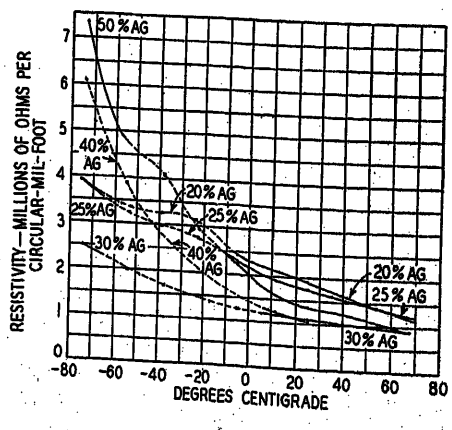

**Figure 8. Temperature - resistivity curves of Ag-Te alloys with 20 per cent to 50 per cent Ag annealed 16 hours at 115 degrees centigrade**

temperature compensation, but when used with direct current the current density should not exceed one milliampere in a 0.1 inch diameter resistor. A suitable application of this kind is for compensating the resistance change in a thermocouple temperature indicator with cold-junction compensation for measuring temperatures in aircraft engines or for portable use in measuring temperatures of molds, bearings, and molten metals.

An application in which the 15 per cent Ag-Te alloy has been tried with good results is in the compensation of "class 2" temperature error in watt-hour meters. This error is principally due to the change in phase angle of the flux of the potential coil due to the change in resistance of the potential winding with changing temperature. It has been entirely corrected by substituting for the usual solid copper lag plate a wound copper lag coil with a resistor of Ag-Te alloy connected across its terminals. The maximum aging change of 2.1 per cent for this alloy as tested under similar conditions with alternating current would cause an error not greater than 0.1 per cent in the meter accuracy. Another method, as described by Kinnard and Trekell,[5] which has recently been developed for correcting this error has the advantage of a better mechanical design.

In compensating millivoltmeters with these materials, it is necessary on account of the high thermal electromotive force of Te and of Ag-Te to shield them from rapid temperature fluctuations and to mount them so as to equalize the temperatures at the ends of the resistor.

Figure 9 illustrates 2 resistors which have been made for use in instruments.

## Theory

Because the results just described were obtained with tellurium which was not investigated spectroscopically to determine its purity and which was known to contain dissolved oxide, they are not directly comparable with those of Cartwright and Haberfeld-Schwarz[3] who used tellurium of high purity melted in vacuum. They considered the increase in resistivity which occurred during annealing to be due to the formation of cracks. This theory does not explain the increase in temperature coefficient which accompanied the increase in resistivity in our tests. Neither pressure up to the crushing strength of the material, nor a current which would have fused the resistor had it not been cooled in liquid, decreased the resistance of our annealed tellurium resistors.

**Table I. Summary of Electrical Characteristics of Resistor Materials**

Single Crystals Annealed 15 Hours at 115 Degrees Centigrade

| Composition Per Cent Ag | Composition Per Cent Te | Resistivity at 25 Degrees Centigrade in Megohms Per Circular-Mil-Foot | Temperature Coefficient of Resistance at 25 Degrees Centigrade | Effect of Direct Current | Effect of 60-Cycle Alternating Current |
|---|---|---|---|---|---|
| 0 | 100 | 1.7 | —1.2 | Thermal | Thermal |
| 5 | 95 | 1.9* | —1.1* | Thermal and electrolytic | Thermal |
| 10 | 90 | 2.0 | —1.3 | Thermal and electrolytic | Thermal |
| 15 | 85 | 2.8 | —1.3 | Thermal and electrolytic | Thermal |

* These data based on tests on only one sample.

The behavior of all the resistors tested by the writer may be explained as follows: In rapid cooling from the melting temperature, silver telluride and other impurities are held in solid solution in the tellurium, which solid solution has the property of metallic conduction with a very small temperature coefficient of resistance. Assuming that the impurities are precipitated during the heat treatment, the conductivity decreases due to the reduction in the number of free electrons. This theory is supported not only by the fact that the temperature-resistivity curves of the impure and the pure tellurium are made to coincide by heat treatment, but also by the fact that the thermal electromotive force of the Ag-Te alloy is lowered by the heat treatment. Cartwright and Haberfeld-Schwarz[3] have shown that the thermal electromotive force of pure tellurium is much lower than the value usually given and that is increased by the additions of small amounts of silver and of other metals.

The breakdown of the Ag-Te resistors produced by direct current may be due to electrolysis of silver telluride accompanied by migration of the silver ions toward the cathode. Evidence has been shown to indicate that this effect does not take place when the voltage across the resistor is very low.

The observations here recorded were obtained in determining the utility of tellurium and of its alloys with silver as special resistor materials. It is hoped that the data thus obtained may be of some value in the further determination of the nature of the conductivity of semiconductors.

# Regulation of Grid-Controlled Rectifier

By L. A. KILGORE ASSOCIATE AIEE J. H. COX ASSOCIATE AIEE

## Synopsis

This paper discusses several factors which have not been included in the previously published regulation formulas and which should be considered in the practical application of rectifiers. Approximate solutions are given to take system reactance, and the load inductance into account. The effect of grid pickup characteristics on regulation, and means of modifying the inherent regulation characteristics by regulators or compensators are discussed.

## Introduction

SEVERAL PAPERS[3,4] have been written on the general characteristics of grid-control rectifiers, and formulas have been derived for the regulation. The conventional formula, equation 1, is based on the assumptions that a sinusoidal voltage exists at the point where the rectifier is connected to the system, and that the inductance in the load circuit is sufficiently large to prevent the current from going to zero when the voltage drops below the counter electromotive force of the load circuit. These assumptions are sufficiently accurate for some cases, but in many practical cases other factors, such as the effect of system reactance and the effect of a limited amount of inductance in the load circuit must be considered.

The conventional formulas and regulation curves involve the angle of delay ($\alpha$). In the practical application of these formulas it may not be correct to assume that the actual angle of delay is constant for a certain setting of the grid-control apparatus. The angle of delay may vary with the load due to a variation in the grid pickup voltage, and in some cases it may vary due to a shift of phase of the grid voltage due to system reactive drop.

It is the purpose of this paper to consider these other factors and to present approximate methods of including them in the determination of regulation. A more exact solution is outlined in the appendix. The use of regulators and compensators for the purpose of modifying the inherent regulation of grid-controlled rectifiers and ignitrons is also discussed, and results obtained with certain types are given.

## Conventional Regulation Formula

What might be termed the conventional regulation formula for grid-controlled rectifiers (equation 1) has been derived several times;[2,3] and the derivation will not be repeated.

$$E_d = \left[\frac{\sqrt{2}EP \sin\frac{\pi}{P}}{\pi}\right]\cos\alpha - \frac{IX_TP}{g2\pi} - \frac{W_T}{I} - A \qquad (1)$$

This formula is exact within the limits of the assumptions made in deriving it. These assumptions are: (1) a sinusoidal voltage at the terminals of the rectifier transformer, (2) a load inductance sufficiently high to prevent the current from going to zero, (3) the effect of all the transformer and lead resistance to be equivalent to a series resistance in the d-c circuit giving the same loss, and (4) only 2 anodes in one group firing at one time. This formula gives straight-line regulation curves as shown by the dotted lines of figure 1, providing the curve of arc drop against current is straight. It should be noted that the curves are parallel; that is, a given angle of grid delay ($\alpha$) drops the output voltage the same number of volts whether at no load or at full load.

If a rectifier is supplied through a line of appreciable reactance directly from a large system whose voltage is

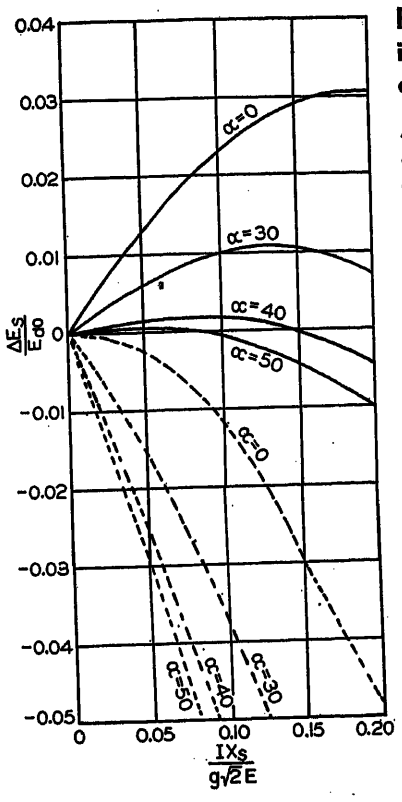

**Figure 2. Apparent increase in regulation due to system reactance**

A normal transformer with about 3 per cent reactive drop is assumed. Full lines are for double 3-phase and dotted lines are for 12-phase quadruple zigzag

not affected by the rectifier load, the line reactance can obviously be included in the total commutating reactance. In this case $E$ in equation 1, is the system voltage. The additional commutating reactance due to the line is calculated by multiplying the ohms per phase (line to neutral) by the square of the ratio of primary to secondary line to neutral voltages.

For the more common case where the system voltage is affected appreciably by the rectifier load, equation 1 can still be used as an approximation if the primary voltage is known. However, a further analysis as presented below is necessary to obtain an accurate method of dealing with this case.

## Effect of System Reactance

In the general case of a rectifier connected to an a-c system there is no one source of constant sinusoidal voltage. It greatly simplifies the problem if an equivalent sinusoidal source voltage can be found which may be considered as unaffected by rectifier currents. The principle of superposition, which has proved such a useful tool in other system problems, may be applied to determine a voltage which can be considered as acting through the combined impedance of the system and the rectifier transformer.

Since the back current of a power rectifier is negligible, the effect is equivalent to opening each anode circuit whenever the current tends to reverse. A method of applying superposition to obtain as complete a solution as desired is outlined in the appendix. For practical purposes, the capacity and resistance of the a-c circuit and any effect of harmonics produced by other rectifiers, will be neglected.

As shown in the appendix, the voltages acting in the secondary to produce the anode currents are the voltages which would exist with no rectifier currents flowing. This voltage acts through the reactance of the transformer and the reactance of the system measured from the point of connection. This voltage may be treated as an equivalent sinusoidal source voltage and the system reactance may be added to the commutating reactance of the transformer as described for the line reactance in the simpler case mentioned previously.

In general the voltage $E$ at the primary of the rectifier transformer is known or can be calculated. The system reactance $X_s$ can be measured or estimated. As shown in appendix $B$, the system reactance to be used is the same as that used for calculating single-phase short-circuit current; that is, the average of the negative-sequence and positive-sequence subtransient reactances: $X_s = (X_2 + X_d'')/2$.

The fundamental frequency voltage $E$, at the primary terminals may be taken equal to the root-mean-square value for practical purposes. If the fundamental-frequency system reactive drop be added vectorially to the terminal voltage the equivalent sine-wave source voltage $E''$ is obtained. Using $E''$ instead of $E$ and $(X_T + X_s)$ in place of $X_T$ in equation 1, gives the general equation;

$$E_d = \left[\frac{\sqrt{2}\,E''P\sin\frac{\pi}{P}}{\pi}\right]\cos\alpha - \frac{I(X_T + X_s)}{g2\pi} - \frac{W_T}{I} - A \qquad (2)$$

where

$$E'' = \sqrt{(E + I_1X_s\sin\theta_1)^2 + I_1^2X_s^2\cos^2\theta_1} \qquad (3)$$

With good approximation,

$$I_1 = \frac{I\sqrt{2}}{\pi g}\sin\frac{\pi}{P} \qquad (4)$$

The fundamental-frequency power factor is approximately:

$$\cos\theta_1 = \cos\alpha - \frac{\text{transformer reactive drop}}{\text{voltage at no load no delay}} \qquad (5)$$

This may be demonstrated as follows. All the power is supplied by the fundamental since the source voltage is

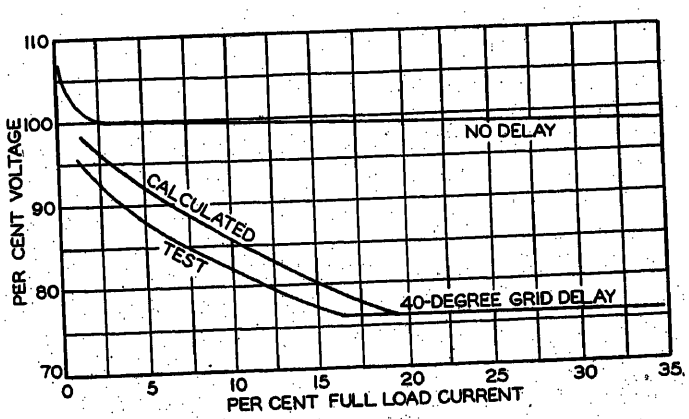

**Figure 3. Light-load voltage regulation curves**

Experimental grid-controlled rectifier, double 3-phase connection

assumed sinusoidal. This power factor can then be written as power divided by fundamental-frequency volt-amperes:

$$\cos \theta_1 = \frac{E_d I}{E I_1 p g}$$

and neglecting arc drop and resistance losses, this reduces to equation 5.

The fundamental reactive drop adds to $E$ the amount nearly equal to $I_1 X_s \sin \theta_1$. If the average of the power factor angles at the source and at the terminals be used the accuracy of this approximation is improved. The effect of the system reactance is to add to the source voltage and to the reactive drop. The net correction expressed as an addition to the regulation (to be subtracted from the right-hand side of equation 1) is:

$$\Delta E_s = \frac{I X_s P}{2\pi g}\left[1 - \frac{4g}{\pi}\sin^2\frac{\pi}{p} \times \cos\alpha \sin\cos^{-1}\left\{\cos\alpha - \frac{I\left(X_T + \frac{X_s}{2}\right)}{2\sqrt{2}gE\sin\frac{\pi}{p}}\right\}\right] \qquad (6)$$

Curves of $\Delta E_s/E_{d0}$ for different values of $IX_s/g\sqrt{2}E$ are given in figure 2, for a rectifier with about 3 per cent regulation in the transformer. It will be seen that the correction can be either positive or not depending on the type of connection and the angle of delay. It should be noted that the angle of delay ($\alpha$) is measured relative to the source voltage, and that the angle of overlap ($u$) as measured on an oscillogram will be determined by the total reactance ($X_T + X_s$) thus:

$$\cos(u + \alpha) = \cos\alpha - \frac{I(X_T + X_s)}{g\sqrt{2}\,E' \sin\frac{\pi}{P}} \qquad (7)$$

To illustrate the importance of the correction for system reactance, consider a rectifier where the primary voltage is held constant as it might be in a regulation test. If the system reactance is 10 per cent based on the rectifier kilovolt-amperes and the transformer reactive drop is 3 per cent, the ratio of $X_s$ to $X_T$ is 1.74 for a double 3-phase connection and the measured regulation may be 2.3 per cent less with zero delay than the value which would be obtained if a sine-wave voltage were impressed. That is, the regulation might measure 2.7 instead of 5 per cent. As another example take a 12-phase quadruple zigzag connection with the same per cent line reactance and transformer reactive drop. In this case the ratio of $X_s$ to $X_T$ is 0.87 and the regulation will be increased only 0.3 per cent at no delay; but at 20 per cent reduction in voltage by grid delay the measured regulation will be decreased 4 per cent, that is; it may measure one per cent instead of 5 per cent.

## Light Load Voltage Rise

The rise in voltage at very light loads on a double 3-phase rectifier is a well-known phenomenon. This has been explained by saying that below some transition value of load, at which the load current just equals the interphase transformer excitation current, the rectifier is operating 6 phase; and that the commutating current flows between anodes of alternate groups through the windings of the interphase transformer. This is an accurate explanation for the case of straight resistance load or for the theoretical case of infinite inductance in the load circuit.

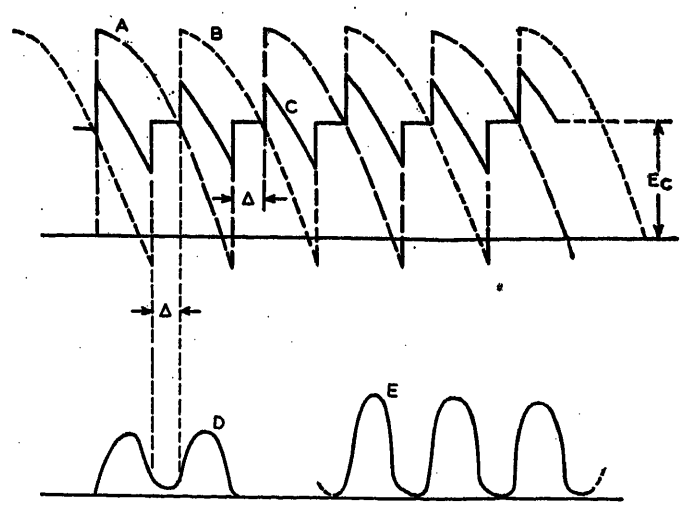

**Figure 4. Current and voltage waves when operating at light load with counter electromotive force**

Curve *A*—Voltage of one group of double 3-phase winding
Curve *B*—Voltage of other group
Curve *C*—Net voltage output
Curve *D*—Current in first group
Curve *E*—Total current output

However, for the case of load with a counter electromotive force and with normal inductance a different phenomenon appears which radically alters the light-load regulation characteristics, especially when operating with appreciable grid delay. Whenever the output voltage of the rectifier dips below the counter electromotive force the total load current tends to go to zero but is restricted in this action by the inductance of the circuit. Above a certain critical load the current is prevented from reaching zero. This phenomenon occurs for all type of rectifiers both with and without interphase transformers.

When interphase transformers are used the action is more complicated. Interphase transformers are designed to have a high inductance ($L_i$) between the 2 transformer neutrals so as to prevent one group from dropping the current ahead of the other except at light loads. However, it is the leakage inductance ($\mathfrak{L}_i$) between the 2 halves of the winding which opposes the rise and fall of total current so long as both groups are conducting. This leakage inductance, measured with the windings in parallel, the magnetomotive forces being opposed, is very much smaller than $L_i$. This is true because the windings are normally made with close coupling.

As long as both groups are firing, it is the total inductance ($\mathfrak{L}$) of the load circuit, including $L_i$ and the paralleled inductance of the phase circuits of the anodes which are conducting at the same time, which damps out the pulsations of load current.

As discussed in the appendix, a complete solution would require consideration of the effective resistance and reactance of fundamental frequency as well as the impedance to suddenly applied voltages. The resistance in the load circuit causes a voltage drop both on the rising and dropping parts of current cycle and thus has relatively little effect on the total swing of the current unless the total line drop is 10 per cent or more at the load considered.

For most practical purposes the following equation determines the amplitude of total current pulsation:

$$i_\Delta = \frac{1}{L}\int e_x - E_c\,dt \qquad (8)$$

At a critical value of load this pulsation of current ($i_\Delta$) reaches a value equal to the average current, and the total current tends to go out between each pulse.

Consider the voltage waves for a double 3-phase circuit at light load and some delay, as shown in figure 4, for the interval of 1/6 of a cycle. The total current will rise and fall during this period, but since there is a slight difference in the currents of the 2 groups due to difference in voltage acting through the high inductance, $L_0$, only the current in one group goes out, and the current in the group having the last anode to pickup is maintained but at some very low value. One group at a time will be out for a period $\Delta$ and the current wave of each group will be as shown by curve $D$ of figure 4. The total current shown by curve $E$ will not go completely out but will be very low for the period $\Delta$. The output voltage at the neutral point of the interphase rises to the counter electromotive force value ($E_c$), assuming the inductance of half the interphase to be large compared with that of the load circuit. Equations could be written for the critical load value in terms of inductance and the angle of delay, but for practical purposes a graphical solution is satisfactory. Plotting the output voltage for an assumed value of $\alpha$ and $\Delta$ as shown in figure 4, the current can be solved by taking the area of one half cycle of the voltage ripple in volt seconds divided by the inductance $L$ as indicated by equation 8. Also from this curve the average voltage may be determined graphically.

The results of this method are given in figure 5 plotted as the rise in voltage ($\Delta E_c$) versus ($I\omega L/\sqrt{2}E$). Curves obtained in a laboratory test with counter electromotive force are shown in figure 3. This rise in voltage at light loads with appreciable angles of delay is much more pronounced than the usual light-load voltage rise at no delay. However, in practice this is not generally a serious matter since danger due to overvoltage exists in the great majority of cases only when the normal voltage at no delay is exceeded.

If exactly straight-line regulation curves are desired at very light loads and appreciable angles of delay it may be necessary to use more than normal load inductance. An iron-core reactor may be used in series with the d-c bus to provide a high inductance at low values of current.

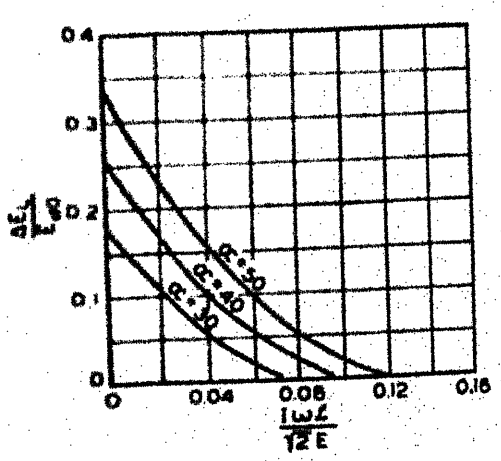

**Figure 5. Rise in voltage at light load as a function of d-c circuit inductance and load current**

## Effect of Grid Characteristics

The regulation formula and conventional regulation curves are based on the actual angle of delay. However, the angle of delay for a given phase shifter or bias setting may vary appreciably with load. This may be due to variation of the pickup voltage or an actual shift of the grid voltage with respect to the source voltage.

The pickup voltage will vary with the degree of ionization and the vapor pressure in the tank. At light loads a slight positive voltage relative to the cathode may be required to make the grids pickup, and at higher loads an appreciable negative voltage may be required to prevent them from picking up.

A simplified explanation of the action of the grids is as follows: A positive ion space charge sheath is formed around the grids when they are negative with respect to the ionized gas preventing the ionization from reaching the anode. The thickness of this layer[6] varies roughly as the $^3/_4$ power of voltage and inversely as the $^1/_2$ power of the ionization. When the thickness of the space charge sheath just fails to close the holes in the control-grid structure, positive voltage on the anode accelerates the electrons sufficiently to increase the ionization and further reduce the space charge thickness and cause complete pickup.

It is difficult to test for the pickup voltage of the grid under actual operation but a method of testing the grid characteristics statically was developed. An arrangement was made whereby the load could suddenly be removed from one anode and definite continuous voltages applied to that anode and control grid. Curves of grid voltage at which the anode picked up for different values of total load were plotted as shown in figure 6. These characteristics were found to vary some with anode voltage and the temperature of the cooling water. Obviously conditions were not identical with those under actual operating conditions. However, it was found that these static curves could be used to predict approximately the deviation of the test regulation curves from a straight line under overload conditions as shown in figure 1.

In order to explore a range of grid characteristics an experimental rectifier was built with grids having large holes so that the variation in pickup voltage caused a noticeable effect on the regulation curves even at rated load when using a sine-wave grid voltage. Without appreciably increasing the arc drop, it was possible to build a grid structure with sufficiently limited variation in pickup voltage so that it had no appreciable effect on regulation out to at least 200 per cent load. The test curves of

figure 1 show a flattening out of the regulation curves at about 250 per cent load at large angles of delay. However, grids sufficiently tight to give straight line regulation curves at very high overloads result in excessive arc drop.

When paralleled with other apparatus having a straight or drooping characteristic on high overloads, this effect will add to the tendency for the rectifier to take more than its share of the overload. However, so long as the departure from straight line regulation occurs at well over 150 per cent load, the rectifier will return to normal after the load is decreased, and no damage is done since the rectifier is suited to short time overloads.

By the use of steep-wave-front impulses on the grids it is possible to obtain straight-line regulation even with comparatively loose grid structures, since in this case a variation in the pickup voltage has little influence on the time of pickup.

The voltage control characteristics of an ignitron rectifier are similar to those of a multianode rectifier except that the pickup of the auxiliary tubes is not affected by the load current. Tests on a 6-phase ignitron rectifier, both as grid-controlled rectifier and as an inverter, show straight line regulation curves at all angles of delay and advance out to very high overloads.

Where the system reactance is comparable with the transformer reactance an increase in delay with load, due to a shift of the fundamental voltage at the point where the grid transformers are attached to the system, might be expected. For the sine wave grid transformer with only resistance in the grid circuits, tests show the effect on regulation to be negligible, even though the fundamental voltage shifts several degrees. This may be explained by the fact that the voltage applied to each grid through a resistance has almost identically the wave shape of the primary voltage. That is, it will have a wave proportional to the source voltage with nicks cut into it due to commutating currents, rather than a sine wave shifted in phase. Since the nicks in the voltage wave occur only during commutation they do not affect the voltage just before pickup provided only 2 anodes are commutating at one time, as is normally true.

## Regulators and Compensators

It is possible to regulate the output voltage of a grid-controlled rectifier, or ignitron, with the same types of current or voltage regulators that are used for rotating machines. The regulator may act to change the angle of delay, either by shifting the phase of the grid voltage or by varying the bias voltage applied to the neutral of a sine-wave grid transformer, which causes pickup to take place at a different point on the wave. The regulator may be made to give any desired regulation curve by using current compensation, and by cross current compensation units may be made to divide load under varying conditions. In some installations regulators have been applied so as to come into play only at high load for the purpose of limiting the overload. In electrochemical service current regulators have been used to control the output at any voltage.

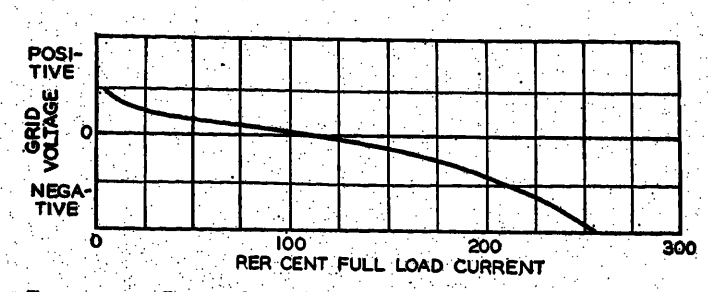

**Figure 6. Curve showing variation of grid pickup voltage with load current. Experimental rectifier**

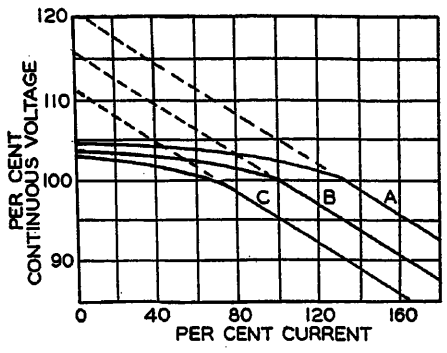
In considering voltage regulation by grid control, either automatic or otherwise, it is essential to keep in mind its chief limitations. The transformer must provide the maximum voltage desired and any reduction in voltage is accomplished, first, at the expense of an almost proportional reduction in power factor and, second, an increase in d-c harmonics. For these reasons it may in some cases be more desirable to regulate the output voltage over the normal range by an induction regulator in the primary or by tap changing under load. A combination of tap changing and grid control can be made to give continuous control and good power factor.

Inherent compensation or compounding can be used on a grid controlled rectifier or ignitron with results similar to compounding in a d-c generator. The action of such a compensator can be made practically instantaneous, thus eliminating the tendency to hunt or overshoot.



There are several methods of obtaining this compounding effect. One method is to use small series transformers, in the primary of the supply transformer, with a rectifier connected to the neutral of a sine-wave grid transformer. When adjusted for some grid delay at no load, the load current will cause an increase in positive bias which advances the phase and tends to raise the output voltage. This may be adjusted to compensate for the regulation of the transformer and line reactance or it may be made to more than compensate for the natural regulation, thus giving an overcompound regulation characteristic.

Another method of obtaining some compounding effect, and at the same time reducing the variation in continuous voltage due to variations in the a-c supply, is to connect the neutral of the grid transformer to the negative bus through a source of fixed positive bias. This gives a net bias on the grids which is proportional to the difference between the output voltage and the constant positive bias. An increase in output voltage will cause an increase in net negative bias and so increases the angle of delay and reduces the voltage. The sensitivity of this scheme will be limited by the lowest grid impulse voltage which may be used and still obtain accurate pickup of the anodes so as to insure balanced currents.

A combination of the 2 schemes of inherent regulation mentioned above may be used to give almost any regulation characteristic desired. Results similar to those discussed here were described in a recent paper by Goodhue and Power.[1] The method used by them differed in that they employed no grid transformer, but relied on the tube characteristics and the ripple of the output voltage to time the pickup of the anodes.

The regulation curves for an ignitron rectifier with current and voltage compensation are shown in figure 7. In this case as shown by the curves, the regulation is reduced from 17 per cent to 3.5 per cent and the variations in output voltage with the high line are reduced except at higher loads. The desirability of such characteristics for certain applications is obvious.

**Figure 7. Rectifier regulation curves, showing the effect of compounding to correct for a high reactive drop and variations in high line voltage**

Curves *A*, *B*, and *C* are for 104, 100, and 96 per cent high line voltage

## Conclusions

The following conclusions may be drawn from the work presented in this paper:

1. Accurate determination of the regulation of a rectifier connected to system, whose voltage is affected by the rectifier current, requires a modification of the conventional regulation formula as given in equation 2. The effect of the system reactance may also be taken into account by adding a correction term given by equation 6 and by the curves of figure 2.

2. With a normal amount of load inductance the conventional formula (equation 1) is not accurate at light loads where there is a counter electromotive force. This effect is much more pronounced with appreciable grid delay than at no delay. A graphical method of evaluating this effect is given and the results plotted in figure 5 as a correction term which is a function of delay and load circuit inductance. A comparison with test is given in figure 3. This is generally not important but may be corrected by adding inductance.

3. There is a tendency for the regulation curves of a rectifier, operating with a fixed phase-shifter or grid-bias setting, to curve up at overloads. This effect is due to the fact that with high ionization in the tank the grids pick up at a more negative voltage. The results of this effect on the regulation curves of the rectifier are shown in figure 1. This effect may be minimized by applying steep-wave-front impulses to the grids, or making a grid structure whose pickup voltage is only slightly affected by the amount of ionization in the tank.

4. Current and voltage regulators of the same general type as used for controlling the fields of rotating machines may be used to control the output voltage of grid-controlled rectifiers and ignitrons. It is also possible to use current and voltage compensation inherently to modify the regulation characteristics giving results similar to compounding on a d-c machine.

## List of Symbols

$A$ = arc drop
$e_d$ = instantaneous output voltage
$E$ = root-mean-square voltage anode to neutral, at no load
$E''$ = fundamental-frequency voltage back of system reactance
$E_c$ = counter electromotive force
$E_d$ = average output voltage
$E_{d0}$ = theoretical no-load output voltage
$f$ = fundamental frequency
$g$ = number of groups
$I$ = average total current output
$I_1$ = fundamental of secondary current
$L_t$ = total interphase inductance, from one transformer group to the other
$\mathfrak{L}$ = total output circuit inductance
$\mathfrak{L}_t$ = interphase leakage inductance, measured with windings in parallel, magnetomotive forces opposed
$P$ = number of phases per group
$P'$ = total number of phases for the rectifier
$u$ = angle of overlap
$W_T$ = copper loss of main and interphase transformers
$X_e$ = effective value of generator reactance to be used in rectifier calculations
$X_d''$ = direct-axis subtransient reactance
$X_q''$ = quadrature-axis subtransient reactance
$X_s$ = system commutating reactance converted to secondary ohms per phase
$X_T$ = transformer commutating reactance in ohms per phase in secondary
$X_2$ = negative-phase-sequence reactance
$\alpha$ = angle of retard or delay
$\Delta E_L$ = increase in voltage due to lack of inductance in load circuit
$\Delta E_s$ = increase in voltage regulation due to system reactance
$\theta_1$ = power factor angle of fundamental-frequency power

## Appendix A. Outline of a General Method of Analysis

The discussion of the paper has been confined to practical solutions which involved numerous assumptions and approximations. It is interesting therefore, to consider what might be done in the way of a more general solution taking into account many more factors. Although the mathematical formulas are not given, such a general method of analysis is outlined here in order to give a physical picture of what is involved and to aid in judging the simplifying assumptions made in the practical formulas.

The principle of superposition has been previously used[8] in the calculation of commutating currents. This principle can be extended to the solution of the currents and voltages in the complete rectifier system including both a-c and d-c circuits by solving a series of transient states. The a-c system impedance including capacity and resistance as well as reactance, may be accurately dealt with. Also the counter electromotive force, the inductance of the d-c system, and the shunt capacity of any filter circuits may be included in the analysis.

The only limitations of this method of analysis, other than the general limitation that the circuit constants must remain fixed are: (1) that the currents drawn by the rectifier being analyzed must have negligible effect on any other sources of harmonics such as those from another rectifier and, (2) that the arc drop is constant for a given value of average current. Where several similar rectifiers are connected to the same source and are similarly loaded they may be analyzed as if they were a single rectifier.

For this exact analysis the voltage on each anode at no load, and the actual angle of delay must be known. The picking up and the extinction of the arcs in the rectifier may be thought of as switching operations. In the analysis for any given condition the arc drop may be considered as a voltage source in series with each anode.

The ripple on the output voltage wave has a period equal to $1/P_1$ times the period of the fundamental frequency. This period may be further broken down into several time intervals, one for each different combination of anodes firing. The principle of superposition can be used in solving the transient within each interval. In general a transient resulting from a change in the circuit may be

solved by assuming an imaginary voltage equal and opposite to the applied no-load voltage so that the circuit may be left closed with no current flowing. A second imaginary voltage is then applied to cancel the first and to give the transient current.

When 2 anodes are firing they are in effect connected together. Using the above method the average of their no-load voltages opposed by the counter electromotive force for the load may be thought of as acting through the paralleled impedances of the transformer windings and their associated primary and system impedances, and through the load impedance.

An accurate analysis would require that equivalent circuits be constructed for the system as viewed from the rectifier terminals. It may also be necessary to set up an equivalent circuit for the load if there are several branches. If there are several sources of counter electromotive force an equivalent value may be obtained.

If the no-load voltages consist of several appreciable harmonics, as well as a suddenly applied fundamental, the equivalent circuit must be solved for each. If the harmonics are negligible the solution can be greatly simplified.

In order to determine the length of time an anode fires it is necessary to determine when the resultant current goes to zero. When the current reaches zero there is no reverse current (except in case of an arcback), hence the circuit is in effect switched open. The total current in an anode circuit is the resultant of the load component calculated as described above and a commutation current which is circulating due to the difference in voltages of any anodes that are firing at the same time. This commutating current can be solved by the same general methods outlined above, in which case the load circuit is not involved. The interphase transformer may be involved if the commutating current between 2 groups is considered, as in calculating the light-load voltage rise.

From this outline it is apparent that we can resolve the calculation of all voltages and currents involved into the solving of a series of transient states. Because it is necessary to determine the time intervals from the solutions for the total current in an anode, the mathematical determination of the boundary conditions may be difficult.

## Appendix B. Generator Reactance to Be Used in Rectifier Calculations

If a rectifier is fed from a single generator the generator adds to the commutating reactance increasing the angle of overlap and affecting the output voltage. The generator reactance drop to fundamental-frequency current may be added to the fundamental of the terminal voltage to get the internal sine-wave voltage. Using this internal voltage and the total commutating reactance the regulation can be calculated by the conventional formulas as indicated in the first part of the paper.

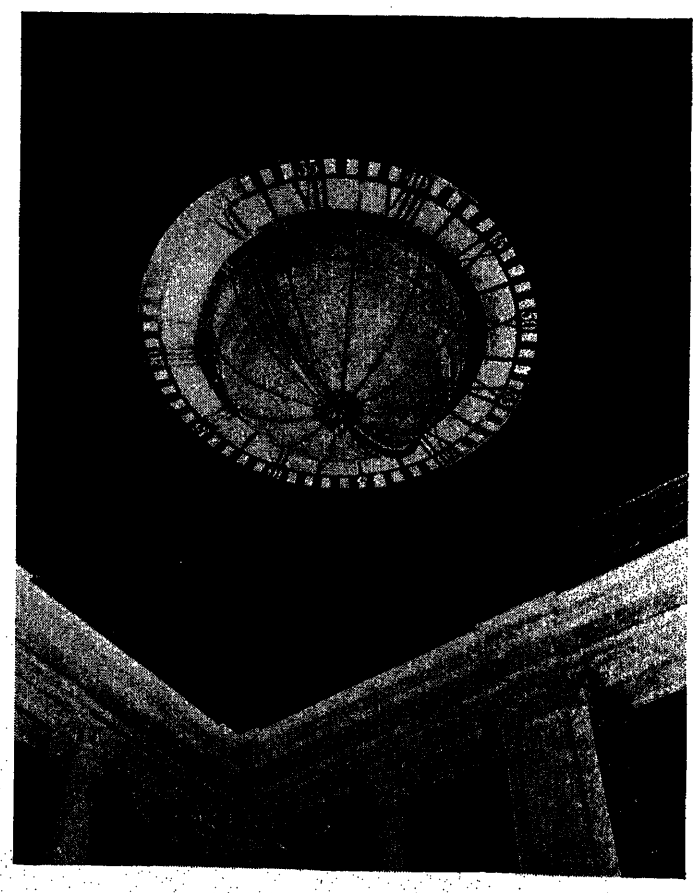
A question arises as to what generator reactance should be used. Since commutation is equivalent to a momentary short circuit the same reactance is effective as for the first fraction of a cycle of a single-phase short circuit. This reactance may vary between the direct-axis subtransient reactance ($X_d''$) and the quadrature-axis subtransient reactance ($X_q''$) depending on the load and the instant of short circuit. For zero delay and no load on the generator, $X_d''$ would be the value at the first instant of short circuit. For a delay angle $\alpha$, and load angle $\gamma$ between internal voltage and the terminal voltage, the effective reactance would be:

$$X_e = \frac{X_d'' + X_q''}{2} - \frac{X_q'' - X_d''}{2} \cos(2\alpha + 2\gamma) \qquad (1B)$$

If we use the method of symmetrical components to calculate the fundamental component of single-phase short circuit for a fundamental voltage applied, the effective reactance

$$X_e = \frac{X_d'' + X_2}{2} = \frac{3X_d'' + X_q''}{4} \qquad (2B)$$

This corresponds in the first equation to $\alpha + \gamma = 30$ degrees which is probably an average for conditions in which $\alpha$ does not exceed 30 degrees.



For the great majority of cases $X_d''$ and $X_q''$ will be so nearly equal that the approximate equation 2$B$, consistent with the method of symmetrical components, is sufficiently accurate and should be used.

## Unusual Electric Clock

BEAUTY and individuality are combined with utility in this unique terrestrial-globe electric clock hanging in the foyer of the Christian Science Monitor Building in Boston, Mass. Lights in the dial around the globe indicate the hours by large Roman numerals and minutes by the smaller Arabic numerals around the edge. A twin celestial globe at the other end of the foyer gives the day of the month. Both are driven by Telechron motors.

# Tension Measurement and Control in Cold-Strip Mills

By C. M. HATHAWAY ASSOCIATE AIEE M. MOHLER Member Assn. Iron and Steel Engrs.

## Introduction

THE COLD rolling of steel strip on tandem mills requires the measurement and control of tension in the strip, and to meet this requirement the tensiometer herein described has been developed. The tensiometer produces a continuous indication of the tension in the strip during the rolling operation, and functions in connection with auxiliary control equipment to automatically maintain the tension at any desired value. An additional function of the tensiometer is the instantaneous indication of any difference in tension between the 2 edges of the strip.

## Value of the Tensiometer

A brief outline of the process of cold-strip rolling and of the problem involved is as follows:

A tandem mill consists of 2 or more mill stands placed in line so that the strip passes from one mill directly into the other. It is highly desirable to maintain tension in the strip between these stands. Greater reductions can be obtained, a greater number of elongations can be made without intermediate annealing to soften the strip, and a flatter and smoother strip can be rolled if the proper tension in the strip is maintained. Furthermore, much can be done to compensate for defects in roll shape, strip lubrication, mill-housing stretch, etc., by properly manipulating the tension.

However, in order to control tension it must be measured, and the control cannot be more accurate than the measurement. So far only 2 methods have been discovered for measuring this tension. One method is by electrically measuring the input to the motor producing the tension, and the other is by means of the tensiometer to be described. A brief comparison of these methods of control follows.

### Input Control

The input to a motor can be measured by measuring the armature voltage and current, and if the voltage is constant, it is only necessary to measure the current. The current in the armature of the motor driving the mill stand is therefore a function of the tension in the strip, provided all the input to the motor goes into tension.

This is not the case in a tandem mill, however. In this case the rolling load may represent about 90 per cent, and the tension 10 per cent, of the motor input. It is hardly conceivable that the rolling load does not vary at least plus and minus 10 per cent. This is equivalent to a variation in tension of 200 per cent if the total input to the motor is maintained at 100 per cent by a current regulator. The difficulties involved in attempting to control the strip tension by means of motor input control are apparent.

### Mechanical Control

Because of the difficulties involved in controlling the strip tension by controlling motor input, various mechanical schemes of measuring tension have been tried, but the major difficulty with such devices has centered around the inertia of the moving parts. These devices usually involve a roller over which the strip passes in such a way that the strip tension produces a force on the roller. If the roller is resiliently mounted and connected to some device for measuring its displacement when the tension is applied, a measure of the tension can be obtained. If this roller has to move an appreciable distance troubles are experienced in high-speed rolling due to inertia forces of the roller itself, so that the strip tension could change considerably before the roller could be accelerated and moved to its new position. The tensiometer makes use of this general scheme but uses a sensitive electric gauge for measuring the roller deflections, so that very small deflections are required. The natural frequency of the roller can then be made high enough to eliminate troubles resulting from inertia of the moving parts.

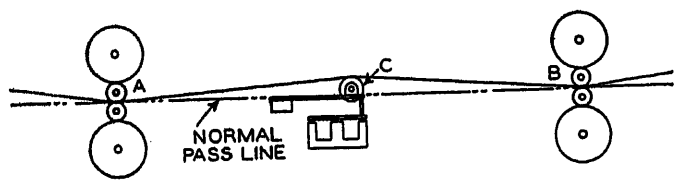

**Figure 1. Diagram showing location of pass roller C between 2 stands A and B**

### Level Indication

In addition to the tension problem, there has been a great need for some method of indicating whether the strip was the same thickness throughout its width. One edge can be measured with a flying micrometer but not the entire width. If one edge is the proper thickness and the tension is the same in both edges of the strip, it is reasonable to assume that the thickness of the other side is the same as that measured. If the other side is thicker, the tension will be greater on that side, and vice versa.

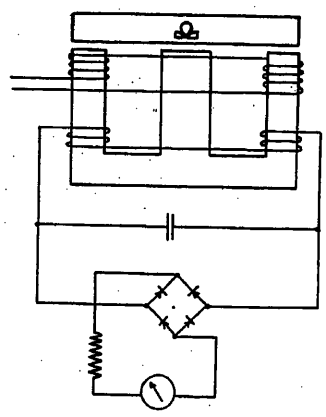
A paper recommended for publication by the AIEE committees on instruments and measurements and applications to iron and steel production. Manuscript submitted March 27, 1937; released for publication July 20, 1937.

C. M. Hathaway and M. Mohler are employed by the General Electric Company, Schenectady, N. Y.

This differential tension or "level" indication can also be obtained with the tensiometer.

## The Tensiometer

The need for a device for the measurement of total strip tension and of differences in tension between the 2 edges of the strip has been pointed out. The tensiometer produces a continuous indication of the total tension, provides a sensitive indication of any out-of-level condition, and operates in conjunction with standard control equipment to automatically maintain the total tension at any desired value by controlling the input to the mill motors. The tensiometer measures the total tension by measuring the force necessary to deflect the strip a given distance from the normal pass line. The strip as it passes from one mill to the next is caused to pass over a roller located so as to deflect the strip a small distance from the normal pass line. A force is thus produced on the roller at right angles to the normal pass line, and this force is proportional to the total strip tension. The arrangement is shown sche-



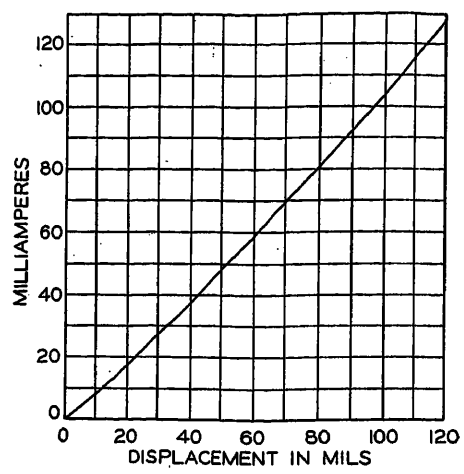


**Figure 2. Electric gauge for measurement of pass-roller deflection**

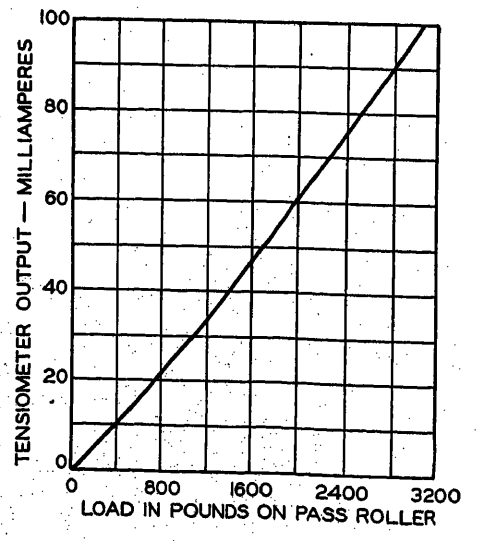
matically in figure 1 in which the strip is shown passing from *A* to *B* over the pass roller *C* of the tensiometer.



Each end of the pass roller *C* is mounted by means of antifriction self-aligning bearings on a stiff cantilever beam, and the deflection of each beam when load is applied to the pass roller is measured by means of an electric gauge. The electric gauge is a device capable of modulating or controlling an electric current in proportion to a small linear displacement. Each electric gauge has an output directly proportional to the deflection of the beam to which it is attached, and therefore, to the vertical load supported by the beam. The sum of the outputs of the 2 electric gauges is proportional to the total vertical load applied to the pass roller, and this is in turn proportional to the total strip tension if the deflections of the cantilever beams are small enough to be negligible in comparison to the elevation of the pass roller *C* above the normal pass line. The outputs of the 2 gauges are added by an instrument calibrated directly in thousands of pounds total strip tension. A second instrument is used to indicate any difference in output between the 2 gauges so that an indication can be obtained of any out-of-level condition that may exist in the mill.

**Figure 3. Electric gauge output current versus armature displacement**

The electric gauges used for the measurement of the deflection of the pass-roller supports consist of a stack of E-shaped laminations mounted adjacent to a laminated armature as shown in figure 2, so that a small air gap exists between the 2. The armature is supported at its center on knife-edge bearings, so that a movement of the armature on its bearings will increase the air gap at one end and decrease it at the other. On each of the outer legs is a primary and a secondary winding. The primary windings are connected in series across the a-c power source, and in such a direction that the resultant primary flux passes through the center leg. The secondaries are also connected in series, but in such a direction that the resultant flux due to a secondary current will flow around the outside of the laminated structure rather than through the center leg. With the primary and secondary windings connected in this manner, the induced voltage across the secondary terminals will be zero when the armature is in its mid-position and the air gaps at its ends are equal. For this condition, the voltages induced in the 2 secondary coils are equal and opposite. A displacement of the armature from this position will decrease one air gap and increase the other causing an unequal distribution of primary flux between the 2 secondary coils, and a voltage will appear across the secondary terminals that is a function of the armature displacement.

**Figure 4. Tensiometer output current versus pressure on pass roller**

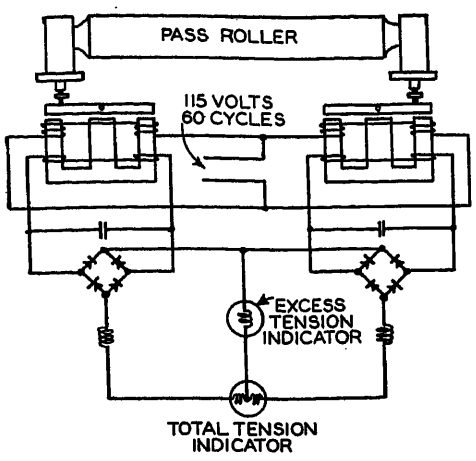


**Figure 5. Connection diagram of tensiometer indicating instruments**

The electric gauge unit can, therefore, be used to measure the deflection of the springs supporting the pass roller. The secondary output is rectified by a copper-oxide rectifier as shown in figure 2, and the rectified output is used to operate the indicating instrument and the control equipment. A capacitor across the secondary terminals greatly increases the sensitivity of the gauge because of the voltage rise produced by the passage of the leading current of the capacitor through the leakage reactance of the secondary.

The relationship between armature deflection from the neutral position and the rectified current in the secondary circuit is shown in figure 3. In figure 4 is shown the rectified current as a function of pressure on the pass roller as obtained by actual measurement on a typical tensiometer equipment.

If it is desired to indicate unequal tension between the 2 edges of the strip as well as the total tension, each end of the pass roller must be mounted on a separate spring and the deflection of each spring measured separately so that 2 electric-gauge units are required. The outputs of the 2 gauges can be added to obtain the total tension, and any difference between the outputs will be an indication of an out-of-level condition. These indications are obtained as shown in figure 5, in which *A* is the instrument for indicating total strip tension. This instrument carries 2 separate windings on its moving element. Each winding is connected in one of the detector unit circuits so that the instrument torque is proportional to the sum of the 2 electric-gauge outputs or to the total strip tension. Any difference in current between the 2 circuits will flow through the instrument *B* and will produce a sensitive indication of an out-of-level condition.

In some cases it may be desired to roll strip of a wide range of width and thickness in the same mill, and in such cases the total tension may vary over such wide limits that it is necessary to provide a means for changing the scale of the tensiometer. This could, of course, be done by changing the springs on which the pass roller is mounted when it is desired to change scales, but it can be done more easily by changing the mechanical ratio of the

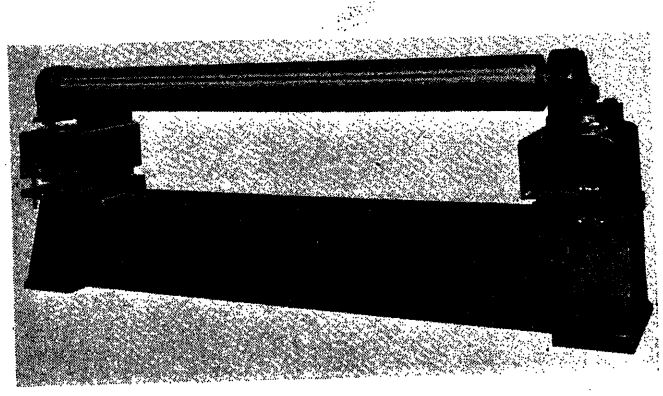

**Figure 7. Tensiometer stand with 93-inch pass roller**

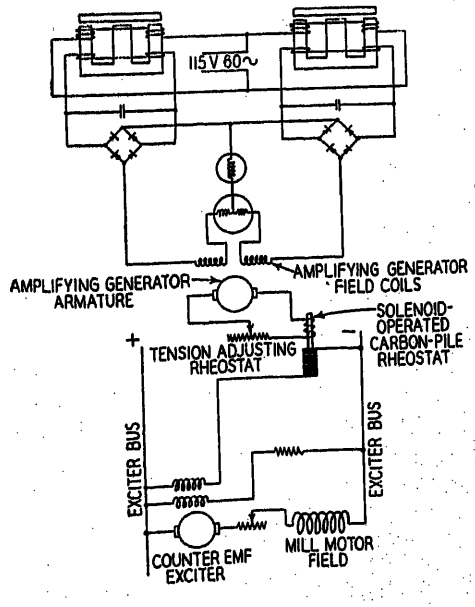

**Figure 6. Tension control system**

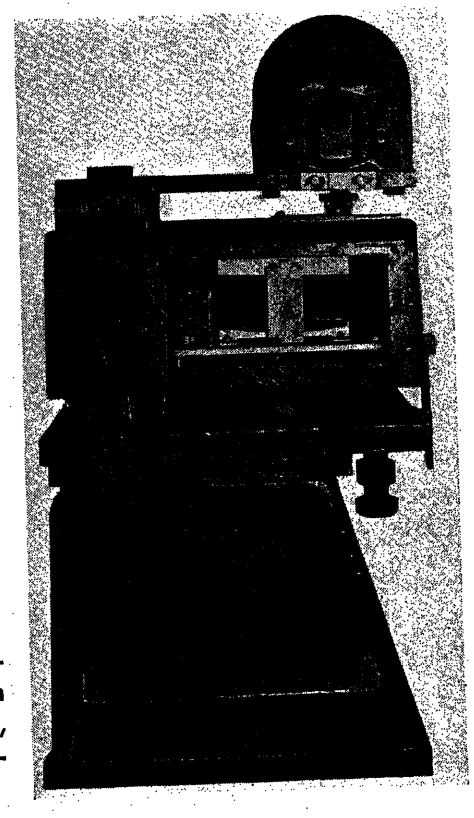

**Figure 8. Tensiometer stand with cover removed, showing electric-gauge unit**

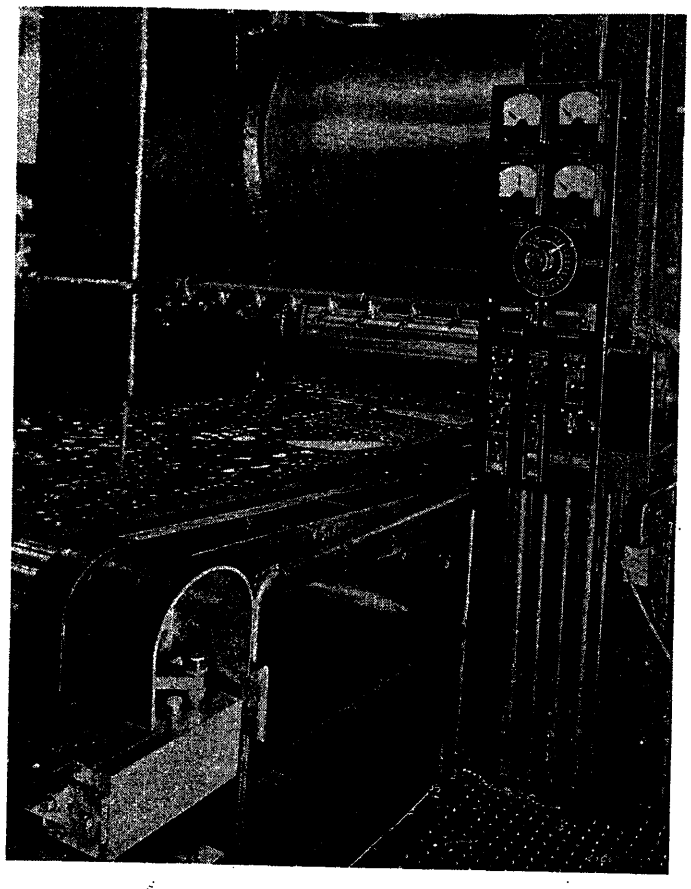

Figure 9. Tensiometer installation

linkage between the pass roller bearings and the electric-gauge armatures.

The upper element of the pass roller is located 2 or 3 inches above the normal pass line and the distance between stands is usually of the order of 10 or 20 feet. The diameters of the working rolls on the mills on each side of the tensiometer roller are not fixed but decrease with time due to wearing and resurfacing, so that the normal pass line is variable by as much as several inches. Provision must be made, therefore, for conveniently adjusting the elevation of the pass roller above the normal pass line, so that this value can be maintained at standard. To aid in making this adjustment, vernier height gauges are attached to each of the pass roller bearings. These gauges are calibrated directly in working-roll diameter, and must at all times be set to coincide with the average measured diameter of the 2 lower working rolls.

## Tension-Control System

A satisfactory control system for use in association with the tensiometer equipment for automatically maintaining the total strip tension at any desired value is shown schematically in figure 6. Referring to this figure the electric gauge outputs are amplified by means of a small 150-watt amplifying generator so that sufficient output is available for operation of a constant-current regulator. The regulator is used to control the field current in one winding of the counter-electromotive-force generator in the field circuit of the mill motor of the stand preceding the tensiometer.

## Typical Installations

In figure 7 is shown a tensiometer stand equipped with a pass roller 93 inches long. The electric-gauge units are enclosed in the steel boxes at each end of the roller, and the cantilever springs on which the pass roller is mounted are clearly shown. The cover is removed in figure 8, showing one of the electric-gauge units. Figure 9 shows a tensiometer and its associated control cabinet installed in a mill. One end of the tensiometer roller can be seen under the strip at the extreme left side of the photograph.

## Conclusions

A device termed a tensiometer has been described for the measurement of the tension in the strip during rolling in a cold-steel mill, and for the indication of any difference in tension between the 2 edges of the strip. The tensiometer can function in connection with auxiliary control equipment for the automatic maintenance of the total tension to any desired value. The value of tension measurement and "level" indication has been outlined, and the use of the tensiometer will aid to a more scientific study and operation of the cold-strip mill.

# "Science More or Less"

EVERY technical change brings about maladjustments, more or less serious depending on the number of people involved. Much more is involved than mere unemployment or the lowering of price to consumers. New processes may destroy the capital investments of sleeping corporations; they render men and equipment obsolete; they uproot whole industries and ways of life. To date, invention and scientific discovery have kept to the black side of the ledger; they have been credits to civilization. We should like to keep them there.

No one has yet solved the problems of human obsolescence, mass motivation, or technological unemployment. Unless our sociological inventiveness can show great improvement in the next 25 years we will not have made much progress no matter how pleasant and comfortable the air-conditioned lives of a few of us may be. I do not mean to imply that to get out of the woods we must have rigidly planned economy. The problem is much too complicated for that. The best plan in the world would be useless without the proper personnel, and with the proper personnel the plan, with its attending unpleasantness, is unnecessary. Education is far more important than coercion.

# Mechanical High-Speed Resistance-Welder Control

By F. H. ROBY
ASSOCIATE AIEE

*Operating speeds of 350 or more welds per minute are made practical with a new type of control equipment for pneumatically operated portable welding tools.*

A DEMAND for higher production rates in the automobile and related industries has resulted in the adoption of pneumatically operated portable type resistance welding machines.[1] Fully automatic repeat control devices are needed to obtain maximum operating speeds without sacrificing the quality of the welds. To be practical this control must be simple and inexpensive.

This paper is concerned with a control device developed for use in connection with a high-speed portable air-operated machine now commonly used in the automobile industry. The principles outlined apply as well to other types of equipment.

A "stitch" welder consists of a pneumatically operated welding tool, a solenoid-operated valve and a separate welding transformer connected to the tool by means of water-cooled cables, 6 feet or more in length. When the operator squeezes a momentary contact push button in the pistol-grip handle of the tool, the automatic control device closes the electrodes, applies power, disconnects it, opens the electrodes and keeps them open for a definite period of time before repeating the cycle. Repeat operation continues for as long as the push button is closed. The term "stitch" welder has been applied because of similarity to an electric sewing machine.

Those connected with the application of resistance welding to the fabrication of sheet metal are familiar with the principle upon which the art depends—that the heat generated in the weld is proportional to the product of the welding current squared, the resistance between pieces of work and the time during which the current flows.[2] Few realize the difficulties encountered in satisfactorily controlling these 3 variables.

The current is determined by selecting the turn ratio of the welding transformer by means of a tap switch on the primary side. The resistance of the weld decreases or increases as the pressure applied to the work increases or decreases, respectively, and is controlled by regulating that pressure. Timing has previously involved the use of expensive and complicated control equipment. A recent trend is toward simplified but more comprehensive control.

## Control Equipment Now Used

Electronic control devices (power interrupted by electronic tubes instead of magnetic contactors) are made to accurately control the period of time during which the welding current is allowed to flow.[3] These devices select the point on the current wave at which the circuit is made and broken. Such equipment is necessary for some special applications but the first cost is high and complicated circuits make highly trained maintenance men necessary.

Other less-expensive systems of control consist of a magnetic contactor and some form of timing device. The timer may be mechanical, electromagnetic, or electronic.[4,5,6] Most designs determine only the period of time during which the welding current flows. A few control the interval of time between welds as well as the welding period.

## Four Independent Timing Periods Required

Recent experience has made clear that the factor of time in the weld has 4 component parts. For purpose of identification these have been named "delay," "weld," "hold," and "off."

The "delay" period is the interval required between the operation of the solenoid valve and the application of power. Two conditions may result from insufficient time delay. If the electrodes are energized before they touch the work a "flash" will result, leaving the surface of the work mutilated and the electrodes damaged. If the electrodes are closed but are under insufficient pressure when power is applied, the weld will appear to be satisfactory but it will not hold. Reference to the thermal gradient chart (figure 1) will make clear that heat is generated at 3 points in the secondary circuit. If the pressure on the work is low when the transformer is energized, the heat generated at points *A* and *C* will be large compared to that generated at *B*. The surfaces of the work will be burned before the temperature at point *B* is raised to the fusion point.

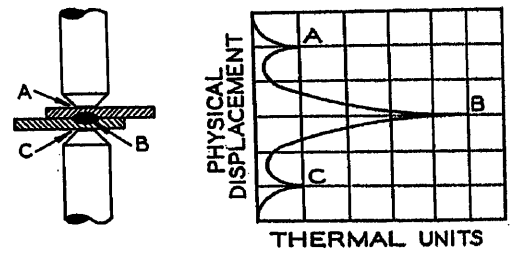

**Figure 1. Thermal gradient chart showing distribution of heat in weld**

Some manufacturers of welding equipment have recognized the need for obtaining a sufficient amount of pressure

A paper recommended for publication by the AIEE committee on electric welding. Manuscript submitted July 6, 1937; released for publication July 22, 1937.

F. H. Roby is a sales engineer for the Square D Company, Milwaukee, Wis.

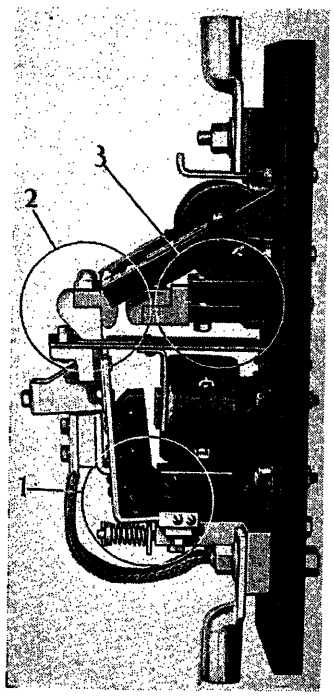

**Figure 2. Profile view of high-speed magnetic contactor**

on the electrodes within the shortest possible time and to this end have designed tools with favorable operating characteristics. Short strokes, large ports, and operating valves mounted as close to the tool as possible are essential. At least one automobile body manufacturer speeded up production by designing a solenoid valve in the handle of the tool itself, thereby eliminating the delay involved in building up pressure in the line between the valve and the tool.

A pressure switch is ordinarily connected in the air line in such a manner that the contacts of the switch close when the pressure on the operating piston has reached the desired value. The closing of the switch initiates the remainder of the welding cycle. Although satisfactory for most applications, the pressure switch has been eliminated from stitch-welder control. It represents an additional delay in the time required for the pressure to build up and exhaust in the line between the tool and the switch. Also, experience has determined that pressure switches will close prematurely because of turbulent air conditions, "slugs" of water in the line or because the electrodes are called upon to force together 2 or more pieces of work which have been formed improperly and do not fit perfectly. The solution of the problem lies in including in the control means for providing a definite time delay between the operation of the valve controlling the electrodes and the application of power. This period must be adjustable to compensate for the difference in the design of tools and the idiosyncrasies of the installation.

Much has been said about the "weld" time in other published information.[3,4,5,6] It is sufficient to point out that in the interest of high-speed production and improved welds, this period has been continually shortened until 5-cycle welds (60-cycle frequency) are considered average in industries using sheet metal ranging in thickness from 12 to 22 gauge. Shortened timing periods give less time for the heat generated in the weld to be conducted to the surface of the metal, thereby defacing or deforming the work.

In general, "fixed" timing is used. There is little need for "current responsive" timing which, in one manner or another, compensates for variations in the welding current.[5] The value of this current is essentially predetermined by the secondary voltage and the short-circuited impedance of the secondary circuit. The resistance of the weld itself has little effect on the impedance of the circuit formed by a pair of electrodes at the end of 2 cables at least 6 feet in length. Then, too, high-grade body stock is not usually subject to scale, rust, or other imperfections which materially influence the resistance of the weld. Changes in resistance of the weld affect results because of the presence of the resistance factor in the heat equation. Even accurate compensation for minor current changes would not alter this condition.

The shortest timing period practical when magnetic contactors are used to interrupt the primary of the welder transformer is between 2 and 3 cycles. There are 3 limitations. The so-called high-speed welder contactor requires slightly less than a cycle to close after the operating coil has been energized, and a little more than a cycle to open after it has been de-energized. If a contactor, when once closed, remains so for over a cycle, it cannot be used to energize a transformer for a period of time less than this amount. In fact, a longer period of time should be allowed to insure that the pole pieces of the magnet seal each operation. Otherwise, extremely erratic performance will result.

Secondly, magnetizing current transients[3,7] which result when the transformer is energized at the zero point of the voltage wave, cause wide variations in results if shortened timing periods are used. One welder application studied had peak primary currents of 217 and 1,030 amperes, respectively, on 2 consecutive spot welds. Without a doubt, this case is extreme but it serves to illustrate a limiting factor in shortened weld periods. The transient currents contribute to a lowered secondary voltage and a "cold" spot is the result. Fortunately, such transients die out along an exponential curve with a very steep characteristic, and they are effective for only one or 2 cycles.

Finally, a magnetic contactor will not respond accurately to a given electrical impulse unless that impulse begins each operation at the same point on the reference voltage wave. Otherwise, the transient in the operating coil may cause the contactor to fail to respond.

One solution to the transient problem is the use of a control device having electronic tubes as interrupters instead of magnetic contactors. The point at which the circuit

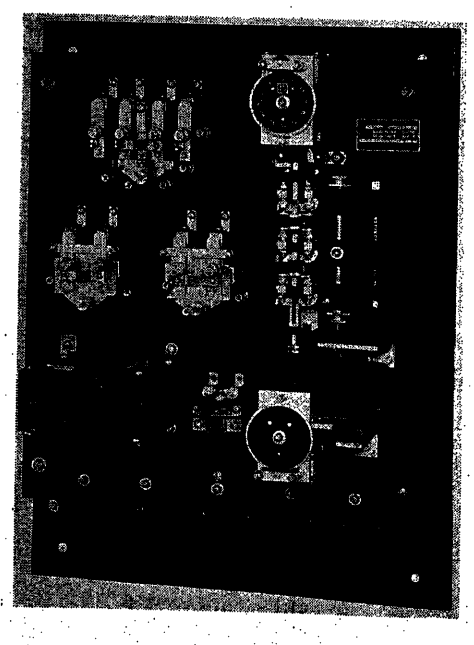

**Figure 3. Mechanical high-speed resistance-welder control unit**

is made and broken can then be controlled. The use of such complicated and expensive control equipment is not necessary when ordinary ferrous metals are being welded because the plastic range of the metal is wide enough to absorb reasonable variations in control. The timing period can be lengthened to 3 or more cycles to make the variations small when compared to the total.

The design of a magnetic contactor which will consistently perform at the rate of 350 or more operations per minute and will have the operating characteristics needed for short timing is a problem in itself. Long mechanical life, immediate interruption of the arc, rapid operation, and accessibility are imperative. The high-speed heavy-duty welder contactor illustrated (figure 2) has knife edge bearings (1); short gap (2); strong blowout coil and large copper contacts with gap adjustment (3).

The "hold" time is the interval least discussed in the timing cycle and yet is one of the most importance. Until recently, it was general practice to de-energize the operating coils of the welding contactor and the solenoid valve at the same instant. It was assumed that the welding contactor would open before the electrodes parted. Such practice was effective for as long as tools were sluggish and exhaust lines restricted. Modern tools, with valve in the handle, open as fast or faster than the welding contactor, making a predetermined "hold" time necessary.

When the electrodes are allowed to remain on the work a period of time after the power is off, the appearance of the weld is improved. The water-cooled electrodes conduct away the heat as it comes to the surface, thereby preventing abnormal discoloration. A weld allowed to cool under pressure also has finer grain structure and greater strength.

Two additional advantages of "hold" time have made themselves apparent in the automobile industry. Welds made on pieces of work not properly fitted together are prevented from breaking open before the weld is cooled below the plastic stage and heat is prevented from traveling ahead of the spot being welded. The electrodes of the tool are apt to stick to the surfaces of work made plastic by heat from a weld immediately adjacent.

The "off" period needs little discussion. When repeat operation is desired, the operator continues to hold down the momentary contact push button in the handle of the tool and the timing device regulates the period during which the electrodes remain open before the cycle is repeated. The minimum "off" time is determined by the interval required to open the gun and the delay involved in moving the tool to a point at which the next weld is to be made.

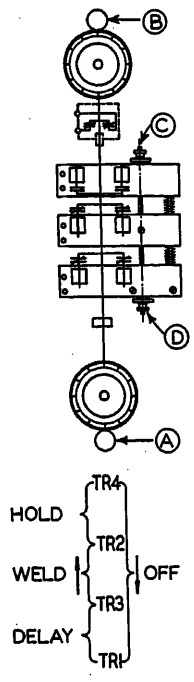

**Figure 5. Graphical representation of control adjustments**

## Description of Control Unit

The need for separately adjustable timing periods is clear. To obtain them without seriously complicating the control device has presented a problem. One solution is illustrated in figure 3. The nucleus of the device is formed by 2 diaphragm-type pneumatic time-delay assemblies joined by means of a rod upon which a series of contacts is mounted. With the rod in its normal position, the top diaphragm *A* of the lower assembly (figure 4) is cupped downward, forcing the air in the upper chamber down through the spring-held release valve *B*. Lower diaphragm *C* responds to the movement of the top diaphragm confining the air to the lower chamber and making it unnecessary to expose the mechanism to the danger of faulty operation because of dust or other foreign matter in the air surrounding the installation. When force is applied to the contact rod, tending to move it upward, air must be drawn into the upper chamber from the lower one. Because valve *B* has seated itself the only possible passage is regulated by needle valve *D*. A similar mechanism coupled to the upper end of the rod regulates its downward travel.

The interval off time required for the rod to complete its upward stroke must be long enough to include the "delay," "weld," and "hold" periods (figure 5). The "off" period is determined by the interval required for the rod's return to its initial position.

Once the rod speed has been established, adjustment *C* can be regulated to provide spacing between contacts *TR*2 and *TR*3 and obtain the "weld" time needed. Adjustment *D* proportions the "delay" and "hold" periods to meet the requirements of the application. The "weld" time is not changed by this adjustment inasmuch as contacts *TR*2 and *TR*3 are moved the same amount.

## Schematic Diagram of Circuit

Figure 6 is a schematic diagram of the electrical connections used. Closing the push button energizes control relay *CR*1 which in turn applies power to the check valve and the operating coil of control relay *CR*2. This relay energizes the solenoid operated 4-way valve which applies air to the tool and also connects the operating coil of timing relay *TR*1 to the line. The armature of the timing relay magnet closes instantly, compressing a spring which applies force to the contact rod. Timing is, therefore, independent of voltage.

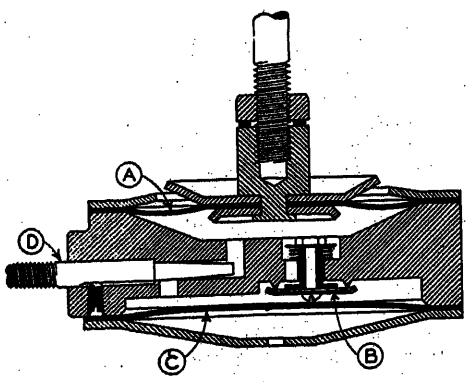

**Figure 4. Cross-sectional view of time-delay unit**

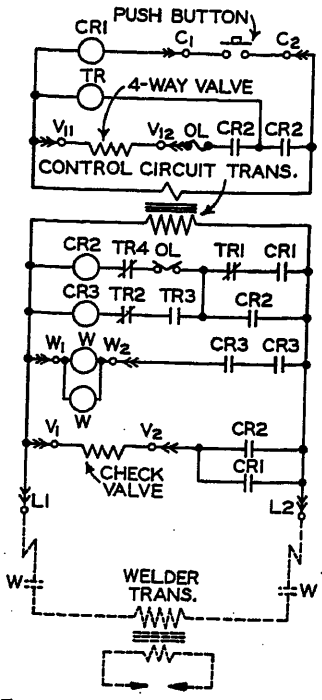

**Figure 6. Schematic diagram of electrical connections**

During the upward travel of the rod, contact *TR*1 is opened first, disconnecting the pole of relay *CR*1 which functions from the push button. Operation continues because relay *CR*2 has formed its own maintaining circuit. Later in the rod travel contact *TR*3 closes, energizing relay *CR*3 which in closing energizes the magnetic contactor that applies power to the machine. Still later contact *TR*2 opens, dropping out relay *CR*3 and de-energizing the welding contactor. The pressure on the electrodes is not removed until the rod reaches the end of its upward travel, opening contact *TR*4 and de-energizing control relay *CR*2. The cycle is not repeated again until the rod is returned to its initial position, reclosing contact *TR*1.

Features not ordinarily required can be included in the control device. The installation of a check valve to close the air-supply line during the period in which the tool is not in use is not difficult. Double action air cylinders are ordinarily used to speed up operation and considerable leakage occurs in the head end of such cylinders.

A low-voltage transformer large enough to supply the solenoid operating valve can be mounted on the panel. It is considered good practice to energize the valve solenoid from a low-voltage supply source if it is located in the handle of the tool where a ground would endanger the operator. To prevent the burning out of the valve solenoid if it should lodge in the open position, a thermal protective device can be included in the circuit.

Maintenance is simplified by the use of a separable connector on the panel to make it unnecessary to disconnect any wiring if the panel is removed. Panels can be interchanged with minimum delay and repairs or adjustments on the defective unit can be made later in the electrician's shop.

## Test Procedure

The information contained in this paper has been verified in a series of field tests conducted by one of the large automobile-body manufacturers. A cathode-ray oscillograph was used to analyze the various components of the timing period previously described. The circuit of the oscillograph was arranged to show simultaneously on the viewing screen 4 elements of the weld cycle. To accomplish this the a-c voltage applied to the solenoid-operated air valve was fed through a rectifier to the vertical plates of the cathode-ray tube. A second a-c signal having as its source the voltage drop across the work itself was applied directly to the same set of plates. Horizontal plates of the cathode-ray tube were energized from a sweep circuit which forms a part of the oscillograph. A pattern similar to that illustrated in figure 7 resulted. Synchronizing contacts on the control device being studied caused the image to appear at the same place on the screen each operation.

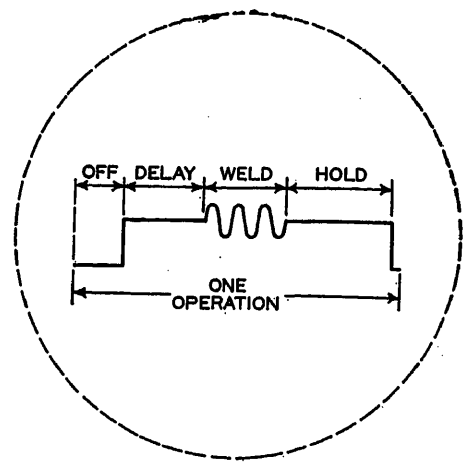

**Figure 7. Representation of oscillograph screen showing method of measuring weld cycle.**

Practical problems in welding were considered and a theoretical solution to each problem was advanced. Adjustment of the timing device to meet the specifications outlined in the theoretical solution was accomplished with the aid of the oscillograph. Samples of materials were welded and results checked. In each instance it was determined that satisfactory welds could be made if the 4 component parts of the welding cycle were properly proportioned. At least 25 installations of the type described have been in operation for several months on an automobile-body assembly line. Reports indicate that the conclusions reached during laboratory tests were justified.

## Conclusions

Under laboratory controlled conditions good welds have been made at the rate of 600 per minute. Commercial results will depend upon the design of the equipment being used and the application involved. It is certain, however, that good welds will be made at the maximum rate only if each portion of the welding cycle is accurately and independently controlled.

# Double-Line-to-Neutral Short Circuit of an Alternator

By JAMES B. SMITH
NONMEMBER AIEE

CORNELIUS N. WEYGANDT
ASSOCIATE AIEE

*Starting with R. H. Park's formulas for the flux linkages of an ideal synchronous machine, the case of a fault from 2 line terminals of a generator to neutral is treated in a manner similar to that used by Doherty and Nickle for other unsymmetrical faults. Expressions are given for the armature currents in the faulted phases and for the main field current, at any time after the short circuit. An expression for the voltage across the open phase a short time after the fault is also developed.*

## Introduction

THE PROBLEM of short circuits at the terminals of synchronous machines is one that has been studied extensively for a number of years. R. H. Park[1] has given a rigorous solution of the 3-phase symmetrical fault, and Doherty and Nickle[2] have developed expressions for the currents flowing during single-phase short circuits both between lines and from line to neutral which give excellent checks with experimental results. The present paper derives similar expressions for currents flowing in a machine when 2 lines are faulted to neutral. Park's formulas for the armature and field flux linkages of an ideal synchronous machine are used as a starting point. They are simplified by the additional assumption that all resistances are negligible. Decrement factors are applied to the resulting expressions for current and voltage in a manner analogous to that used by Doherty and Nickle. The final formulas are found to give results which are in good agreement with experiment.

The basic assumptions made in the treatment of this problem are:

1. The assumptions made by R. H. Park in his definition of an ideal synchronous machine.[5]
2. That the resistances of all field and armature circuits are negligible except where they appear in decrement factors.
3. That the speed of the rotor is constant at all times.

The second assumption is equivalent to saying that the flux linkages in both the direct and quadrature axes remain constant, that is, the effects of the terms $p\psi_d$ and $p\psi_q$ of reference 1 are neglected. If this assumption were strictly adhered to, the initial values of the currents as given by equations 11 would persist indefinitely. We know, however, that if assumption 2 were not made the fluxes and consequently the currents would decrease according to certain decrement factors obtained from the roots of a determinantal equation arising in the solution of equations 11, 12, and 13 of reference 1. Since in the case of a double-line-to-neutral fault this equation cannot be solved algebraically these decrement factors are obtained approximately and applied to the appropriate terms of equations 11. This treatment should not produce much error unless either the decrement factor of some circuit or the armature circuit resistance is large.

The third assumption should not introduce much error except in the case of a machine with a small moment of inertia which might slow down appreciably at the instant of short circuit.

The machine is considered to have 2 field circuits in the direct axis, referred to as the main and the additional field. In the quadrature axis there is no main field, so only the additional (amortisseur) field is present. Direct current excitation is applied only in the main field.

The short circuit is assumed to occur directly at the terminals of the machine at a time when it is carrying no load. If the short circuit occurred through external reactance this reactance could be added to the direct- and quadrature-axis reactances and the sums used in equations 35. If there is much external resistance the equations of this paper cannot be used because of assumption 2.

## System of Units

All quantities said to be in armature terms are in a per-unit system based on the following normal values:

$e_n$ = rated phase voltage of the machine in volts
$i_n$ = rated phase current in amperes
$X_n = r_n = \frac{e_n}{i_n}$ = normal reactance or resistance in ohms
$\omega_n = 2\pi f_n$ = normal angular velocity in radians corresponding to a normal frequency of $f_n$ cycles
$L_n = \frac{X_n}{\omega_n}$ = normal inductance in henrys
$\psi_n = L_n I_n$ = normal flux linkages in volt seconds

The term "per unit" means that the quantity in question is expressed as a fraction of the appropriate normal value. Note that at normal frequency per-unit reactance equals per-unit inductance. The symbol $x$ as used in the paper can therefore be thought of as either an inductance or a reactance, whichever is most convenient.

For reasons that will be brought out later it is sometimes convenient to express quantities in field terms. Quantities said to be in main field terms have the following normal values:

$E_{fn} = \frac{e_n R_{fd}}{x_{afd}}$ = voltage in volts which if connected to main field terminals will cause normal field current to flow

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted April 30, 1937; released for publication July 30, 1937.

JAMES B. SMITH is employed by the Associated Factory Mutual Fire Insurance Companies, Boston, Mass., and CORNELIUS N. WEYGANDT is an instructor in electrical engineering at the University of Pennsylvania, Philadelphia. The authors wish to acknowledge the help of Professor J. C. Balsbaugh, of the Massachusetts Institute of Technology, under whose direction the work leading up to the present paper was first undertaken, and also to thank Mr. S. B. Crary, of the General Electric Company, for his interest and helpful suggestions.

1. For all numbered references, see list at end of paper.

where

$R_{fd}$ = per-unit resistance of the main field in armature terms
$x_{afd}$ = per-unit mutual inductance of the armature with the main field in armature terms
$I_{fn} = \frac{i_n}{x_{afd}}$ = normal main-field current, that is main-field current which will produce rated terminal voltage on open circuit

$R_{fn} = \frac{e_n}{i_n} R_{fd}$ = normal main-field resistance

Quantities said to be on additional field terms are based on similarly defined normal values except that the subscript $f$ is replaced by one.

To change a per-unit quantity from one system to another simply multiply the per-unit quantity in the old system by the ratio of its normal value in the old system to its normal value in the new system. Thus for example:

$$I = I_{fd} \times \frac{i_n}{I_{fn}} = x_{afd} I_{fd}$$

where:

$I$ = main-field current in main-field terms, direct axis
$I_{fd}$ = main-field current in armature terms, direct axis

## Development of General Equations

Let the following symbols represent per-unit quantities in armature terms:

$\psi_a, \psi_b, \psi_c$ = armature phase flux linkages in phases $a$, $b$, and $c$
$i_a, i_b, i_c$ = armature phase currents in phases $a$, $b$, and $c$
$x_d'', x_d', x_d$ = subtransient, transient, and synchronous reactances in the direct axis
$x_q'', x_q', x_q$ = subtransient, transient, and synchronous reactances in the quadrature axis
$x_0$ = zero-sequence reactance
$\theta$ = angular position of the rotor in degrees measured from the axis of phase $a$
$e$ = open-circuit terminal voltage for one phase
$r$ = resistance of one armature phase

Let the following symbols represent per-unit quantities in main field terms:

$I$ = current in main field, direct axis
$E$ = excitation voltage in main field, direct axis. It is also numerically equal to the sustained steady state d-c current in main field, direct axis

Let the following symbols represent per-unit quantities in additional field terms:

$I_{d1}$ = current in additional field, direct axis
$I_{q1}$ = current in additional field, quadrature axis

It is also convenient to talk about the total excitation due to all fields in an axis. In terms of the above defined quantities there is:

$I_d = I + I_{d1}$ = excitation in direct axis
$I_q = I_{q1}$ = excitation in quadrature axis

Park gives the following formulas for armature flux linkages:

$$\psi_a = I_d \cos\theta - I_q \sin\theta - \frac{x_0}{3}(i_a + i_b + i_c) - \frac{x_d + x_q}{3}\left(i_a - \frac{i_b + i_c}{2}\right) - \frac{x_d - x_q}{3}[i_a \cos 2\theta + i_b \cos(2\theta - 120) + i_c \cos(2\theta + 120)] \quad (1a)$$

$$\psi_b = I_d \cos(\theta - 120) - I_q \sin(\theta - 120) - \frac{x_0}{3}(i_a + i_b + i_c) - \frac{x_d + x_q}{3}\left(i_b - \frac{i_c + i_a}{2}\right) - \frac{x_d - x_q}{3} \times [i_a \cos(2\theta - 120) + i_b \cos(2\theta + 120) + i_c \cos 2\theta] \quad (1b)$$

$$\psi_c = I_d \cos(\theta + 120) - I_q \sin(\theta + 120) - \frac{x_0}{3}(i_a + i_b + i_c) - \frac{x_d + x_q}{3}\left(i_c - \frac{i_a + i_b}{2}\right) - \frac{x_d - x_q}{3}[i_a \cos(2\theta + 120) + i_b \cos 2\theta + i_c \cos(2\theta - 120)] \quad (1c)$$

When the assumption is made that $r = 0$, equations 4$a$ and 5 of reference 1 become:

$$I_d = E + (x_d - x_d'')i_d \quad (2)$$

$$I_q = (x_q - x_q'')i_q \quad (3)$$

where

$$i_d = \frac{2}{3}[i_a \cos\theta + i_b \cos(\theta - 120) + i_c \cos(\theta + 120)] \quad (4)$$

$$i_q = -\frac{2}{3}[i_a \sin\theta + i_b \sin(\theta - 120) + i_c \sin(\theta + 120)] \quad (5)$$

also in the per-unit systems used

$$E = e \quad (6)$$

After substituting equations 2 to 6 into equations 1 there results:

$$\psi_a = e\cos\theta - \frac{x_0}{3}(i_a + i_b + i_c) - \frac{x_d'' + x_q''}{3}\left(i_a - \frac{i_b + i_c}{2}\right) - \frac{x_d'' - x_q''}{3}[i_a \cos 2\theta + i_b \cos(2\theta - 120) + i_c \cos(2\theta + 120)] \quad (7a)$$

$$\psi_b = e\cos(\theta - 120) - \frac{x_0}{3}(i_a + i_b + i_c) - \frac{x_d'' + x_q''}{3}\left(i_b - \frac{i_c + i_a}{2}\right) - \frac{x_d'' - x_q''}{3}[i_a \cos(2\theta - 120) + i_b \cos(2\theta + 120) + i_c \cos 2\theta)] \quad (7b)$$

$$\psi_c = e\cos(\theta + 120) - \frac{x_0}{3}(i_a + i_b + i_c) - \frac{x_d'' + x_q''}{3}\left(i_c - \frac{i_a + i_b}{2}\right) - \frac{x_d'' - x_q''}{3}[i_a \cos(2\theta + 120) + i_b \cos 2\theta + i_c \cos(2\theta - 120)] \quad (7c)$$

If $\theta_0$ is the angular position of the rotor at the last instant before short circuit, then at that instant

$$\psi_a = e\cos\theta_0$$
$$\psi_b = e\cos(\theta_0 - 120)$$
$$\psi_c = e\cos(\theta_0 + 120) \quad (8)$$

since because of our assumption that the armature resistance is negligible the flux linkages before the short circuit must equal the flux linkages after the short circuit. When equations 7$a$, 7$b$, 7$c$, and 8 are combined and solved for

$i_a$ and $i_b$ under the special condition for a double-line-to-neutral fault, $i_c = 0$, there results:

$$i_a = \frac{1}{2}\sqrt{3}e\left\{\frac{(x_d'' + x_q'')[\cos(\theta - 30) - \cos(\theta_0 - 30)]}{D} + \frac{(x_d'' - x_q'')[\cos(2\theta - \theta_0 - 30) - \cos(\theta - 30)]}{D} + \frac{2x_0[\cos(\theta + 30) - \cos(\theta_0 + 30)]}{D}\right\} \quad (9a)$$

$$i_b = \frac{1}{2}\sqrt{3}\,e\left\{\frac{(x_d'' - x_q'')\,[\cos(\theta - 90) - \cos(\theta_0 - 90)]}{D} + \frac{(x_d'' - x_q'')\,[\cos(2\theta - \theta_0 - 90) - \cos(\theta - 90)]}{D} - \frac{2x_0\,[\cos(\theta + 30) - \cos(\theta_0 + 30)]}{D}\right\} \quad (9b)$$

where

$$D = x_d''\left(x_0 + \frac{1}{2}x_q''\right) + x_q''\left(x_0 + \frac{1}{2}x_d''\right) + \left[x_d''\left(x_0 + \frac{1}{2}x_q''\right) - x_q''\left(x_0 + \frac{1}{2}x_d''\right)\right]\cos(2\theta + 60) \quad (10)$$

It can be seen that each of the phase currents is made up of 3 components. Each of these components may be expanded into a harmonic series by assuming a Fourier series and finding the appropriate coefficients. When this work is carried out there results:

$$i_a = \frac{1}{2}\sqrt{3}e\,[M(x_d'' + x_q'')(A_{ep} + A_{0p}) + M(x_d'' - x_q'') \times (A_{en} + A_{on}) + Mx_0(A_{e0} + A_{00})] \quad (11a)$$

There is a similar expression for $i_b$:

$$i_b = \frac{1}{2}\sqrt{3}e\,[M(x_d'' + x_q'')(B_{ep} + B_{0p}) + M(x_d'' - x_q'') \times (B_{en} + B_{on}) - Mx_0(A_{e0} + A_{00})] \quad (11b)$$

where

$$M = \frac{1}{2\sqrt{x_d''\left(x_0 + \frac{1}{2}x_q''\right)x_q''\left(x_0 + \frac{1}{2}x_d''\right)}}$$

$$A_{ep} = -2\cos(\theta_0 - 30)\left(\sum_{n=2}^{\infty} b^{\frac{n}{2}}\cos n(\theta + 30) + \frac{1}{2}\right)$$

The subscripts indicate that this is the series of even harmonics which is multiplied by $x_d''$ plus $x_q''$.

$$A_{0p} = +\frac{1}{2}(1 + b)\sum_{n=1}^{\infty} b^{\frac{n-1}{2}}\cos n(\theta + 30) + \frac{1}{2}\sqrt{3}(1 - b)\sum_{n=1}^{\infty} b^{\frac{n-1}{2}}\sin n(\theta + 30)$$

$$A_{en} = +\cos\theta_0(1 - b^2)\sum_{n=2}^{\infty} b^{\frac{n-2}{2}}\sin n(\theta + 30) - b\sin\theta_0 - \sin\theta_0(1 + b^2)\sum_{n=2}^{\infty} b^{\frac{n-2}{2}}\cos n(\theta + 30)$$

$$A_{0n} = -A_{0p}$$

$$A_{e0} = -4\cos(\theta_0 + 30)\left[\sum_{n=2}^{\infty} b^{\frac{n}{2}}\cos n(\theta + 30) + \frac{1}{2}\right]$$

$$A_{00} = 2(1 + b)\sum_{n=1}^{\infty} b^{\frac{n-1}{2}}\cos n(\theta + 30)$$

$$B_{ep} = -2\cos(\theta_0 - 90)\left[\sum_{n=2}^{\infty} b^{\frac{n}{2}}\cos n(\theta + 30) + \frac{1}{2}\right]$$

$$B_{0p} = -\frac{1}{2}(1 + b)\sum_{n=1}^{\infty} b^{\frac{n-1}{2}}\cos n(\theta + 30) + \frac{1}{2}\sqrt{3}(1 - b)\sum_{n=1}^{\infty} b^{\frac{n-1}{2}}\sin n(\theta + 30)$$

$$B_{en} = +\cos(\theta_0 + 60)(1 - b^2)\sum_{n=2}^{\infty} b^{\frac{n-2}{2}}\sin n(\theta + 30) - b\sin(\theta_0 + 60) - b\sin(\theta_0 + 60) - \sin(\theta_0 + 60)(1 + b^2) \times \sum_{n=2}^{\infty} b^{\frac{n-2}{2}}\cos n(\theta + 30)$$

$$B_{0n} = -B_{0p}$$

$$b = \frac{\sqrt{x_q''\left(x_0 + \frac{1}{2}x_d''\right)} - \sqrt{x_d''\left(x_0 + \frac{1}{2}x_q''\right)}}{\sqrt{x_q''\left(x_0 + \frac{1}{2}x_d''\right)} + \sqrt{x_d''\left(x_0 + \frac{1}{2}x_q''\right)}}$$

Only odd values of $n$ are to be used in the summations from $n$ = one to $n = \infty$. Only even values of $n$ are to be used in the summations from $n = 2$ to $n = \infty$. Doherty and Nickle have shown in the case of single-phase short circuits that all d-c and even harmonic terms in the armature current die to zero according to a time constant depending on constants of the armature. Odd harmonic terms die to a steady state value according to time constants depending on constants of the field circuits. In the double-line-to-neutral short there are 3 armature time constants, one to be used with the even harmonic terms of each of the components of the armature current. Before proceeding with the derivation of these time constants it will first be necessary to find an expression for the field current.

## Field Current

Let the following symbols represent per-unit quantities in armature terms:

$\psi_{fd}$ = flux linkages with the main field
$\psi_{1d}$ = flux linkages with the additional field
$I_{fd}$ = main-field current
$I_{1d}$ = additional field current
$i_d$ = current flowing in the direct-axis armature circuit
$X_{ffd}$ = self-inductance of main field
$X_{f1d}$ = mutual inductance of main field with additional field
$X_{11d}$ = self-inductance of additional field, direct axis
$x_{afd}$ = mutual reactance of armature with main field
$x_{a1d}$ = mutual reactance of armature with additional field
$E_{fd}$ = voltage across main-field terminals
$R_{fd}$ = resistance of main field
$R_{11d}$ = resistance of additional field

Waring and Crary[3] have given expressions for the field flux linkages in armature terms. In the main field, direct axis:

$$\psi_{fd} = X_{ffd}I_{fd} + X_{f1d}I_{1d} - x_{afd}i_d \tag{12}$$

and in the additional field, direct axis:

$$\psi_{1d} = X_{f1d}I_{fd} + X_{11d}I_{1d} - x_{a1d}i_d \tag{13}$$

before the fault

$$\psi_{fd} = E_{fd}/R_{fd}X_{ffd} \tag{14}$$

$$\psi_{1d} = E_{fd}/R_{fd}\,X_{1fd} \tag{15}$$

Assuming constant flux linkages these four equations may be solved simultaneously and there results:

$$I_{fd} = \frac{E_{fd}}{R_{fd}} - \frac{X_{a1d}X_{f1d} - x_{afd}X_{11d}}{X_{11d}X_{ffd} - X_{f1d}^2}\,i_d \tag{16}$$

$$I_{1d} = -\frac{x_{afd}X_{f1d} - x_{a1d}X_{ffd}}{X_{11d}X_{ffd} - X_{f1d}^2}\,i_d \tag{17}$$

Equations 16 and 17 can be rewritten in individual field terms and there results:

$$I = E - \frac{X_{a1d}X_{f1d} - x_{afd}X_{11d}}{X_{11d}X_{ffd} - X_{f1d}^2}\,(x_{afd})i_d = E + A_{fd}x_d i_d \tag{18}$$

$$I_{d1} = -\frac{X_{afd}X_{f1d} - x_{a1d}X_{ffd}}{X_{11d}X_{ffd} - X_{f1d}^2}\,(x_{a1d})i_d = A_{1d}x_d i_d \tag{19}$$

If 16 is multiplied by $x_{afd}$ and 17 by $x_{a1d}$ and the resulting equations are added it is found that:[3]

$$x_{afd}I_{fd} + x_{a1d}I_{1d} = \frac{E_{fd}}{R_{fd}}\,x_{afd} + (x_d - x_d'')i_d \tag{20}$$

If the field quantities in this equation are now expressed in terms of their individual fields 20 becomes:

$$I + I_{d1} = E + (x_d - x_d'')i_d \tag{21}$$

where

$$x_d'' = x_d - \frac{X_{11d}x_{afd}^2 - 2X_{f1d}x_{a1d}x_{afd} + X_{ffd}x_{a1d}^2}{X_{11d}X_{ffd} - X_{f1d}^2}$$

Note that equation 21 is the same as equation 2.

The factors $A_{fd}$ and $A_{1d}$ serve to divide the rotor current into the portions which flow in the main and amortisseur fields. For the transient d-c components of the rotor currents these factors can be put in a simpler form. In most practical machines the transient d-c component of $I_{1d}$ dies out very rapidly so that it is zero for most of the time that the transient part of $I_{fd}$ is flowing. Therefore we may consider that for d-c transients $X_{f1d}$ in equations 18 and 19 is equal zero. Under these conditions

$$x_d A_{fd} = x_d - x_d' \tag{22}$$

$$x_d A_{1d} = x_d' - x_d'' \tag{23}$$

Substituting in equation 18 for $i_d$ and $E$ their values from equations 4, 9, and 6 there results:

$$I = e + ex_dA_{fd}\left\{\frac{x_d'' + x_q''}{2}\left[\frac{1 - \cos(\theta - \theta_0)}{D}\right] - \frac{x_d'' - x_q''}{2}\left[\frac{1 - \cos(\theta - \theta_0)}{D}\right] + \frac{x_0[1 - \cos(\theta - \theta_0) - \cos(\theta + \theta_0 + 60) + \cos(2\theta + 60)]}{D}\right\} \tag{24}$$

The current in the additional field is the same except that the constant term is missing and $A_{fd}$ is replaced by $A_{1d}$.

Equation 24 may be expanded into a set of harmonic series in a manner similar to that used for equation 9. It then becomes:

$$I = e + ex_dA_{fd}[M(x_d'' + x_q'')(C_{ep} + C_{op}) + M(x_d'' - x_q'')\times(C_{en} + C_{on}) + Mx_0(C_{eo} + C_{oo})] + eM(x_d - x_d')\times(x_q'' + x_0 + bx_0) \tag{25}$$

Note that the d-c component is multiplied by its special value of $A_{fd}$.

In equation 25:

$$C_{ep} = \sum_{n=2}^{\infty} b^{\frac{n}{2}} \cos n\,(\theta + 30)$$

$$C_{op} = -\frac{1}{2}\cos(\theta_0 + 30)\,(1 + b)\sum_{n=1}^{\infty} b^{\frac{n-1}{2}} \cos n(\theta + 30) - \frac{1}{2}\sin(\theta_0 + 30)\,(1 - b)\sum_{n=1}^{\infty} b^{\frac{n-1}{2}} \sin n\,(\theta + 30)$$

$$C_{en} = -C_{ep}$$

$$C_{on} = -C_{op}$$

$$C_{eo} = 2\sum_{n=2}^{\infty} b^{\frac{n}{2}} \cos n\,(\theta + 30) + (1 + b^2)\sum_{n=2}^{\infty} b^{\frac{n-2}{2}} \cos n\,(\theta + 30)$$

$$C_{oo} = -2(1 + b)\cos(\theta_0 + 30)\sum_{n=1}^{\infty} b^{\frac{n-1}{2}} \cos n\,(\theta + 30)$$

Similarly the current in an additional field in the direct axis is

$$I_{d1} = ex_dA_{1d}[M(x_d'' + x_q'')(C_{ep} + C_{0p}) + M(x_d'' - x_q'')\times(C_{en} + C_{0n}) + Mx_0(C_{e0} + C_{00})] + eM(x_d' - x_d'')\times(x_q'' + x_0 + bx_0) \tag{26}$$

Decrement factors must be applied to the various terms in these expressions for field currents in the same way as to the armature currents except that the armature decrement factors apply to the odd harmonics and the field decrement factors to the even harmonics.

## Decrement Factors

In order to apply field decrement factors to the odd harmonic terms of the armature current, it is necessary to divide the armature current into portions, each of which is dependent only on the current flowing in a particular field circuit. The decrement factor for each portion is then the reciprocal of the time constant of its field circuit. Since this division will be the same at all times it will be sufficient to determine it at the initial instant.

At the initial instant the total direct current field excitation in the direct axis is:

$$e + eM\,(x_d - x_d'')(x_q'' + x_0 + bx_0)$$

from equations 25 and 26.

The field excitation due to direct currents flowing in the additional field in the direct axis is:

$$eM(x_d' - x_d'')(x_q'' + x_0 + b_{x0})$$

The fraction of the total armature current dependent on this additional field current, that is the subtransient part, is then the ratio:

$$K''i_{a0} = \frac{M(x_d' - x_d'')(x_q'' + x_0 + bx_0)}{1 + M(x_d - x_d'')(x_q'' + x_0 + bx_0)} i_{a0} \tag{27}$$

where $i_{a0}$ is the odd harmonic terms of $i_a$.

Similarly the fraction of the total armature current dependent on the transient current in the main field, that is the transient part, is:

$$K'i_{a0} = \frac{M(x_d - x_d')(x_q'' + x_0 + bx_0)}{1 + M(x_d - x_d'')(x_q'' + x_0 + bx_0)} i_{a0} \tag{28}$$

This leaves for the sustained part:

$$Ki_{a0} = \frac{1}{1 + M(x_d - x_d'')(x_q + x_0 + bx_0)} i_{a0} \tag{29}$$

The same factors of course serve to divide $i_{b0}$, the odd harmonic terms of $i_b$.

To calculate field time constants for a double-line-to-neutral short it is necessary to rely upon some physical reasoning rather than a strict mathematical derivation. When a short circuit of any kind occurs in a machine having 2 field circuits in the direct axis, the inductance of each field circuit is altered by the fact that there are 2 other closed circuits linking at least part of the flux linked by the circuit in question. However, the amortisseur circuit in most machines has such low reactance that its d-c component of current dies so rapidly that it is nearly zero for most of the time that a transient current is flowing in the main field. Therefore the amortisseur circuit may be considered open in calculating the time constant of the main field. Under these circumstances the per-unit self-inductance of the direct axis field circuit is $X_{ffd}$. The current flowing in the direct axis before the fault is equal to $E = e$. Shortly after the fault the average value of main field current is, from equation 25:

$$I = e + eM(x_d - x_d')(x_q'' + x_0 + bx_0)$$

Since the flux linkages remain constant the main field inductance after the fault must be:

$$\frac{1}{1 + M(x_d - x_d')(x_q'' + x_0 + bx_0)} X_{ffd}$$

The main field (transient) decrement factor will then be the ratio of the main field resistance to the main field inductance.

$$\alpha_d' = \frac{r_{fd}[1 + M(x_d - x_d')(x_q'' + x_0 + bx_0)]}{X_{ffd}} \tag{30}$$

The self-inductance of the additional field considering the main field as a closed circuit is:

$$X_{11d} - \frac{X_{1fd}^2}{X_{ffd}}$$

The average value of the current in the additional field immediately after the fault is, from equation 26:

$$I_{d1} = eM(x_d' - x_d'')(x_q'' + x_0 + bx_0)$$

Therefore the inductance of the additional field after the fault is:

$$\frac{1}{1 + M(x_d' - x_d'')(x_q'' + x_0 + bx_0)} \left(X_{11d} - \frac{X_{1fd}^2}{X_{ffd}}\right)$$

The additional field (subtransient) decrement factor is:

$$\alpha_d'' = \frac{X_{ffd}r_{1d}[1 + M(x_d' - x_d'')(x_q'' + x_0 + bx_0)]}{X_{11d}X_{ffd} - X_{1fd}^2} \tag{31}$$

The even harmonic terms of the armature current are grouped into 3 separate series. Each series may be considered as a current flowing in a closed armature circuit. The decrement factor to be used with each series is the ratio of the resistance of this circuit to its inductance. From an inspection of equation 11 the inductance met by the first even harmonic component of armature current is

$$\frac{1}{(x_d'' + x_q'')M}$$

The decrement factor for this component is therefore:

$$\alpha_{ap} = r(x_d'' + x_q'')M \tag{32}$$

Similarly for the other 2 components:

$$\alpha_{an} = r(x_q'' - x_d'')M \tag{33}$$

$$\alpha_{a0} = rx_0M \tag{34}$$

The final expression for the armature current in phase $a$ at any instant is:

$$i_a = \frac{1}{2}\sqrt{3}\,eM[(x_d'' + x_q'')\epsilon^{-\alpha_{ap}t}A_{ep} + (x_d'' - x_q'')\epsilon^{-\alpha_{an}t}A_{en} + x_0\epsilon^{-\alpha_{a0}t}A_{e0} + K''\epsilon^{-\alpha_{d''}t}(2x_q''A_{0p} + x_0A_{00}) + K'\epsilon^{-\alpha_{d'}t}(2x_q''A_{0p} + x_0A_{00}) + K(2x_q''A_{0p} + x_0A_{00})] \tag{35a}$$

The current in phase $b$ is:

$$i_b = \frac{1}{2}\sqrt{3}\,eM[(x_d'' + x_q'')\epsilon^{-\alpha_{ap}t}B_{ep} + (x_d'' - x_q'')\epsilon^{-\alpha_{an}t}B_{en} - x_0\epsilon^{-\alpha_{a0}t}A_{e0} + K''\epsilon^{-\alpha_{d''}t}(2x_q''B_{0p} - x_0A_{00}) - K'\epsilon^{-\alpha_{d'}t}(2x_q''B_{0p} - x_0A_{00}) + K(2x_q''B_{0p} - x_0A_{00})] \tag{35b}$$

The current in the main field is:

$$I = e + eMx_dA_{fd}[(x_d'' + x_q'')\epsilon^{-\alpha_{ap}t}C_{0p} + (x_d'' - x_q'')\epsilon^{-\alpha_{an}}C_{0n} + x_0\epsilon^{-\alpha_{a0}t}C_{00} + (x_q'' + x_0 + bx_0)\epsilon^{-\alpha_{d'}t} + K''\epsilon^{-\alpha_{d''}t}(2x_q''C_{ep} + x_0C_{e0}) + K'\epsilon^{-\alpha_{d'}t}(2x_q''C_{ep} + x_0C_{e0}) + K(2x_q''C_{ep} + x_0C_{e0})] \tag{35c}$$

The current in the additional field is the same except that the sustained d-c term is missing, and the transient d-c term has the decrement factor $\alpha_d''$, and the factor $A_{fd}$ is replaced by $A_d$.

If $x_0$ becomes infinitely large equations 35 become identical with the equations developed by Doherty and Nickle for a line-to-line fault, as should be expected.

## The Voltage Across the Open Phase

To get an expression for the voltage across the open phase the flux linkages can be found by setting $i_c = 0$ in

equation 7c. $i_a$ and $i_b$ can be eliminated from the resulting expression by substituting their values from equation 9. The result can then be expanded into a series and decrement factors applied as in the case of the currents and there is:

$$v_c = eM\,[3x_q''x_0K''\epsilon^{-\alpha_{d''}t}F_1 + 3x_q''x_0K'\epsilon^{-\alpha_{d'}t}F_1 + 3x_qx_0KF_1 + \frac{x_d - x_0}{2}(x_d'' + x_q'')\epsilon^{-\alpha_{ap}t}F_2 - \frac{(x_d'' - x_q'')^2}{4}\epsilon^{-\alpha_{an}t}F_2 - \frac{x_d'' + x_q'' - 2x_0}{4}(x_d'' - x_q'')\epsilon^{-\alpha_{an}t}F_4 - x_0(x_d'' - x_q'')\cos(\theta_0 + 30)\epsilon^{-\alpha_{a0}t}F_3] \quad (36)$$

To get the voltage equation 36 may now be differentiated with respect to time. It is much more convenient to expand the functions into Fourier series and then differentiate them term by term. This procedure is valid because the functions $F$ satisfy the rigid conditions under which the term by term derivative of a Fourier series is also the derivative of the function.[4]

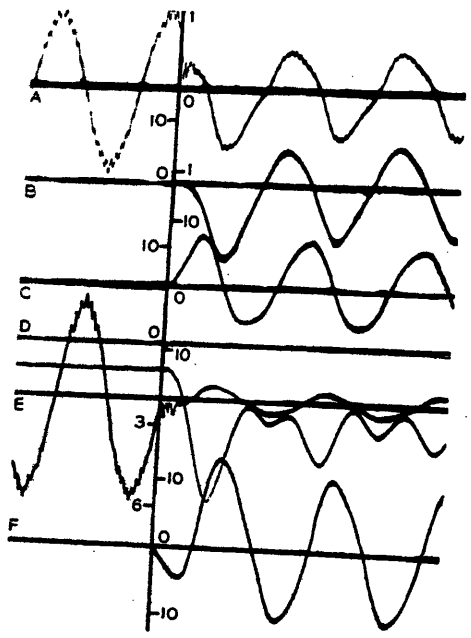

**Figure 1a.** $\theta = 0$

*A*—Voltage across the open phase

*C*—Current in line *b*

*E*—Voltage of phase *a*

*B*—Current in line *a*

*D*—Main-field current

*F*—Neutral current

The final expression for the voltage across the open phase a short time after a double-line-to-neutral fault is:

$$v_c = -eM[3x_q''x_0K''\epsilon^{-\alpha_{d''}t}(pF_1 - \alpha_{d''}F_1) + 3x_q''x_0K'\epsilon^{-\alpha_{d'}t}(pF_1 - \alpha_{d'}F_1) + 3x_q''x_0KpF_1 + \frac{x_d'' - x_0}{2}(x_d'' + x_q'')\epsilon^{-\alpha_{ap}t}(pF_2 - \alpha_{ap}F_2) - \frac{(x_d'' - x_q'')^2}{4}\epsilon^{-\alpha_{an}t}(pF_2 - \alpha_{an}F_2) - \frac{x_d'' + x_q'' - 2x_0}{4}(x_d'' - x_q'')\epsilon^{-\alpha_{an}t}(pF_4 - \alpha_{an}F_4) - x_0(x_d'' - x_q'')\cos(\theta_0 + 30)\epsilon^{-\alpha_{a0}t}(pF_3 - \alpha_{a0}F_3)] \quad (37)$$

where

$$F_1 = -(1-b)\sum_{n=1}^{\infty} b^{\frac{n-1}{2}}\sin n(\theta + 30)$$

$$pF_1 = -(1-b)\sum_{n=1}^{\infty} b^{\frac{n-1}{2}}\cos n(\theta + 30)$$

$$F_2 = -2\cos(\theta_0 - 60)\left[\sum_{n=2}^{\infty} b^{\frac{n}{2}}\cos n(\theta + 30) + \frac{1}{2}\right]$$

$$pF_2 = 2\cos(\theta_0 - 60)\sum_{n=2}^{\infty} nb^{\frac{n}{2}}\sin n(\theta + 30)$$

$$F_4 = b\cos(\theta_0 - 60) + \sin(\theta_0 - 60)(1 - b^2)\sum_{n=2}^{\infty} b^{\frac{n-2}{2}} \times \sin n(\theta + 30) + \cos(\theta_0 - 60)(1 + b^2)\sum_{n=2}^{\infty} b^{\frac{n-2}{2}}\cos n(\theta + 30)$$

$$pF_4 = \sin(\theta_0 - 60)(1 - b^2)\sum_{n=2}^{\infty} nb^{\frac{n-2}{2}}\cos n(\theta + 30) - \cos(\theta_0 - 60)(1 + b^2)\sum_{n=2}^{\infty} nb^{\frac{n-2}{2}}\sin n(\theta + 30)$$

$$F_3 = (1 - b^2)\sum_{n=2}^{\infty} b^{\frac{n-2}{2}}\sin n(\theta + 30)$$

$$pF_3 = (1 - b^2)\sum_{n=2}^{\infty} nb^{\frac{n-2}{2}}\cos n(\theta + 30)$$

## Steady-State Currents and Voltages

From equations 35 the sustained line currents are:

$$i_a = \frac{1}{2}\sqrt{3}\,eMK(2x_q''A_{0p} + x_0A_{00}) \quad (38)$$

$$i_b = \frac{1}{2}\sqrt{3}eMK(2x_q''B_{0p} - x_0A_{00}) \quad (39)$$

The neutral current is their sum:

$$i_N = \sqrt{3}\,eMKx_q''(A_{0p} + B_{0p}) \quad (40)$$

Substituting for $A_{0p}$ and $B_{0p}$ their values:

$$i_N = 3eMKx_q''(1 - b)\sum_{n=1}^{\infty} b^{\frac{n-1}{2}}\sin n(\theta + 30) \quad (41)$$

From equation 37 the sustained voltage across the open phase is:

$$v_c = -3\,eMKx_q''x_0(1 - b)\sum_{n=1}^{\infty} nb^{\frac{n-1}{2}}\cos n(\theta + 30) \quad (42)$$

If only the fundamental terms are considered, which can be done with very little approximation if $b$ is small, then the root-mean-square values of the time functions in equations 41 and 42 are equal. Therefore the ratio of the root-mean-square values is

$$\frac{V_c}{I_N} = x_0$$

which we would expect since this is one of the methods of measuring $x_0$.

## Comparisons of Calculated and Test Results

In order to check equations 35 and 37, oscillograms were taken of a number of short circuits on 2 different machines. Figure 1*a* is a typical oscillogram taken on the following machine: General Electric Company, 45 kva, type *ATB*, form P.B., frame 7,621, 118 amperes, 220 volts, 60 cycles, 1,200 rpm, serial number 302,689. The constants of this machine in per-unit on a 220-volt 118-ampere base are:

$x_d = 0.9$
$x_d' = 0.241$
$x_d'' = 0.220$
$T_{do}' = 339$
$x_q = x_q' = x_q'' = 0.470$
$x_0 = 0.07$
$r = 0.033$
$T_{do}'' = 7.6$

The amortisseur winding of the machine had been removed.

Figure 1*b* shows curves calculated from equations 35 and 37. The armature currents check very closely, especially in the first cycle where there is no difference of more than 8 per cent. The calculated curve of the field current

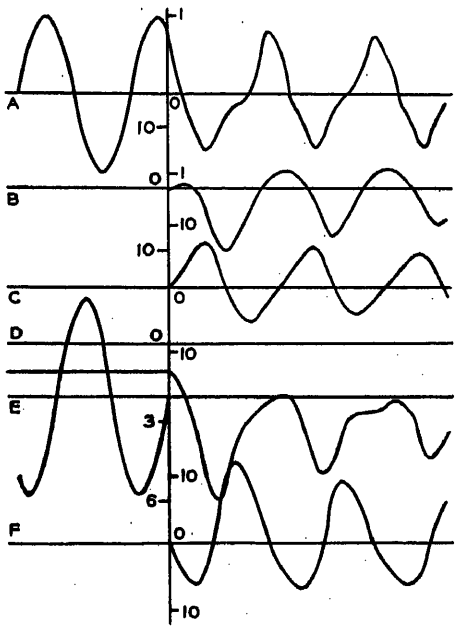

**Figure 1b.** $\theta = 0$

*A*—From equation 37

*C*—From equation 35*b*

*E*—e sin $\theta$

*B*—From equation 35*a*

*D*—From equation 35*c*

*F*—From equations 35*a* and 35*b*

shows too large a percentage of harmonics. This can be partly explained by the fact that in the actual calculation $A_{fd}$ was computed from equation 22 because all the constants in equation 18 were not available. All of the calculated curves show too large a percentage of even harmonics in armature quantities and odd harmonics in the field current, especially after the first cycle. This indicates that the values of the armature decrement factors as calculated from equations 32, 33, and 34 are somewhat too small. The short circuits were all made at normal voltage, so that saturation of the iron undoubtedly affected the test curves. The constants used in the calculations were measured under unsaturated conditions.

In order to find the largest possible value of current that can occur plots of both $i_a$ and $i_b$ were made for a number of different valus of $\theta_o$. These plots showed that the largest peak of $i_a$ occurred very near the point where $\theta_o = 0°$ and $\theta_o = 180°$. For $i_b$ the largest peak occurred near $\theta_o = 90°$ and $\theta = 270°$.

When these values are substituted in equations 9 there is:

$$i_a = \frac{6e(x_q'' + x_0)}{3x_d''x_0 + x_q''x_0 + 2x_d''x_q''} \tag{43}$$

$$i_b = \frac{2\sqrt{3}\,e(2x_q'' + x_0)}{x_d''x_0 + 3x_q''x_0 + 2x_d''x_q''} \tag{44}$$

These values do not give quite the theoretical maximum values of equations 9, but since actually we should consider the decrements as well, these expressions, are close enough and have the advantage of being relatively simple. In table I values of current calculated from equations 43 and 44 for the machine described and another similar machine are compared with the largest peaks for other types of faults calculated from analogous expressions. For line-to-neutral[2] fault:

$$i_a = \frac{6e}{2x_d'' + x_0} \tag{45}$$

For line-to-line fault:

$$i_a = \frac{\sqrt{3}\,e}{x_d''} \tag{46}$$

For 3-phase fault:

$$i_a = \frac{2e}{x_d''} \tag{47}$$

**Table I**

| Type of Fault | Current | Machine I | Machine II |
|---|---|---|---|
| $l - n$ | $i_a$ | 11.8 | 14.2 |
| $l - l$ | $i_a$ | 7.9 | 10.0 |
| $l - l - l$ | $i_a$ | 9.1 | 11.5 |
| $l - l - n$ | $i_a$ | 11.4 | 14.0 |
| $l - l - n$ | $i_b$ | 10.7 | 13.0 |

The table shows that for 2 typical machines the theoretical peak value of the line current in a double line-to-neutral fault is of about the same order of magnitude as that in a line-to-neutral fault.

# Flywheels for A-C Generating Units

By F. K. BRAINARD
MEMBER AIEE

SO MUCH has been written on the subject of flywheels and parallel operation of generating units, that the object of this paper is not to attempt to develop any entirely new method of flywheel calculation, but rather to collect and apply the available information and put it into convenient shape for practical use. The consideration of torsional vibrations in connection with the determination of flywheel sizes is frequently of the greatest importance, especially in the case of large multicylindered oil engines, and should not be overlooked. However it is beyond the scope of this paper and so will not be considered here.

In addition to the above, there are 3 quite distinct conditions which the flywheel of a proposed unit must satisfy.

The first is the very obvious condition that it must be large enough to prevent objectionable variations in frequency (and voltage) when the unit is the only generating unit on the system. Failure to provide for this will result in objectionable flickering of lighting handled by the generator. These variations may be (*a*) the result of violent changes in load combined with a somewhat sluggish prime mover or governor, or (*b*) the result of pulsating torque of the prime mover.

A convenient criterion for the (*a*) condition is the ratio of the kinetic energy of the rotating parts to the rated output of the unit. This will be the time required by the unit when operating at full load to develop energy equal to the kinetic energy of the rotating parts at full speed. There is nothing new about this as the equivalent of this has been used for many years. If this time is in seconds, then:

$$WR^2 = \frac{433\ kw\ T_1}{\left(\frac{\text{rpm}}{100}\right)^2} \qquad (1)$$

For hydroelectric units this effect is important, $T_1$ in this case varying between about 1.4 and 2.0 seconds, for a normal machine, depending upon the head, length of penstock, speed of operation of governor as well as gates, etc. For other applications this effect is, as far as the writer is aware, never the limiting feature, although it would seem that it might be in the case of certain multicylinder steam engines.

The (*b*) condition is important in the case of reciprocating engine units, on account of the varying turning effort developed by the engine for different crank angles. A convenient criterion for this condition is the well-known "irregularity factor." The use of this is also very old. It is the variation in speed expressed as a fraction of normal speed, during a power cycle, the load being assumed constant, e.g., an irregularity factor of $^1/_{200}$ means a variation in speed of 0.5 per cent during one revolution of a 2-cycle engine or 2 revolutions of a 4-cycle engine. It can be easily shown that the following is a very close approximation for flywheel effect in terms of irregularity factor:

$$WR^2 = \frac{130\ kw\ Z}{\left(\frac{\text{rpm}}{100}\right)^2} \times \frac{A_2}{A_1} \qquad (2)$$

Permissible values of irregularity factor depend upon the character of the load served and the frequency of the impulses causing the variations in speed, i.e., the number of power impulses per minute. For a miscellaneous factory load in which good lighting is not important an irregularity factor of $^1/_{100}$ will usually be satisfactory. However since office or residence lighting is almost always an important factor, and since low-wattage metallic filament lamps are used so generally, it is practically always necessary to make the irregularity factor low enough to avoid serious flickering of such lamps. The voltage variation necessary to produce an objectionable flicker varies with the frequency of the variation, being a maximum at about 500 cycles per minute. The available data are somewhat conflicting but it would seem that the following are reasonable values of irregularity factor:

| Frequency of impulses in cycles per minute | $\frac{1}{Z}$ |
|---|---|
| 100 | 1/125 |
| 300 | 1/175 |
| 500 | 1/225 |
| 700 | 1/175 |
| 1,000 | 1/125 |

The value of $A_2/A_1$ depends upon the shape of the tangential effort diagram, being the ratio of certain areas (see figure 1), and so varies widely for different engines. The following table gives approximate values for single acting oil engines:

| Number of Cylinders | $\frac{A_2}{A_1}$ 2 Cycle | $\frac{A_2}{A_1}$ 4 Cycle |
|---|---|---|
| 1 | | |
| 2 | 1.3 | |
| 3 | 0.40 | 1.4 |
| 4 | 0.19 | 0.45 |
| 5 | 0.11 | 0.20 |
| 6 | 0.075 | 0.14 |
| | 0.055 | 0.10 |

The second condition is that the flywheel must be suitable for satisfactory parallel operation of the unit with a very large system. This limitation can best be expressed in terms of the quantity $C$, which is the same as the "com-

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted March 29, 1937; released for publication July 22, 1937.

F. K. BRAINARD is a designing electrical engineer for the Allis-Chalmers Manufacturing Company, Milwaukee, Wis.

pressor factor'' as standardized by the National Electrical Manufacturer's Association. The expression for $WR^2$ in terms of $C$ is:

$$WR^2 = \frac{1.34\,P_r f\,C}{\left(\frac{\text{rpm}}{100}\right)^4} \tag{3}$$

The limiting values of $C$ can be determined from the tangential effort diagram of the engine as follows: Calculate the $CY$ ($Y$ = power pulsation of generator) curve by first assuming a reasonable unbalance between cylinders. Since the operation of internal combustion engines is somewhat irregular the amount of unbalance is largely a matter of judgment and hence the $CY$ curves cannot be calculated with the same accuracy as, for instance, compressor curves are calculated. For this reason and also because the flywheels are relatively large (which results in the effect of damping being relatively small) the damping can usually be neglected entirely. This results in a considerable simplification of the equations as follows:[2] For a 2-cycle engine

$$P = 100 + \sum y_n \frac{9.25}{9.25 - n^2 C} \sin(n\omega t + \phi_n)$$

and for a 4-cycle engine

$$P = 100 + \sum y_n \frac{37}{37 - n^2 C} \sin(n\omega t + \phi_n)$$

Then after having analyzed the tangential effort curve and determined the coefficients in the Fourier series representing the same, the procedure is to select a value of $C$ and calculate the curve of $P$ from $t = 0$ to $t = 2\pi$, i.e., over one power cycle which will be one revolution for a 2-cycle engine or 2 revolutions for a 4-cycle engine. Then $Y$ will be the maximum difference in the ordinates of this curve and the result one point on the $CY$ curve. Repeat for different values of $C$ until sufficient points are obtained to set limits of $C$ corresponding to the power pulsation desired.

The following are approximate values of $C$ based upon 66 per cent power pulsation and 10 per cent unbalance, for oil engines:

| Number of Cylinders | C: 2-Cycle Single-Acting | C: 4-Cycle Single-Acting |
|---|---|---|
| 1 | 100 or over | 500 or over |
| 2 | 20 or over | 150 or over |
| 3 | 16 or over | 75 or over |
| 4 | 3.5 to 4.5 or 14 or over | 60 or over |
| 5 | 3.3 to 5.0 or 13.5 or over | 57 or over |
| 6 | 3.0 to 6.0 or 12.5 or over | 55 or over |

The above values must not however be considered as final since as mentioned above they cannot be calculated with as much precision as would be desirable. Also the permissible values depend upon the maintenance of the engine. Hence the limits will have to be determined ultimately by experience, and so the above table must be considered as empirical and subject to some variation.

2. For all numbered references, see list at end of paper.

The third condition is that the flywheel must be suitable for parallel operation of the unit with certain particular units whose characteristics are known. A simple method of checking this after the other conditions are satisfied is to compute the natural frequency $F$ of each of the units with an infinite system using the AIEE formula:

$$F = \frac{35{,}200}{\text{rpm}} \sqrt{\frac{P_r f}{WR^2}}$$

Then if these natural frequencies are all well below the lowest forced frequency, say 20 per cent below, the operation will be satisfactory. This is because the combined natural frequencies of any combination of units is always between the natural frequencies of the individual units on an infinite system. However if the lowest forced frequency of one of the units is below the natural frequency of another unit, the combined natural frequencies of all combinations should be calculated and care taken to see that none of the forced and natural frequencies are dangerously close to each other.

The expression for combined natural frequency[1] of 2 units is

$$F_{1-2} = \frac{35{,}200}{\text{rpm}_1} \sqrt{\frac{P_{r1} f}{WR_1^2} \times \frac{1 + \left(\frac{\text{rpm}_1}{\text{rpm}_2}\right)^2 \times \frac{WR_1^2}{WR_2^2}}{1 + \frac{P_{r1}}{P_{r2}}}}$$

and in the case of 3 units, the expression is

$$F_{1-2 \text{ and } 3} = 9.55 \sqrt{\frac{N_2}{2N_1} \pm \sqrt{\left(\frac{N_2}{2N_1}\right)^2 - \frac{N_3}{N_1}}}$$

where

$$c_1 = 4.22 \times 10^5 \frac{P_{r1} f}{(\text{rpm}_1)^2}$$

$$d_1 = 5.74 \times 10^{12} f^2 \left[ \frac{P_{r1} P_{r2}}{(\text{rpm}_1)^2 (\text{rpm}_2)^2 WR_2^2} + \frac{P_{r1} P_{r3}}{(\text{rpm}_1)^2 (\text{rpm}_3)^2 WR_3^2} \right]$$

$$e_1 = 7.85 \times 10^{19} f^3 \left[ \frac{P_{r1} P_{r2} P_{r3}}{(\text{rpm}_1)^2 (\text{rpm}_2)^2 (\text{rpm}_3)^2 WR_2^2 WR_3^2} \right]$$

$$N_1 = c_1 + c_2 \left(\frac{\text{rpm}_2}{\text{rpm}_1}\right)^2 + c_3 \left(\frac{\text{rpm}_3}{\text{rpm}_1}\right)^2$$

$$N_2 = d_1 + d_2 \left(\frac{\text{rpm}_2}{\text{rpm}_1}\right)^2 + d_3 \left(\frac{\text{rpm}_3}{\text{rpm}_1}\right)^2$$

$$N_3 = e_1 + e_2 \left(\frac{\text{rpm}_2}{\text{rpm}_1}\right)^2 + e_3 \left(\frac{\text{rpm}_3}{\text{rpm}_1}\right)^2$$

Subscripts 1, 2, and 3 refer to units 1, 2, and 3 respectively.

For $c_2$, $d_2$, and $e_2$ interchange subscripts 1 and 2 in expressions for $c_1$, $d_1$, and $e_1$, respectively.

For $c_3$, $d_3$, and $e_3$ interchange subscripts 1 and 3 in expressions for $c_1$, $d_1$, and $e_1$, respectively.

It is sometimes assumed that parallel operation is always a more severe condition than operating alone and that if the flywheel is satisfactory from the former standpoint it will also be satisfactory from the latter. A few trials using equations 2 and 3 will show the fallacy of this,

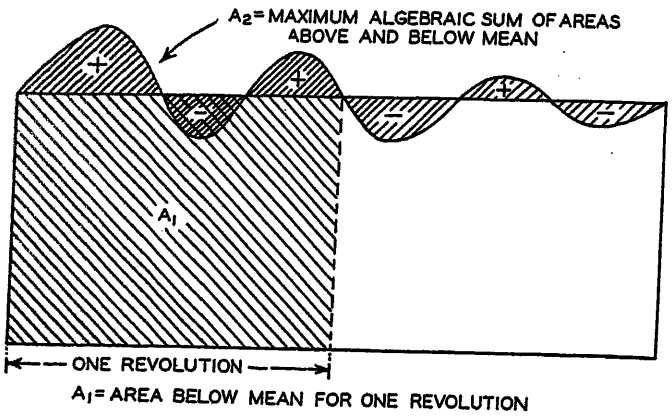

**Figure 1. Tangential effort diagram**

since sometimes it is one and sometimes the other which requires the greater flywheel effect. It is interesting to note that according to equation 1 the flywheel effect varies inversely as the square of the speed, according to equation 2 inversely as the cube of the speed, and according to equation 3 inversely as the fourth power of the speed. Hence the limiting feature depends to a considerable extent upon the speed of the unit. Also from equation 3 it is seen that the flywheel effect necessary on account of parallel operation varies directly with the frequency of the system. Hence parallel operation is relatively less important, and operation alone (which means irregularity factor) more important on 25 cycles than on 60 cycles.

## Appendix I. Symbols

$WR^2$ = flywheel effect of unit in (pound-feet)$^2$ (i.e., pounds weight multiplied by the radius of gyration in feet squared)

$kw$ = rated output of the unit in kilowatts

$T_1$ = time in seconds required by the unit when operating at full load to develop energy equal to the kinetic energy of the rotor at full speed. This is equal to the commonly accepted inertia constant $H$ divided by rated power factor

rpm = rated speed in revolutions per minute

$\frac{1}{Z}$ = irregularity factor = ratio of maximum variation in speed during a power cycle to normal speed

$A_1$ = area in tangential effort diagram below mean for *one revolution*

$A_2$ = maximum algebraic sum of small areas in tangential effort diagram above and below mean (see figure 1)

$P_r$ = synchronizing power in kilowatts per electrical radian as defined in AIEE rules

$f$ = frequency of system in cycles per second

$C$ = engine factor = $9.25\left(\frac{\text{rpm}}{F}\right)^2$

$F$ = frequency of oscillation of unit on an infinite system in cycles per *minute*

$y$ = $.100 + \Sigma y_n \sin(n\omega t + \phi_n)$ = Fourier analysis of tangential effort curve, in which

$n$ = order of harmonic

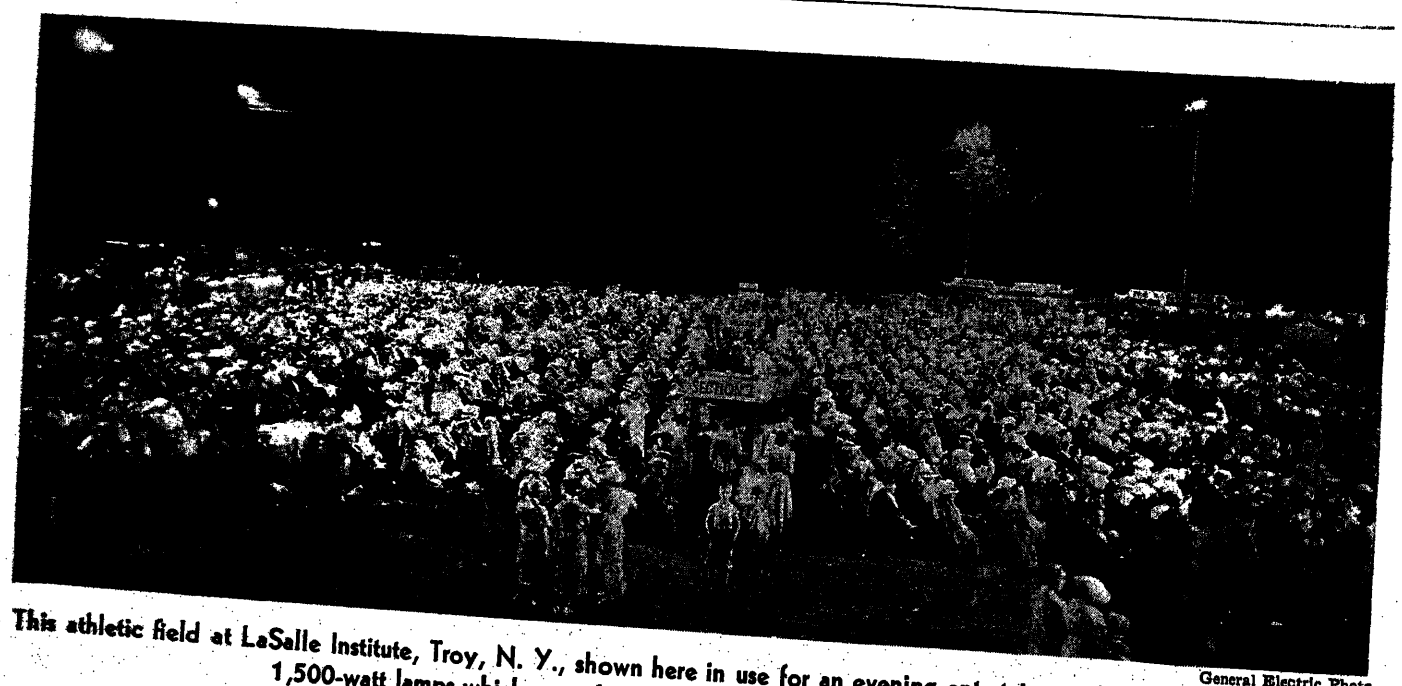
$y_n$ = amplitude of $n$th harmonic expressed as a percentage of rated output of unit

$\omega_n$ = 0.1045 $n$ rpm for 2-cycle engines, or 0.05225 $n$ rpm for 4-cycle engines

$t$ = time in seconds

$\phi_n$ = phase angle of $n$th harmonic

$P$ = power output of generator expressed as a percentage of the rating



$Y$ = power pulsation of generator expressed as a percentage of the rating in kilowatts

# Coupling Between Parallel Earth-Return Circuits Under D-C Transient Conditions

By K. E. GOULD
ASSOCIATE AIEE

## Introduction

IN TESTS conducted in connection with several d-c railway electrifications, the induced voltages recorded in paralleling communication circuits at times of short circuit on the railway have shown marked divergences from values computed on the basis of uniform earth resistivity and a rate of change of earth current determined from measurements in trolley and rail circuits. Due to the numerous factors which might contribute to these divergences, such as nonuniform division of transient current along the tracks and associated return conductors, the presence of shielding conductors along or near the right-of-way, etc., it was felt that a better understanding of the problem of induction under d-c transient conditions could be obtained by experimental studies of the transient coupling between parallel earth-return circuits, free from the effects of shielding conductors, and with concentrated, rather than distributed, grounds. The study described in this paper was undertaken for this purpose.

The locations for the tests were selected to provide a reasonably large range of earth resistivity; also, at one location it was known that the earth structure departed substantially from uniformity. At each of these locations d-c transient coupling tests were performed in which transient currents, approximately of the form encountered during faults on d-c railway electrifications, were produced in an earth-return circuit, herein referred to as the primary, and measurements were made of the resultant voltages in earth-return circuits, herein called secondary circuits, parallel to and at separations from the primary circuit of from 50 or 60 to 2,000 feet. In addition to the d-c transient tests, measurements were made at each location of the steady state a-c coupling, in magnitude and phase angle, over a range of frequencies from 20 or 30 cycles to 3,200 cycles. From these a-c measurements the transient voltages were computed for a number of cases by evaluating the Fourier integral. The results of the a-c coupling tests were useful also in helping to explain, in a general way, the departures of the measured transient voltages from the voltages computed for uniform earth resistivity.

The measured transient voltages and voltages computed (1) from the a-c coupling measurements and (2) on the basis of a uniform earth resistivity, are shown for several representative cases in figures accompanying the paper.

A paper recommended for publication by the AIEE committees on communication, transportation, and basic sciences. Manuscript submitted June 1, 1937; released for publication July 30, 1937.

K. E. GOULD is a member of the technical staff of the Bell Telephone Laboratories, New York, N. Y. The author wishes to acknowledge the assistance of W. L. Gaines, J. H. Harding, and G. Wascheck in obtaining the experimental data and of Miss J. D. Goeltz, in supervising the extensive computations required to compute the transient voltages from the measured a-c coupling.

## Test Conditions

Three sets of tests were performed, near Savannah, Ga., Macon, Ga., and Jennings, La., respectively. The primary circuit was nearly straight in each case and was installed along a telephone line. The length of the primary circuit was 5.65 miles, 9.3 miles, and 4.7 miles at the respective locations, these lengths being great enough that end effects were not large even under the d-c transient conditions. The secondary circuits, 4,200 feet in length, were laid out parallel to and near the middle of the primary circuit, and at radial separations therefrom of 50 feet (Macon) or 60 feet (Savannah and Jennings), 200 feet, 500 feet, 1,000 feet, and 2,000 feet.

By means of a 500-volt gasoline-engine-driven d-c generator, and with the use of an air-core choke with taps giving inductances of roughly 1, $^3/_4$, $^1/_2$, or $^1/_4$ henry, it was possible to produce primary currents approximately of the form $I(1-e^{-at})$, with $a$ from about 40 to 110 for $t$ in seconds, and with $I$ somewhat less than 10 amperes. Conductors were brought in from each secondary so that the voltages produced in the secondaries under transient conditions could be recorded by a movie-type oscillograph, on 70-millimeter film moving at a speed of approximately 7 feet per second. Direct-coupled amplifiers were used to obtain the requisite sensitivity for the oscillograph, the over-all response of the measuring equipment being nearly constant for frequencies from zero to 4,000 cycles. The rate of change of primary current was recorded, simultaneously with the secondary voltages, by means of a search coil external to and coaxial with the primary choke.

For the a-c coupling tests a power amplifier driven by a variable frequency oscillator was used to energize the primary circuit and the voltages produced in the secondary circuits were measured with an a-c potentiometer, so that both components of the coupling could be determined. The continuity of the telephone conductors on the pole line carrying the primary circuit was interrupted during both the d-c transient tests and the measurements of a-c coupling to eliminate any possible shielding effects from these conductors.

## Typical Results

In figures 1 to 6, inclusive, are shown curves selected from the large amount of data collected as typical of the results of this study. The cases chosen for these illustrations are those in which the time constant of the pri-

mary circuit was most nearly representative for d-c railway electrifications, being about $^1/_{46}$, $^1/_{60}$, and $^1/_{45}$ second for the respective locations. The closest and widest separations were chosen for examples, and although the examples of the transient voltages computed from the a-c coupling measurements are thus limited to the cases of the 2,000-foot separation alone, the value of the illustrations is not significantly impaired thereby. As explained in a later section of the paper, it was not possible to compute the transient voltages for the closest separation from the a-c coupling measurements. Figures 1 to 6 illustrate the fact that with transient earth currents of the type considered here, the induced voltages not only decrease with increased separation, as in the steady-state a-c case, but also attain their maximum values later.

Figure 1 shows the measured transient voltage for the 60-foot separation in the Savannah tests and the computed voltage for a uniform earth resistivity of 100 meter-ohms, using the measured rate of change of primary current. This value of earth resistivity, chosen on the basis of the measured a-c coupling, was found to be about the best one as regards over-all agreement between the measured transient voltages and voltages computed on the basis of uniform earth resistivity.

tests, is similar to figure 1, except that the computed voltage from the a-c coupling measurements, using the measured rate of change of primary current, has been plotted also.

Figure 3, for the 50-foot separation in the Macon tests, is similar to figure 1, except that 2 computed curves are shown, one for a uniform earth resistivity of 500 meter-ohms, about the best single value which could be chosen, and the other for the same resistivity but with the ground potentials taken as corresponding to a resistivity of 1,500 meter-ohms. This was found to result in a fairly good approximation for the substantial increase observed in the effective earth resistivity at the low frequencies.

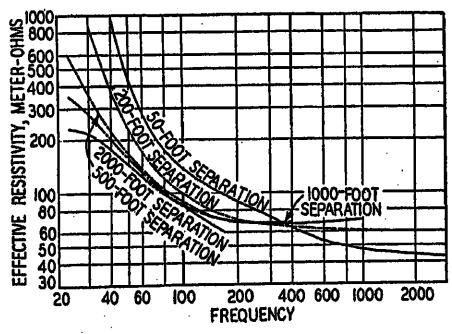

**Figure 10. Macon tests; effective earth resistivity corresponding to measured quadrature coupling**

Figure 4, for the 2,000-foot separation in the Macon tests, is similar to figure 2, except that computed curves are shown for the 2 conditions represented in figure 3. Figures 3 and 4 illustrate the fact that ground potentials were of greater relative importance at the wider separations.

Figure 5, for the 60-foot separation in the Jennings tests, is similar to figure 1, except that an earth resistivity of 10 meter-ohms was used for the computed voltage. Figure 6, for the 2,000-foot separation, is similar to figure 2, except for the change noted in the uniform resistivity used.

## Methods Used in Computing Transient Voltages

Two methods were used in computing the transient voltages for uniform earth resistivity, one a rigorous method, the other an approximate and simpler method giving sufficiently accurate results for the cases involved here. In the simpler method, which was used to obtain the curves in figures 1 to 6 for uniform earth resistivity, the transient voltage was computed for a primary circuit infinite in length, and to this voltage was added a term equal to the product of the primary current and the d-c mutual resistance, for uniform earth resistivity, of the actual primary and secondary circuits. For the case of an infinite length of primary circuit, the simple formal expression for $h(t)$, the voltage produced in the secondary circuit by unit step current (0 for $t < 0$, one ampere for $t > 0$) in the primary circuit, is given by[1]

$$h(t) = \frac{10^4\,\rho}{9.6x^2}\left[1 - \exp\left(\frac{-2.92 \cdot 10^{-8}x^2}{\rho t}\right)\right] \text{ volts per kilofoot}$$

where

$\rho$ = earth resistivity, meter-ohms
$x$ = separation, feet
$t$ = time, seconds

and thus a great part of the labor involved in exact computations for circuits of finite length is avoided.

A rigorous solution for $h(t)$, for circuits of finite length and with uniform earth resistivity, is available,[2] $h(t)$ so computed being but little different, in the present cases, from $h(t)$ for a primary circuit of infinite length, and only for large values of $(t)$. However, for the rigorous method, it appeared easier to compute $h(t)$ for the finite circuits involved by plotting the in-phase component, $a(\omega)$, of the coupling from curves based on the mutual impedance formulas,[1] in the form $a(\omega)/\omega$ and evaluating the Fourier integral[4] numerically, since previous computations made this process a simple one.

The voltage $V(t)$ produced in a secondary circuit by a primary current $I(t)$, the rate of change of which is $I'(t)$, is given by one form of the extension theorem[5] as

$$V(t) = \int_0^t h(t - \lambda)I'(\lambda)d\lambda$$

From this formula, using the measured rate of change of primary current, the transient voltage was computed for uniform earth resistivity.

1. For all numbered references, see list at end of paper.

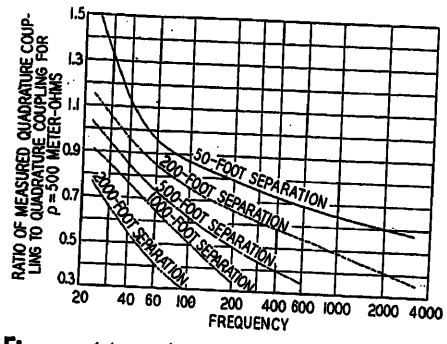

**Figure 11. Macon tests; ratio of measured quadrature coupling to quadrature coupling for uniform earth resistivity of 500 meter-ohms**

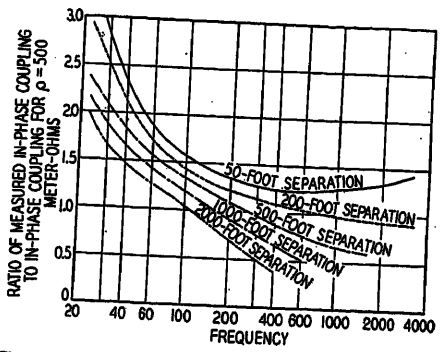

**Figure 12. Macon tests; ratio of measured in-phase coupling to in-phase coupling for uniform earth resistivity of 500 meter-ohms**

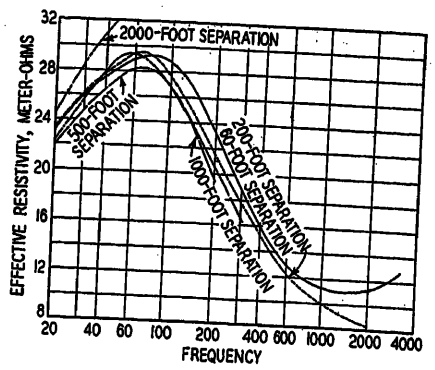

**Figure 13. Jennings tests; effective earth resistivity corresponding to measured quadrature coupling**

In computing the transient voltages from the in-phase and quadrature components, $a(\omega)$ and $b(\omega)$, of the measured a-c coupling, $a(\omega)/\omega$ and $b(\omega)/\omega$ were plotted from the experimental data and the Fourier integral[4]

$$h(t) = \frac{2}{\pi}\int_0^\infty \frac{a(\omega)}{\omega}\sin \omega t \cdot d\omega$$

$$= a(0) + \frac{2}{\pi}\int_0^\infty \frac{b(\omega)}{\omega}\cos \omega t \cdot d\omega$$

was evaluated numerically. The measured coupling was extrapolated to $\omega = 0$ on the assumption of the uniform resistivity used in computing the transient voltages. For the closest separation these computations could not be made with any significant degree of accuracy, largely because $b(\omega)/\omega$ did not converge with sufficient rapidity toward zero with increasing $\omega$, but for the other separations $h(t)$ could be computed with satisfactory accuracy from $b(\omega)$ for small values of $t$ and from $a(\omega)$ for larger values of $t$, up to about 10 milliseconds. The results from $a(\omega)$ and from $b(\omega)$ agreed within perhaps 10 per cent or less over a considerable range of $t$, thus providing a fairly conclusive check of the computations. For values of $t$ from 10 milliseconds to 30 milliseconds, the upper limit it seemed advisable to adopt, it was assumed that $[h(t) - a(0)]$ varied inversely with $t$. When end effects are negligible and the earth homogeneous, this relation is true for large values of $t$ and apparently represented a sufficiently accurate approximation here. The extension theorem was applied, as for the case of uniform resistivity, to obtain the transient voltages corresponding to the measured rate of change of primary current.

## Correlation of Results With Measured A-C Coupling

Figure 7 shows, for each separation in the Savannah tests, and as a function of the frequency, the effective earth resistivity corresponding to the quadrature component of the measured a-c coupling, that is, the value of uniform earth resistivity for which the quadrature component of the coupling, as determined from formulas for mutual impedance of grounded circuits of finite lengths,[3] would be equal to the measured quadrature coupling. The quadrature component was used in this connection because the effective earth resistivity could be determined more satisfactorily from it than from the in-phase component, although even from the quadrature component the effective resistivity could be determined satisfactorily only for the ranges of separation and frequency for which the resistivity is plotted in figure 7.

Figures 8 and 9 have been prepared to show the coupling data from the Savannah tests in a convenient form for correlating the behavior of the transient voltages with the behavior of the a-c coupling. Figure 8 shows the ratio of the measured quadrature coupling to the quadrature coupling corresponding to a uniform earth resistivity of 100 meter-ohms. Figure 9 shows the corresponding ratio for the in-phase coupling. The fact that the computed transient voltage for a resistivity of 100 meter-ohms was smaller than the measured voltage in the case of the 60-foot separation seems reasonable in view of the curves of figures 8 and 9 for this separation, since the ratios in this case are generally greater than unity, more than offsetting the smaller quadrature ratio at the higher frequencies. That the computed voltage for a resistivity of 100 meter-ohms was larger than the measured voltage in the case of the 2,000-foot separation is in accord with the fact that the ratios in figures 8 and 9 for this separation are considerably less than unity for the entire frequency range.

Figures 10, 11, and 12, for the Macon tests, are similar to figures 7, 8, and 9, respectively. Here the principal condition, illustrated in figures 3 and 4, to be correlated with the measured a-c coupling is that, for both separations, the computed voltages for a resistivity of 500 meter-ohms were greater than the measured voltages at small values of time and smaller at large values of time. The computations involving the Fourier integral showed clearly that at small values of time the transient voltages are closely related to the quadrature coupling at the higher frequencies, especially if the earth resistivity is not too low, whereas at large values of time the in-phase coupling at low frequencies is of most significance in predicting the transient voltages. Thus the above mentioned con-

dition regarding computed and measured voltages is seen to be consistent with the curves of figures 11 and 12. The high ratios shown in figure 12 for the low frequencies tend to substantiate the pragmatic approximation of taking the ground potentials to correspond to an earth resistivity of 1,500 meter-ohms.

Figures 13, 14, and 15, from the Jennings tests, are similar to figures 7, 8, and 9, respectively. On the basis of figure 13, it would appear that the best single earth resistivity to use in computing the transient voltages would be some 25 meter-ohms. However, as the computations involving the Fourier integral showed, the in-phase coupling at the low frequencies is of principal significance with regard to the maximum values of the transient voltages at wide separations, especially where the earth resistivity is as low as that indicated here, and an earth resistivity of 10 meter-ohms is seen, from figure 15, to be more nearly

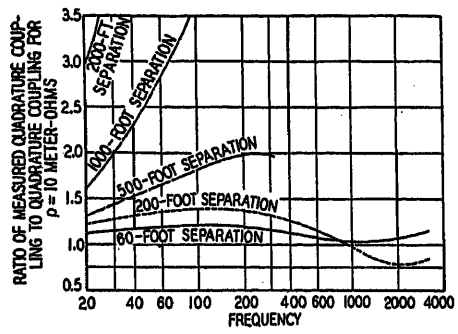

**Figure 14. Jennings tests; ratio of measured quadrature coupling to quadrature coupling for uniform earth resistivity of 10 meter-ohms**

consistent with this criterion. A resistivity of 10 meter-ohms was found to result in about as good an over-all agreement as could be obtained between the measured voltages and voltages computed on the basis of uniform earth resistivity.

As illustrated in figures 5 and 6, the use of an earth resistivity of 10 meter-ohms results in a maximum value for the computed voltage smaller than the maximum value of the measured voltage at the closest separation and greater than the maximum value of the measured voltage at the widest separation. Moreover, the computed voltages increased more slowly than the measured voltages, subsequent to the beginning of the transient, attained their maximum values later, and decreased more slowly at large values of time. These conditions are consistent with the curves of figures 14 and 15, since (1) for the close separations the transient voltages at small values of time can be predicted only from the measured quadrature coupling at the higher frequencies, whereas at large values of time the in-phase coupling at the lower frequencies is of most significance and (2) for the wide separations the transient voltages are related closely to the behavior of the measured in-phase coupling at low frequencies.

The computed voltages for the 2,000-foot separation, based on the measured a-c coupling, will be seen from figures 2, 4, and 6 to agree quite satisfactorily with the measured voltages and, although in some cases the agreement was not quite as good as that shown by these examples, it was found that in cases where the nonhomogeneity of the earth caused the transient voltages to depart considerably from the voltages which would have occurred with uniform earth resistivity, the computed voltages from the a-c coupling measurements took the effects of such nonhomogeneity into account fairly accurately.

## Summary

Widely different types of earth structure were indicated by the a-c coupling measurements at the 3 locations where these tests were performed, and by the behavior of the transient induced voltages. The departures of the measured transient voltages from the values which would have occurred with a uniform earth resistivity could generally be correlated satisfactorily with the measured a-c coupling.

At Savannah, Ga., a value of 100 meter-ohms was found to give about the best over-all agreement between the measured transient voltages and the voltages computed on the basis of uniform earth resistivity, this value being a reasonable one to choose from the standpoint of the measured a-c coupling. The voltages computed for this uniform resistivity were considerably lower than the measured voltages at the closest separation and, with increasing separation, the computed voltages gradually increased in comparison with the measured voltages, until at the widest separation they were substantially higher than the latter.

At Macon, Ga., the earth structure was apparently highly irregular, but with a reasonable value of uniform earth resistivity, 500 meter-ohms, as indicated by the a-c coupling measurements, the maximum values of the computed transient voltages agreed roughly with the maximum values of the measured voltages. However, these computed voltages increased more rapidly than did the measured voltages, subsequent to the beginning of the transient, and decreased more rapidly after the maximum values were attained. It was found that the approximation of taking the ground potentials to correspond to a resistivity of 1,500 meter-ohms improved the agreement between these computed voltages and the measured voltages. This constituted a crude way of taking into account the large in-phase coupling measured at the low frequencies.

At Jennings, La., the departures of the earth structure from homogeneity affected seriously the transient induced voltages, and careful examination of both components of the measured coupling was required to arrive at the

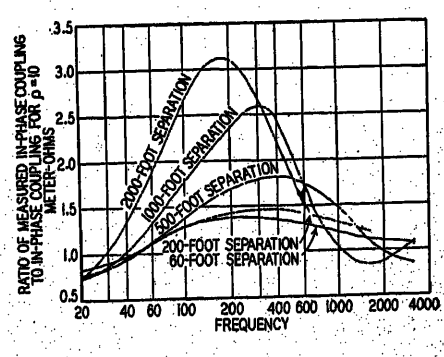

**Figure 15. Jennings tests; ratio of measured in-phase coupling to in-phase coupling for uniform earth resistivity of 10 meter-ohms**

value of earth resistivity, 10 meter-ohms, to give the best over-all agreement between the measured transient voltages and the voltages computed on the basis of uniform earth resistivity. Although the measured voltages and computed voltages for a resistivity of 10 meter-ohms were fairly well in accord as regarded maximum values, the wave shapes were considerably different. The computed voltages increased more slowly, subsequent to the beginning of the transient, than did the measured voltages, and decreased more slowly after the maximum values were attained.

The transient voltages computed from the measured a-c coupling were in satisfactory agreement with the measured voltages, indicating that in this method of computing transient voltages the effects of nonhomogeneities of the earth were taken into account where such effects were of importance.

# Nuclear Physics Chart[1]

| Name | Picture Representation | Probable Composition | Charge | Approximate Mass | Remarks |
|---|---|---|---|---|---|
| Neutrino * | ± | Unknown | Zero | 1/2000 Unit | Undiscovered but theoretically necessary for conservation of mass energy in many nuclear transformations. |
| Electron | ⊖ | Elementary | 1 Unit Neg. | 1/2000 Unit | Carrier of electricity in wire conduction and vacuum tubes. |
| Positron ** | ⊕ | Elementary | 1 Unit Pos. | 1/2000 Unit | Discovered recently. Very unstable. Probably unites with electron and both disappear. ** Particle ejected during breakdown of a large number of artificially prepared radioactive substances. |
| Proton | ⊕ | Elementary | 1 Unit Pos. | 1 Unit | Ordinary hydrogen nucleus or ionized hydrogen atom. |
| Neutron | ± | Proton Electron | Zero | 1 Unit | Discovered recently. Electron and proton are closely bound so there is no external electric charge. This enables it to penetrate matter easily until it unties with a nucleus forming an isotope usually radioactive. |
| Deuteron Heavy Hydrogen Nucleus Diplon | ±⊕ | Neutron Proton | 1 Unit Pos. | 2 Units | Discovered recently. |
| Alpha Particle Helium Neucleus | ±⊕ ±⊕ | 2 Neutrons 2 Protons | 2 units | 4 Units | Given off in ordinary radioactivity. |
| Protium Hydrogen Atom | ⊕ ⊖ | Proton Electron | Zero | 1 Unit | Electron is separated from proton and loosely bound to it. May be ionized in discharges to form proton and free electron. |
| Deuterium *** Heavy Hydrogen Atom Diplogen Hydrogen Isotope | ±⊕ ⊖ | Proton Neutron Electron | Zero | 2 Units | Discovered recently. Occurs one part in ten thousand of ordinary hydrogen. May be easily ionized to form a deuteron. |
| Helium Atom | ⊖ ±⊕ ±⊕ ⊖ | 2 Protons 2 Neutrons 2 Electrons | Zero | 4 Units | Electrons loosely bound. May be ionized in discharges to form alpha particles and two free electrons. |

1. Compiled by Charles M. Lack, Westinghouse Electric and Manufacturing Company, and republished by permission from page 33 of *Electronics* for August 1937.

* In certain nuclear transformations it is necessary to postulate the ejection of small chargeless particles of 2 varieties or else abandon the laws of conservation of mass energy. One of these particles (neutrino) has a variable mass usually less than that of the electron and the other (anti-neutrino) a negative mass of the same amount.

** Modern physics believes mass and energy are different forms of the same thing and under certain conditions can be directly transformed one into the other. The mass of an electron, for instance, is equal to the energy of an electron or proton after being accelerated through 500 kv. When an electron and positron combine and disappear, 2 gamma rays are produced by the 500-kv type.

*** An isotope of an element is a form of the element having the same chemical properties but different mass. The chemical properties of all elements are determined by the number of outer loosely bound electrons. Thus to form an isotope it is necessary to increase or decrease the number of neutrons in the nucleus.

# Carbon Brushes for Steel-Mill Equipment

By W. C. KALB
MEMBER AIEE

*The problems associated with brush application on commutating-type equipment in the iron and steel industry are discussed in relation to type of equipment and conditions encountered in service.*

*The paper also discusses a newly defined measure of brush performance, termed "commutation factor," which provides an improved basis for control of the performance characteristics of brushes.*

*Mention is made of the development of electrographitic grades having mild polishing action, designed to prevent the formation of troublesome surface film on commutators exposed to the contaminating atmospheric conditions frequently encountered in steel mill applications.*

THE PROBLEMS associated with brush application in the iron and steel industry are fundamentally the same as those encountered wherever electrical generating equipment and motive power are used. However, service conditions in this particular industry are in some respects more severe than those usually encountered and, in certain instances, definitely unique. Discussion of the problems of brush application as related to this particular industry would therefore seem to be merited.

For the purpose of this discussion it is convenient to divide the types of equipment considered into 3 classes; first, industrial-type motors having shunt characteristics; second, series-type motors; third, generators and motors of large capacity used on mill drives. The application of brushes to slip rings will not be discussed since the number so used is small in comparison with those used on commutating equipment and the problems of application essentially the same as in other fields of service.

Undercutting of commutator mica has become an almost universal practice in steel mills. This practice removes the necessity for using brushes possessing decided abrasive characteristics. It also constitutes a valid reason for avoiding the use of so-called "self lubricating" brushes, i.e., brushes which have been impregnated with an oil or wax to maintain a film of lubrication on the commutator surface. The presence of such material tends to fill the slots of an undercut commutator with a conducting deposit which increases danger of commutator failure. Nearly all grades of brushes now manufactured have some graphite in their composition, either as a component of the original mix or imparted later by the process of graphitization. This graphite provides ample lubrication for the service conditions under which the brush is ordinarily used.

Industrial type motors of shunt characteristics present few serious problems in brush application. Apart from greater liability to troubles from conducting or abrasive dust and contaminated atmosphere, conditions of service are much the same in steel mills as in other industries. Where provision is made to insure cleanliness within the motor frame, nonabrasive electrographitic brushes give excellent service on this class of equipment. Atmospheric contamination of the commutator surface may require brushes possessing some cleaning action, the amount depending on local conditions. Under such conditions carbon-graphite brushes or special graphite brushes having a moderate cleaning action are often used. Because of variation in the amount of polishing effect required to maintain a clean commutator surface, a brush which works well on one motor may not give satisfactory performance on an identical motor in another part of the same mill. It is not advisable to attempt to offset the presence of abrasive or conducting dust by brush selection. The only sure remedy for troubles arising from this source is to prevent the dust entering the motor. This is best accomplished by piping clean, outside air to the interior of the motor frame. The dust cannot enter against an outward current of air from all openings in the frame.

Series type motors often encounter very severe operating conditions in steel-mill service. Some of the principal applications for this type of motor are on cranes, open-hearth chargers, mill screw-down, side guards, and table rolls. Heat and scale dust are almost always present in the vicinity of these motors, while oil vapor and other atmospheric contamination adds further complication on some applications. Piping in outside air will provide protection against heat, dust, and contaminated atmosphere for those machines which have a fixed location but this protection cannot be given to crane motors or others which are carried on moving equipment. In addition to the heavy load peaks, normally characteristic of the service on which series type motors are applied, the practice of "plugging" further increases the severity of operating conditions. By plugging is meant reversal of the controller before the motor comes to rest. Designers can build motors which will withstand the mechanical stresses resulting from this practice but it is impossible to provide the electrical compensation necessary to maintain good commutating conditions when direction of rotation and impressed voltage are reversed from their normal relationship. As a result, the burden of controlling commutation is thrown almost entirely onto the brushes.

Electrographitic brushes of the harder grades find extensive application on series-type motors in the steel mills. Brushes of this type, in general, have good commutating characteristics and, while not definitely abrasive, possess sufficient mass hardness to provide considerable cleaning action on the commutator. They are also highly resistant to the disintegrating effect of the sparking which inevitably occurs when motors are called upon to meet such extreme demands. In some instances, however, the

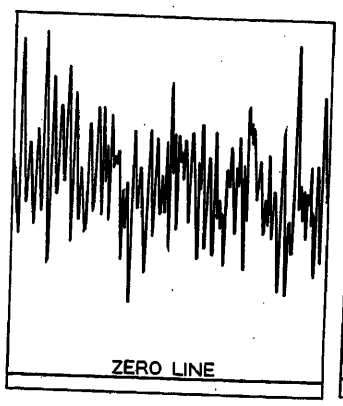

**Figure 1. Oscillographic record of contact drop on commutator with flat spot**

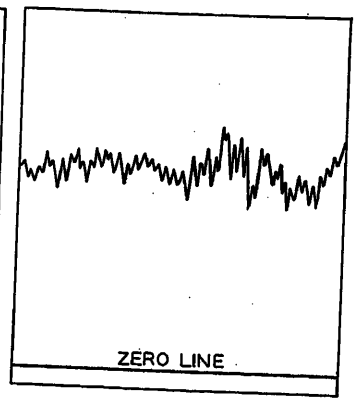

**Figure 2. Oscillographic record of contact drop on smooth commutator**

mass hardness of the electrographitic brush is not enough to overcome the burning of the commutator surface. The use of a carbon-graphite brush, having some abrasive action, is then indicated. While this abrasive action does result in some commutator wear, selection of a grade with the correct degree of abrasiveness will result in less commutator depreciation and lower maintenance expense than will be experienced if burned bars and flat spots are allowed to develop on the commutator. The latter condition may necessitate shutting down the mill for removal of the armature, an expense item of considerable moment. It may also result in more rapid loss of commutator capacity from returning than would be experienced from wear under a set of properly selected abrasive brushes.

The generators and large capacity motors used on modern steel mill drives constitute the third class of equipment on which brush application is considered in this discussion. Brushes of relatively high carrying capacity are required for this service since the motors are sometimes loaded almost to the stalling point and the current density in the brushes on both the motor and the generator rises to a very high value. In view of the sudden and extreme fluctuations of current resulting from the load conditions encountered it is also essential that brushes having exceptionally good commutating characteristics be applied. These requirements have led to the almost universal adoption of electrographitic brushes for motors as well as generators in this field of application.

Due to the industrial importance of heavy-duty electric drives in the steel mills and the fact that the demands there made upon the brushes are among the most severe encountered in heavy duty d-c power service, a thorough investigation of the brush requirements for this class of equipment has been carried on over the past few years. As a first step in this investigation, thousands of brush samples were obtained from service, together with accurate records of performance. Wherever possible these brushes were obtained in complete sets, with each brush identified as to polarity and location on the machine. A large proportion of these samples were taken from heavy duty steel mill drives, although brushes were also obtained from other heavy duty applications. Investigation was concentrated on brushes of the electrographitic type because of their predominance in this class of service. These brushes were then carefully studied in order to isolate some property common to those having good performance records and lacking in those which had failed in service.

It has long been recognized that the tests commonly applied to brush materials are not closely enough identified with the performance characteristics of the brush to provide a reliable basis for control. The tests referred to are specific resistance (electrical resistance per unit cube) hardness (as measured by the Schore scleroscope or other means) and apparent density (weight per unit of volume). These tests are simple to make and, since they do not destroy or impair the stock, they can be applied to each block of brush material. Unfortunately, however, they do not possess a well-defined relationship to the commutating properties of the brush. Contact drop and coefficient of friction are properties closely related to brush performance but tests of these characteristics require a great deal of time and it is impracticable to apply them to each block of brush material. Furthermore, the results obtained are influenced to a large extent by factors independent of the brush itself which affect the surface of the ring or commutator on which the test is being made.[1] Time, temperature, humidity, and atmospheric contamination are some of the factors which may influence the results obtained from tests of these properties. Brush manufacturers, as a class, have tried to control the performance characteristics of brushes by holding specific resistance, hardness, and apparent density within close limits but this plan has not been successful. Frequently 2 brushes which are almost identical in respect to these 3 properties will show entirely different performance characteristics.

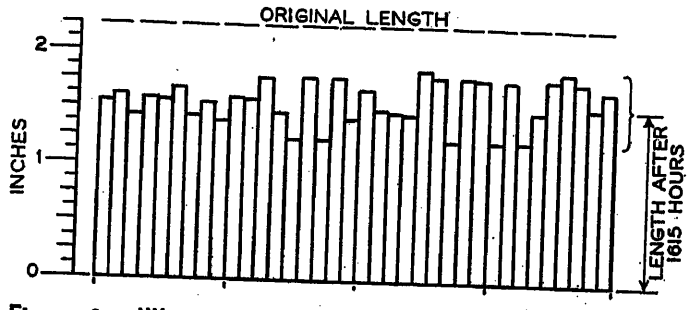

**Figure 3. Wear on brushes manufactured under customary basis of control, after 1,615 hours**

It is a well-known fact that one requisite to good brush performance is the maintenance of intimate contact between brush and commutator. Slight irregularities in commutator surface tend to impair this intimacy of contact thus causing sparking and resultant damage to commutator surface. Figure 1 is traced from an oscillographic record of the contact drop between a brush and a commutator on which a slight flat spot had developed. Figure 2 is a similar record from the same brush and commutator after the flat spot had been removed. Of course, the condition illustrated in figure 1 was accompanied by considerable sparking but no sparking occurred after re-

moval of the flat spot. It is known that irregularities in commutator surface as small as 0.0001 inch may seriously impair intimacy of contact with some grades of brushes while other grades are capable of maintaining firm contact in the presence of surface irregularities of considerably greater magnitude. In the study of this problem it soon became evident that commutating performance is closely associated with the ability of a brush to ride smoothly on the commutator and that property, in turn, with the elastic or, conversely, the shock absorbing properties of the brush.

A means was found to measure the shock-absorbing capacity of a brush and, as established by subsequent service tests, this also proved to be a measure of commutating performance. The test applied is essentially a measure of the elastic properties of the brush material. It disclosed that brushes having exceptionally good commutating properties possess a certain degree of elasticity while brushes less satisfactory in commutation show a different degree of elasticity. The characteristic so measured has been termed "commutation factor," indicating its close relationship to commutating performance. For practical purposes arbitrary numbers are assigned to indicate various commutation factors or differing degrees of elasticity. The test for this characteristic can be made quickly and does not injure the sample tested. It therefore affords an excellent basis for inspection, applicable to every block of brush material passing through production.

A practicable measure of brush performance having been found, methods were developed for the accurate control of materials and processes of production so that the required commutation factor can be imparted in accurately controlled degree to the finished product. By the methods developed it is possible to produce a series of several grades, similar in general characteristics but each having a different and sharply defined performance characteristic in respect to commutation.

This newly defined characteristic serves, not only as a measure of commutating performance, but also as a basis for obtaining improved uniformity in performance by making possible close control of one of the most important physical properties affecting performance. This is an accomplishment of major importance on applications as exacting as heavy-duty steel-mill drives. The superiority of control methods based on the use of "commutation factor" as the controlling property over methods designed to control resistance, hardness, and density, is shown by figures 3 and 4. Figure 3 shows the variation in wear among the brushes from 4 studs of a large synchronous converter after 1,615 hours of service. These brushes were of a well-known electrographitic grade and were all within close limits of tolerance in respect to resistance, hardness, and density. They did not, however, show corresponding uniformity when the test for commutation factor was applied. The brushes represented by figure 4 were manufactured under the commutation factor basis of control. They were placed on the same synchronous converter immediately after removal of the brushes represented by figure 3 and the record of wear was taken from the same 4 studs after 3,082 hours of service. The improvement in commutating performance was as marked as the improvement in uniformity of brush life which these charts indicate. A large number of carefully observed service tests confirm the evidence here presented that commutation factor is a dependable measure of brush performance and provides a reliable basis for production control.

This extensive comparison of brush performance and related physical properties also disclosed a reciprocal relationship between commutation factor and resistance to mechanical wear. Under mild commutating conditions, where electrical wear at the brush face is slight, a brush with comparatively low commutation factor will, as a rule, give longer life than one having high commutation factor. On the other hand, under severe commutating conditions the electrical wear of the brush with lower commutation factor may be so much more than that of one with high commutation factor that the latter will be superior in life as well as in commutating performance.

Atmospheric contamination is perhaps a greater source of difficulty on heavy-duty mill drive equipment than it is on the smaller series and industrial-type motors to which reference has been made in earlier paragraphs. In some mills elaborate air conditioning apparatus has been installed to remove acid fumes, oil vapor, and gaseous contamination which might cause the development of troublesome surface film on the commutators of mill-drive generators and motors. Most electrographitic brush grades are so free from all abrasive properties that they are incapable of polishing off the surface film resulting from contamination of the surrounding air. As a result, on some installations it is frequently necessary to resurface the commutators, an operation which may require shutting down the mill for an appreciable period of time. Naturally, this involves considerable expense and, if of frequent occurrence, may be a source of serious depreciation in commutator capacity. To better meet the needs of such operating conditions there has recently been developed a series of electrographitic grades possessing a mild polishing action. These have been tried out on a number of mill-drive installations and have proved capable of maintaining a clean, well-polished surface on many commutators previously troubled by film deposition when entirely nonabrasive brushes were used. The abrasive effect of these brushes is not great enough to be a source of appreciable commutator wear so that commutator de-

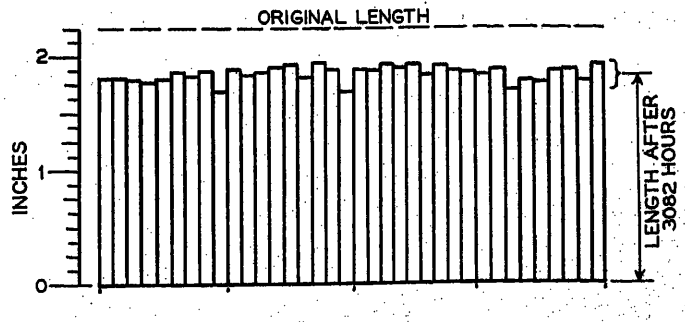

**Figure 4. Wear on brushes manufactured under "commutation factor" basis of control, after 3,082 hours**

preciation is less than that resulting from the necessity for frequent resurfacing. Furthermore, the liability to expensive shut downs and delays is reduced. Because their abrasive effect is so slight these brushes cannot be depended upon to remove existing surface faults such as burned bar edges or flat spots. Except for their slight polishing action these grades have the same general properties as the nonabrasive electrographitic grades and, like the latter, are produced with graduated and accurately controlled commutation factor.

Just why commutation factor should be a measure of the commutating performance of a brush is a point on which there may be diverse opinions. The relationship seems to be associated, at least in part, with the greater shock absorbing property possessed by a material showing high commutation factor and the resulting improvement in intimacy of contact when such a brush is subject to the impact of slight irregularities on the rapidly moving commutator surface. Whatever the explanation of this relationship may be, the fact of its existence has been demonstrated by service as well as laboratory tests. The discovery of this relationship represents another step of progress toward the solution of the many perplexing problems associated with commutation on equipment subject to such exacting conditions of service as are today encountered in the iron and steel industry.

# Large Steel Pipe Welded by Improved Methods

IN preparation for completion of the Colorado River aqueduct, now scheduled for the winter of 1938–39, construction has been under way for some time on the distribution system which the Metropolitan Water District of Southern California is building for delivery of aqueduct water to member cities. The 242-mile main aqueduct from the Colorado River has its western terminus in Cajalco reservoir. Some 150 miles of distribution lines will be required to convey the water to the 13 cities of the District, located on the coastal plain between Cajalco and the sea. These distribution lines are the equivalent of a major water system in themselves, including a large mileage of tunnels, precast concrete pipe up to 12½ feet in diameter, and steel pipe in diameters up to 11½ feet. Because of the large diameter of the steel line, particular interest attaches to methods of fabrication in the shop and in welding metal as thick as $^{31}/_{32}$ inches under trench conditions, that is, where the pipe cannot be rotated during the welding process.

The steel pipe sections are all 33 feet 4 inches in length; diameters range from 10 feet 4 inches to 11½ feet except on the bridge across the Santa Ana River where pipe of 9 feet 8 inches diameter is used. The thickness varies, according to the head, from $^{17}/_{32}$ to $^{31}/_{32}$ inch. Correspondingly, the weight ranges from 18 to 28 tons per section.

*Shop Welding.* Each section is made up of 4 steel plates rolled to the proper curve and requiring only a single longitudinal weld in each plate to form a cylinder of the pipe diameter. The completed section is made up by putting together 4 of these cylinders and welding the 3 circumferential joints. In assembling a section, longitudinal welds are staggered. Circumferential welds are made in a large automatic electric welding machine which completes the weld, even in the $^{31}/_{32}$-inch thickness, with a single pass.

Two types of mounting are used for the welding machines: For longitudinal seams the welding equipment is on a carriage which moves lengthwise of the pipe as the weld progresses; a larger machine, used for making the circumferential welds, is stationary and the pipe is rotated as the weld progresses. Both welding machines operate on top of the pipe.

The adjoining edges of the plates to be welded are beveled so the molten metal flows in a V-shaped groove filled in advance with a flux. The flux is a silicious material applied in a powdered form resembling ground glass. The heat of the electric current, fusing the flux, forms a covering over the molten metal closely resembling glass in texture and brittleness. This glass-like covering is so brittle it is easily broken off with a hammer after the weld has cooled. The automatic welding machines work at about 40 volts and use a current of 1,100 or 1,200 amperes. In the longitudinal welds a pair of plates with a V groove similar to that in the joint itself are tack welded at the end of the joint where welding starts, thus affording a few inches for the welding operation to get well under way before reaching the joint in the pipe. Test coupons, attached at the end of the longitudinal weld, are taken every 800 linear feet of weld. All pipes with metal thicknesses exceeding $^{5}/_{6}$ inch are annealed, after welding, at temperatures of 1,100 degrees Fahrenheit after which they are cooled slowly.

*Welding Field Joints.* When a joint is fully entered ready for welding, it is tacked with welds 4 or 5 inches long spaced as required. This is done to prevent any tendency to creep as welding progresses around the circumference. The tack welding is done by one man on the inside and two on the outside.

Completion of the weld involves a number of passes varying with the thickness of the metal. With 7 passes for the thickest metal, the 11½-foot pipe requires 40 man-hours per joint or the equivalent of one man's time for a full week on the inside and outside of a single joint. With a crew of about 40 welders, joints in the trench are completed, inside and outside, at the rate of 8 sections per day.

All welds, in shop and field, are done electrically. In the field, current is supplied by portable motor-generator sets equipped for remote voltage control. The welder sets the control for any voltage he prefers from 40 to 80; the amperage is about 250.

# The Design of Inductances for Frequencies Between 4 and 25 Megacycles

By DALE POLLACK
ASSOCIATE AIEE

## Summary

The results of a study of the resistance of small single-layer inductances for use at frequencies between 4 and 25 megacycles are given. From experimental and analytical work a procedure has been deduced for the optimum design of such inductances.

## Introduction

WHILE IT HAS long been recognized that radio receiver performance is dependent upon the merit of the inductances employed in the tuned circuits, few data beyond 4 megacycles are available upon which to base the design of such inductances. Because of the lack of this information, design calculations at high frequencies have in general been limited to obtaining the correct inductance values. While some attention has been paid to obtaining low effective resistance, the efforts in this direction have usually been misdirected, with the emphasis on factors which actually are of little consequence in determining coil resistance.

A tuned circuit is represented to a first degree of approximation by the equivalent circuit shown in figure 1. For the small coils considered in this study, $C_0$ is very small,[1] less than 5 micromicrofarads, and it may be combined with the capacitance of the tuning condenser, $C$, with which the coil is associated, since $R_c$ is always small. The effective resistance of the inductance is usually considerably larger than the effective resistance of the condenser, but, at high frequencies, the condenser resistance may also be of importance.

The numerical value of the inductance, $L$, is determined by circuit considerations, and, consequently, is fixed by specification. This paper is concerned with the value of the effective resistance, $R$, of the coil, and with the design of coils to have a minimum effective resistance. It is usual to compare tuned circuits on the basis of the ratio of their reactance to their total effective resistance, $\omega L/R$ or $1/\omega CR$ denoted by $Q$. The highest $Q$ consistent with practical limitations—such as those of cost and space—is the desideratum. The importance of high $Q$ circuits in modern receiver design is well known.

The increase in resistance of an air-core solenoid at high frequencies over its d-c resistance is the result of:[2]

1. Skin effect in the wires, that is, the nonuniform current distribution over the cross section of the wire, caused by the internal flux of the wire itself.
2. Proximity effect, that is, the nonuniform current distribution over the cross section of the wire caused by the flux from neighboring turns of wire.
3. Dielectric losses, caused by hysteresis in the dielectric between turns of wire, or situated near the wire.
4. Eddy current losses in metallic bodies in the field of the coil.
5. Electromagnetic radiation losses.

As a consequence of these losses, the effective resistance of a coil may be many times its d-c resistance. The magnitude of these losses is determined by the construction of the coil, the factors which must be considered in designing a coil being:

1. Coil dimensions: length and diameter.
2. Wire: material, insulation, and size.
3. Coil form: material, insulation, and size.
4. Location of coil with respect to metallic and dielectric bodies.

The design problem is to proportion these factors, so that the resistance of the coil will be a minimum.

## Early Work

The most extended analytic work on coil resistance at high frequencies which can be applied to the types of coils used in radio equipment is that of Butterworth.[3] Butterworth's solution treated both skin effect and proximity effect in short solenoids and multilayer coils. The mathematical analysis made in this paper, in appendix II, is an extension and simplification of Butterworth's conclusions, as applied to short solenoids at frequencies above 4 megacycles. Butterworth's treatment is useful, in that the assumptions which were found necessary did not place any restriction on the frequency. However, his solution to this difficult problem was complicated, and has not received much practical attention. The conclusions were later reduced to a form better adapted to practical computations,[4] but the design method was still involved and has not been generally applied.

Published experimental information on coil resistance above 4 megacycles is meager. Hund and DeGroot[5] carried their measurements as far as 5 megacycles. Hall[6] describes tests at frequencies up to 6 megacycles, and Morecroft[7] presents data on measurements made up to 4 megacycles. A more recent paper, by Schwarz,[8] describes

A paper recommended for publication by the AIEE committee on communication. Manuscript submitted October 10, 1936; released for publication July, 19, 1937.

DALE POLLACK is an engineer with the RCA Manufacturing Company, Camden, N. J.

The experimental work involved in the study was carried out in the Marcellus Hartley Laboratory of the electrical engineering department of Columbia University. The writer wishes to thank Professors Walter I. Slichter, Edwin H. Armstrong, and John B. Russell, of Columbia University, for their kind supervision and assistance, and Doctor George P. Wadsworth, of the Massachusetts Institute of Technology, for checking the equations.

1. For all numbered references, see list at end of paper.

tests made at frequencies up to 10 megacycles. None of these data have been correlated for design purposes. Reference to work above 10 megacycles is almost entirely lacking, only one published paper having been found, by Barden and Grimes,[9] describing measurements at the single frequency, 15 megacycles.

## Experimental

Tests were performed on 2 sets of coils, having inductances of approximately 1.1 and 3.6 microhenrys. A large number of coils was wound, with groups in which one design parameter at a time was varied. The extremes over which the measurements were carried were:

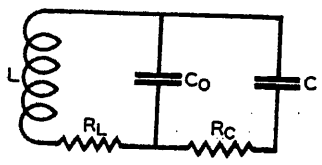

**Figure 1. Approximate equivalent circuit of coil and tuning condenser**

Frequency: 6 to 22 megacycles.
Wire size: 14 to 36, B. and S. gauge.
Coil diameter: 2.5 to 6.5 centimeters.
Coil length: 0.5 to 3.5 centimeters.

In addition, tests were made for a variety of coil form materials, and for several depths of winding grooves for the wire. Except where otherwise noted enameled copper wire was used.

The circuit resistance was measured by the reactance variation method,[10] using 2 condensers in parallel, as in figure 2, and a vacuum-tube voltmeter as the indicator. The condenser, $C_1$, is the tuning condenser, while $C_2$, with a total capacitance variation of only 6 micromicrofarads was employed to obtain the reactance change. The condensers were calibrated by a substitution method at a low radio frequency. The voltmeter was calibrated by comparison with a thermocouple, also at a low radio frequency.

Each of the coils was mounted on a pair of brass pins about 4 centimeters long, which fitted into mercury contact cups mounted in the center of a cubical copper compartment about 20 centimeters on each edge. The frequency of the oscillator used for a power source was maintained constant to within about 0.02 per cent by tuning to zero beat with harmonics of a crystal oscillator and maintaining a continuous audible check on the beat note with a radio receiver. In this way any frequency drift or reaction of the tuned circuit upon the oscillator source would have been detected, if it had occurred.

In the application of the reactance variation method of measurement, the total of all the circuit losses is obtained, including condenser and lead losses, tube input losses, and the coil losses. In this study, the data, except where otherwise noted, include the circuit and condenser resistance, but a correction has been made for the input impedance of the vacuum-tube voltmeter, as mentioned below. Despite the fact that some of the corrections have not been made, at any frequency for a given coefficient of self-inductance, the various experimental curves are comparable, because under such conditions the circuit and condenser losses are constant.

As a matter of interest, an attempt was made to determine the magnitude of the loss resulting from the input resistance of the vacuum-tube voltmeters.[11] In the tests of the 3.6 microhenry coils, a 24*A* tube was used in the voltmeter circuit, while, in the tests of the 1.1 microhenry coils, a 954 acorn tube was employed, in a triode connection. The tube losses were determined by shunting the circuit of figure 2 with a second identical vacuum-tube voltmeter, and remeasuring the $Q$. From the change in the overall $Q$ of the circuit, the effective resistance of the tube can be calculated. This method assumes that the condenser losses are independent of the small capacitance change necessary to retune the circuit to resonance, when the second vacuum tube is added.[12] From the data obtained for the effective input resistance of the voltmeters, correction factors for any $Q$ and any frequency have been plotted. These are shown in figures 3 and 4. While, as has been pointed out previously, it is not essential that these corrections be made, since the information was available, it was employed, and the experimental results presented in this paper have been corrected for the input resistance of the voltmeter.

## Results

In appendix II expressions are derived for the effective resistance and the $Q$ of a coil at high frequency, taking account of the wire losses, i.e., the skin effect and the proximity effect, only. When the frequency is well below the natural frequency of the coil, it is found, after certain assumptions are made, that the $Q$ of an inductance coil is

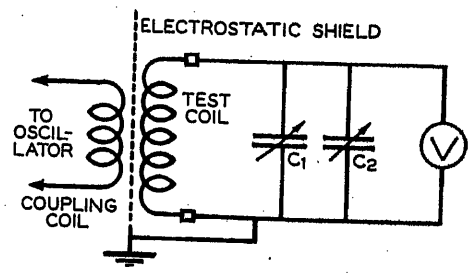

**Figure 2. Measurement circuit. A vacuum-tube voltmeter is used**

$$Q = \frac{f^{1/2}LdS^2D}{10^{3/2}\rho^{1/2}(S^2D^2N + 2N^3d^2)} \qquad (20)$$

or, the $Q$ is directly proportional to the square root of the frequency. For the coils employed in these tests (20) has been found to agree with Butterworth's equations, from which it is derived, by better than 10 per cent.

An exact experimental check on this equation is difficult because of the impracticability of separating precisely the skin and proximity effects from the circuit and coil losses which the equation does not include. Moreover, (20) was not used for design purposes and it consequently was not deemed essential to make a precise check. For illustration, however, a typical set of data are shown in figure 5, in which an attempt is made to break down the various loss components of the measurement circuit. Dielectric

losses in the coil form and wire insulation and vacuum-tube losses were corrected for by measurement, as described elsewhere in this paper. The distributed capacitance correction was made by (12). This correction is necessary, because the tuning condenser in the reactance variation method is calibrated without a coil in the circuit. Effectively, therefore, the addition of the distributed capacitance of the test coil constitutes an error in the calibration of the tuning condenser, and a correction must be made to the measured value. The approximate lead losses were calculated from the d-c lead resistance by applying the usual skin-effect formulas.

The condenser losses were estimated by assuming a condenser resistance of 0.02 ohm at 10 megacycles, increasing to 0.045 ohm at 20 megacycles. This is a conservative estimate. The condenser resistance was probably in excess of these figures, but could not be measured conveniently.

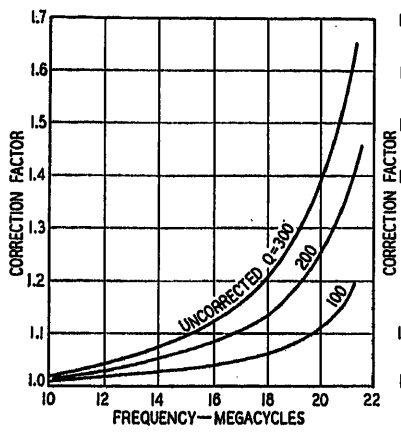

**Figure 3. Correction factor to correct for the input resistance of the 24A tube in the vacuum-tube voltmeter**

Corrected $Q$ = factor × uncorrected $Q$

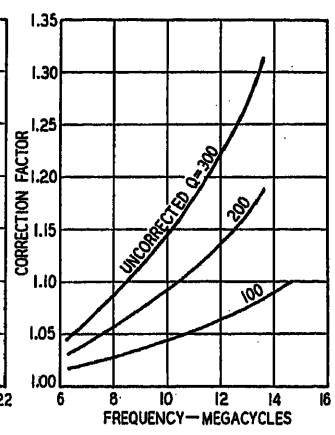

**Figure 4. Correction factor to correct for the input resistance of the triode-connected 954 tube in the vacuum-tube voltmeter**

The only loss components properly chargeable to the coil, besides the skin and proximity effects, are the dielectric losses and the unaccounted losses.

### Effect of Wire Size

An experimental set of curves illustrating the variation in $Q$ with wire size is shown in figure 6. The optimum wire diameter, as obtained in appendix II, is

$$d_0 = b\sqrt{\frac{D}{2L(102S + 45)}} \tag{16}$$

or

$$d_0 = \frac{b}{\sqrt{2N}} \tag{17}$$

In table I the values of the optimum wire size calculated from either of these expressions is compared with experimental values obtained from curves similar to those of figure 6. The test coils were wound on bakelite forms with enameled wire, typical of the construction used in practice. In most cases the agreement is better than the difference between diameters of successive wire sizes, namely, 12 per cent. The probable experimental error is about 8 per cent. It may be concluded that there is an optimum wire size for any given coil, and that this optimum size can be calculated from (16) or (17).

### Length-to-Diameter Ratio

The determination of the proper ratio of length to diameter for a solenoid is more difficult. Some confusion has resulted from the wide variations in conclusions which have been reached by various investigators.[3,9,14] The apparent inconsistencies result from the fact that different variables are considered in different studies. The solution which is reached must always depend upon the geometric or economic limitations which are assumed. The coil volume, surface area, wire length, or any of several other factors may be assumed constant, depending upon the nature of the problem. It should also be noted that either the wire size may be kept constant, or the optimum value may be employed, although, for design purposes, the latter is preferable.

**Table I. Experimental Verification of (16) and (17)**

| Coil Description | | | Optimum Wire Diameter (Centimeters) | | Percentage Difference From Experimental Figure |
|---|---|---|---|---|---|
| Inductance (Microhenries) | Diameter (Centimeters) | Length (Centimeters) | From Equation | From Experiment | |
| 3.6 | 2.5 | 1.55 | 0.090 | 0.102 | 12 |
| 3.6 | 3.8 | 1.45 | 0.108 | 0.115 | 6 |
| 3.6 | 2.5 | 1.55 | 0.090 | 0.115 | 22 |
| 1.1 | 2.5 | 0.89 | 0.105 | 0.100 | 5 |
| 1.1 | 2.5 | 0.56 | 0.079 | 0.093 | 15 |
| 1.0 | 1.3 | 0.69 | 0.055 | 0.064* | 13 |
| 1.0 | 3.8 | 0.79 | 0.142 | 0.134* | 6 |

* From data in Barden and Grimes's paper.[9]

The effect of changes in ratio of coil length to diameter, for a certain group of coils in which the coil diameter, wire size, inductance, and frequency are held constant, is shown in figure 7. A similar set of curves, except that the coil length is held constant, instead of the diameter, is given in figure 8. For the specifications for which these curves are obtained, namely, the wire size, inductance, frequency, and either the diameter or length constant, it appears that the optimum ratio of length to diameter is between 0.5 and 0.3. Fortescue[14] arrived at optimum values of the length: diameter ratio greater than unity, from an analytic treatment based upon similar assumptions, but Butterworth[14] has shown that an error must have been contained in the calculations. The curves also illustrate that the maxima obtained are flat, and values within a reasonably wide range may be employed without departing greatly from the maximum value of $Q$.

### Coil Dimensions

For design purposes the variation in $Q$ with the coil dimensions, when the optimum wire size of (16) or (17) is used, is of greater importance, since higher $Q$'s may be

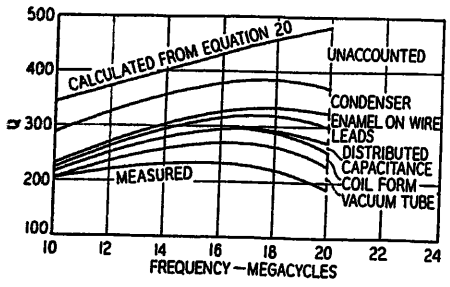

**Figure 5. Comparison of calculated and measured Q**

Coil dimensions for this figure: $L = 1.1$ microhenrys, $D = 2.5$ centimeters, $b = 3.4$ centimeters, wire size, 18 B. and S.

obtained in this way. In appendix II it is shown that, if the wire size is maintained at the optimum value, the figure of merit is given by,

$$Q_m = \frac{f^{1/2}\ Db}{\sqrt{2000}\ \rho^{1/2}\ (102b + 45D)} \tag{22}$$

For convenience in investigating the effect of changes in coil shape (22) is rearranged, giving

$$Q_m' \equiv \frac{Q_m}{\frac{f^{1/2}}{\sqrt{2000}\rho^{1/2}}} = \frac{Db}{102b + 45D} \tag{22a}$$

$$= \frac{D}{102 + \frac{45}{S}} \tag{22b}$$

$Q_m'$ is, of course, directly proportional to $Q_m$. These relations are plotted in figures 9 and 10. It is noted that, for a constant diameter of coil, the $Q$ increases as the coil length is increased, but the increase is less rapid as large values of $b/D$ are attained. Consequently, if an economic or a practical limitation is placed upon the design, there will be an optimum ratio.

Experimental data are shown in figure 11. The curve has been plotted from an equation of the form

$$Q_m = \gamma \frac{D}{102 + \frac{45}{S}} \tag{22c}$$

where $\gamma$ has been selected empirically to cause the curve to pass through one of the experimental points. The curve, therefore, shows the agreement of the experimental data with the shape of (22*b*). If (22*b*) had been plotted directly, it would have shown exactly the same shape as (22*c*), but displaced in the positive ordinate direction, since it does not take account of the circuit losses, radiation losses, and dielectric losses, which are all included in the experimental data.

Frequently, the maximum coil dimensions are fixed by the size of the coil shield, which, in turn, is limited in size by the space available in the apparatus. The presence of a coil shield usually reduces the $Q$, because of the increased eddy current loss. It has been shown by several experimental and mathematical studies[15] that, if the coil diameter is less than half the shield diameter, and the ends of the coil are separated by at least a coil diameter from the ends of the shield, the $Q$ of the tuned circuit is not reduced by more than 5 to 8 per cent. This restriction may be employed to determine the size of a coil enclosed in a shield.

It is of interest to note that, if the wire size, inductance, and length: diameter ratio are kept constant, an optimum diameter of coil can be obtained for which the $Q$ is a maximum. This is shown mathematically in appendix II, and the optimum diameter is found to be

$$D_0 = \sqrt[3]{\frac{10d^2L(102S + 45)}{S^2}} \tag{24}$$

A set of coils was wound which checks this relation very closely. The experimental results are plotted in figure 12, from which the maximum $Q$ is seen to obtain for a diameter of 4.0 centimeters. From (24) a value of 3.9 centimeters is obtained.

### Calculation of Number of Turns

The number of turns, for a given inductance, when the diameter and length of the coil are known, can be calculated from

$$N = \sqrt{\frac{L(102S + 45)}{D}} \tag{14}$$

which is derived in appendix II. This equation will usually give the correct value within about 5 per cent, and the coil, when wound, can be adjusted to the required value in any of the usual ways.

### Dielectric Losses

The magnitude of the dielectric losses in the coil form and in the enamel wire insulation for typical coils at high frequencies was investigated. Examples are given herewith. To measure the dielectric losses in the coil form 2 similar coils, of 2.5-centimeter diameter, were wound, one using a grooved bakelite form with a groove about 0.04 centimeters deep, the other wound self-supporting, except for 3 narrow celluloid strips to which the wire was fastened with collodion. The percentage loss in $Q$ resulting from the grooved bakelite form is shown in figure 13. At 14 megacycles the loss is less than 10 per cent.

The curves of figure 14 are for a set of 3 similar coils, of 5-centimeter diameter, one wound without any supporting material—similar to the coil described in the preceding paragraph—, one wound on a grooved bakelite form, and the third on a grooved cardboard form about one centimeter in thickness: worse than any case one would expect to find in practice. The groove in each case was about 0.04 centimeters deep. At 13 megacycles the reduction in $Q$ resulting from the heavy cardboard form was 27 per cent. A wood form, used for another coil, gave results similar to those obtained for the cardboard. The loss in $Q$ resulting from the grooved bakelite form was 19 per cent at 13 megacycles.

To measure the dielectric loss in the coil form at higher frequencies, a group of 1.1 microhenry coils was wound, one on a smooth bakelite form, one on grooved bakelite with a groove about 0.04 centimeter deep, and one without a supporting form, as described previously. The difference between the smooth bakelite and the air-core samples was smaller than the experimental error. The loss in $Q$ resulting from the groove in the bakelite is plotted in figure 15, and amounts to 13 per cent at 20 megacycles.

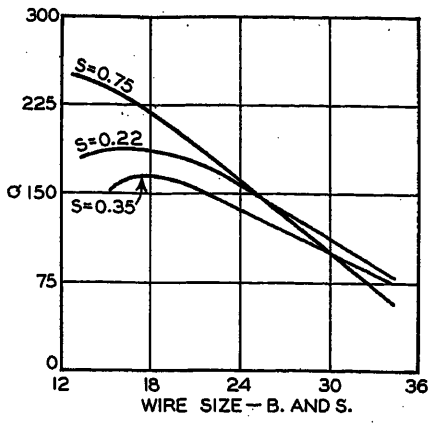

**Figure 6. Experimental curves illustrating variation in Q with wire size**

For this set of curves, $f$ = 20 megacycles, $L$ = 1.1 microhenrys, $D$ = 2.5 centimeters. Curves similar to these were used in preparing the data of table I

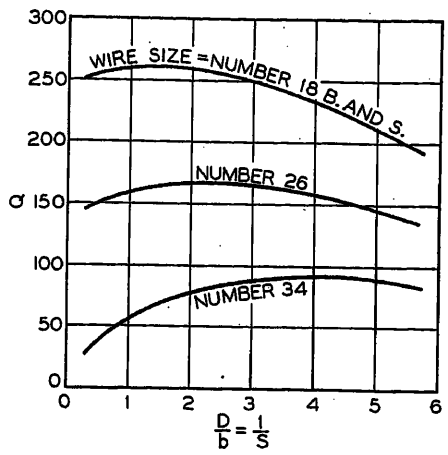

**Figure 7. Experimental curves illustrating the variation in Q with coil length : diameter ratio, when the diameter is constant**

For this set of curves, $f$ = 17 megacycles, $D$ = 2.5 centimeters, $L$ = 1.1 microhenrys

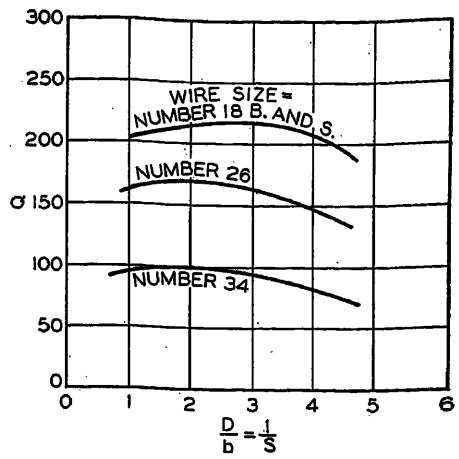

**Figure 8. Experimental curves illustrating the variation in Q with coil length : diameter ratio, when the length is constant**

For this set of curves, $f$ = 13 megacycles, $b$ = 1.5 centimeters, $L$ = 3.6 microhenrys

To investigate the dielectric loss in the enamel wire insulation, 2 similar coils were wound, on smooth bakelite forms, one using enameled wire, the other bare copper wire carefully cleaned to remove corrosion. The per-cent loss in $Q$ resulting from the enamel is plotted in figure 16 and amounts to about 6 per cent at 20 megacycles. This result is quite reasonable, since the dielectric path in a spaced winding is largely in air. Below 5 megacycles the dielectric loss in the wire insulation is difficult to detect. After a time bare copper wire corrodes and the dielectric loss in the enamel insulation may become smaller than the loss resulting from corrosion.

These data indicate the relative unimportance of the dielectric losses in determining coil performance. The choice of coil form material, within reason, and the use of enameled wire, have little effect on the merit of the coil. A loss of less than 10 or 20 per cent can be expected for small diameter coils, if a deeply grooved form is used. A shallower groove may be used with little sacrifice in rigidity and an improvement of a few per cent in the figure of merit. An ungrooved bakelite form causes very little loss in $Q$.

## Summary

The merit of coils for frequencies above 4 megacycles is determined largely by the winding design. A suitable procedure for the optimum design of coils for these frequencies is:

1. Coil diameter and length of winding: Make as large as is consistent with the shield being used. The shield diameter should be twice the coil diameter and the ends of the coil should not come within one diameter of the ends of the shield.

2. A bakelite coil form with a shallow groove for the wire, and enameled wire, may be used with little reduction in the $Q$. The groove should not be any deeper than is necessary to give the requisite rigidity. The use of special coil form constructions and special materials does not appear to be justified.

3. Number of turns: Calculate from

$$N = \sqrt{\frac{L(102S + 45)}{D}} \qquad (14)$$

4. Wire size: Calculate from

$$d_0 = \frac{b}{\sqrt{2}N} \qquad (17)$$

## Appendix I. Notation and Units

$b$ = length of winding, centimeters
$C$ = capacitance, micromicrofarads
$C_0$ = self-capacitance of coil, micromicrofarads
$d$ = diameter of wire, centimeters
$d_0$ = optimum wire diameter, centimeters
$D$ = diameter of coil, centimeters

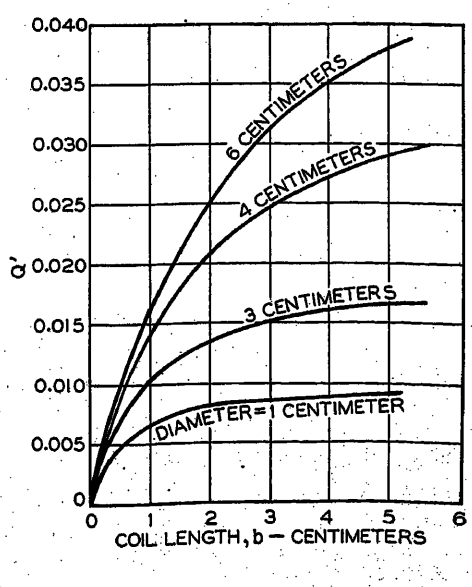

**Figure 9. Plot of (22a), showing the variation in Q with length and diameter of coil, when the wire size is kept at the optimum value**

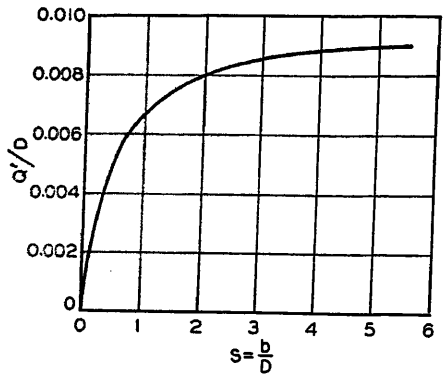

**Figure 10. Plot of (22b) showing the variation in Q with the length : diameter ratio, when the wire diameter is optimum and the coil diameter is constant**

$D_0$ = optimum coil diameter, centimeters
$f$ = frequency, cycles per second
$F$ = skin effect factor, see (1)
$G$ = proximity effect factor, see (1)
$j$ = $\sqrt{-1}$
$K$ = factor depending on $S$, see (1)
$L$ = inductance, microhenrys
$N$ = total number of turns of wire on coil
$Q$ = figure of merit of tuned circuit
$Q_m'$ = factor proportional to $Q_m$. See (22*b*)
$Q_m$ = figure of merit for optimum wire size
$R$ = effective resistance of tuned circuit or of coil, ohms
$R'$ = effective resistance of coil, including effect of self-capacitance
$R_c$ = effective resistance of condenser
$R_d$ = d-c resistance of coil, ohms
$R_L$ = effective resistance of coil
$S$ = ratio of length to diameter of coil = $b/D$
$X$ = reactance of coil, ohms
$z$ = skin effect coefficient, see (4)
$\gamma$ = empirical constant in (22*c*)
$\omega$ = angular velocity = $2\pi f$
$\rho$ = specific resistivity of conductor, in ohms per centimeter. For copper, $\rho = 1.72 \times 10^{-6}$ ohms per centimeter

## Appendix II. Derivation of Equations

Butterworth[3] has shown that the effective resistance of a coil, including the skin and proximity effects, may be expressed by the relation

$$R = R_d\left[1 + F + \frac{1}{4}\left(\frac{KNd}{D}\right)^2 G\right] \tag{1}$$

where, at high frequencies,

$$1 + F = \frac{\sqrt{2}z + 1}{4} \tag{2}$$

$$G = \frac{\sqrt{2}z - 1}{8} \tag{3}$$

and

$$z = \pi d\sqrt{\frac{2f}{10^9\rho}} \tag{4}$$

The quantities are expressed in practical centimeter-gram-second units. $K$ is a factor depending upon the ratio of coil length to diameter.

For copper wire

$$= 0.1d\sqrt{f} \tag{5}$$

, for No. 20 B. and S. wire

$$= 0.008\sqrt{f} \tag{6}$$

and, for frequencies greater than 4 megacycles,

$$z > 16$$

Consequently, for the high frequency case considered in this paper, (2) and (3) may be written, without much error

$$1 + F = \frac{\sqrt{2}}{4}z = \frac{\pi d}{2}\sqrt{\frac{f}{10^9\rho}} \tag{7}$$

$$G = \frac{\sqrt{2}}{8}z = \frac{\pi d}{4}\sqrt{\frac{f}{10^9\rho}} \tag{8}$$

Now, if the turns of the coil are assumed to be circular, which is not exactly true,

$$R_d = \frac{\rho l}{A} = \frac{4\rho DN}{d^2} \tag{9}$$

The factor, $K$, can be computed for any value of $S = b/D$ from series expansions. A simple empirical equation for $K$ has been found from the expansions. This relation is

$$K = \frac{4}{S} \tag{10}$$

For values of $S$ between 0.25 and 1.00 this simple expression gives $K$ to within 3 per cent of its correct value.

Equations 7, 8, 9, and 10 may be substituted into 1, giving an expression for the wire resistance of a coil at high frequencies, in terms of its physical dimensions,

$$R = 2\pi\sqrt{10^{-9}\rho f}\left[\frac{DN}{d} + \frac{2N^2d}{S^2D}\right] \tag{11}$$

If the coil is used at a frequency near its natural resonant frequency, its resistance is modified by its self-capacitance. The apparent resistance of the coil-self-capacitance combination of figure 1 is given by

$$R' = \frac{R}{(1 - \omega^2LC_0)^2} \tag{12}$$

assuming that the self-capacitance is lumped across the terminals of the coil. When the coil is shunted by an external capacitance, as in a tuned circuit, the self-capacitance becomes part of the shunt

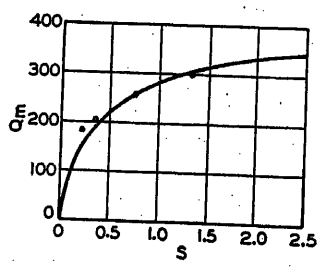

**Figure 11. Relation between the length : diameter ratio and Q, when the wire size is kept optimum. The points are from experimental data; the curve shown was drawn from (22c), after $\gamma$ had been selected to pass the curve through one of the experimental points**

For this curve, $D$ = 2.5 centimeters, $L$ = 1.1 microhenrys, $f$ = 11 megacycles

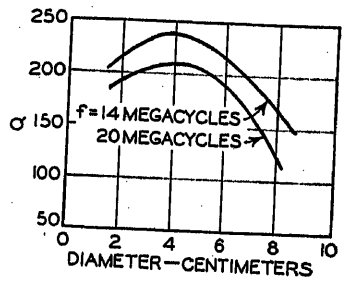

**Figure 12. Plot of Q against coil diameter, when the length : diameter ratio and the wire size are constant**

For these experimental data, $b/D$ = 2.8, $L$ = 1.1 microhenrys, $d$ = 0.081 centimeter

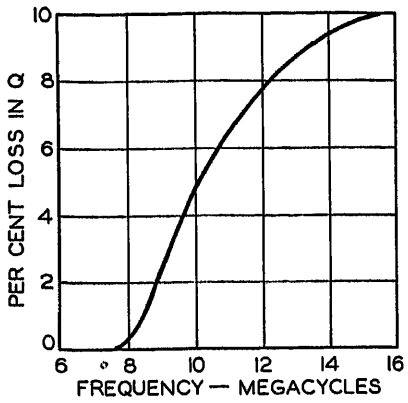

**Figure 13. Per cent loss in Q resulting from grooved bakelite form**

For this figure, $L$ = 3.6 microhenrys, $D$ = 2.5 centimeters, $b$ = 1.5 centimeters, wire size, number 18 B. and S.

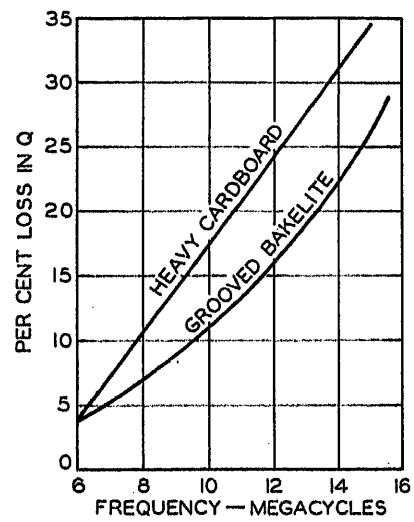

**Figure 14. Per cent loss in Q resulting from heavy cardboard form and grooved bakelite form**

For this figure, $L$ = 3.6 microhenrys, $D$ = 5 centimeters, $b$ = 1.5 centimeters wire size, number 32 B. and S.

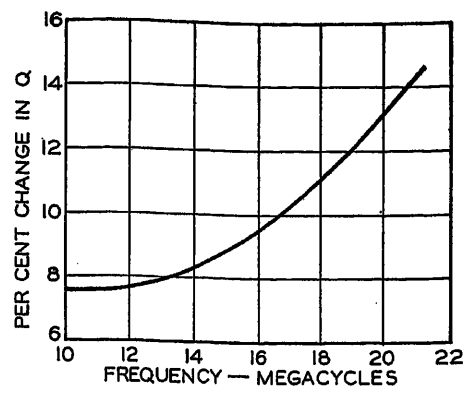

**Figure 15. Per cent loss in Q resulting from groove in bakelite form. No measurable loss resulted from the use of a smooth bakelite form**

For this figure, $L$ = 1.1 microhenrys, $D$ = 2.5 centimeters, $b$ = 1.9 centimeters, wire size, number 14 B. and S. Groove approximately 0.04 centimeter deep

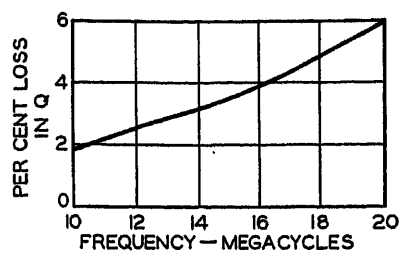

**Figure 16. Per cent loss in Q resulting from enamel wire insulation**

For this figure, $L$ = 1.1 microhenrys, $D$ = 2.5 centimeters, $b$ = 3.4 centimeters, wire size, Number 18 B. and S.

capacitance and the apparent increase in resistance resulting from the distributed capacitance does not represent a physical loss. Note that the reactance variation method of measurement gives the apparent resistance, $R'$, and the correction must be made to obtain the true coil resistance, $R$.

It was found convenient, also, to be able to express the inductance of a coil as a function of the coil dimensions. For this purpose, Rayleigh's equation[16]

$$L = DN^2\left[2\pi \ln \frac{4D}{b} - \frac{1}{2} + \frac{b^2\pi}{4D^2} \ln\left(\frac{4D}{b} + \frac{1}{4}\right)\right] \tag{13}$$

was found suitable. This equation, in common with most inductance formulas, was originally derived assuming the coil to have the form of a cylindrical current sheet, and consequently does not take account of the size of the wire or the frequency. A relatively simple empirical expression was found for the bracketed term, giving[17]

$$L = \frac{DN^2}{102S + 45} \tag{14}$$

This agrees with Rayleigh's equation within 2 per cent for values of $S$ between 0.25 and 1.00. Rayleigh's equation gives values of inductance within better than 3 per cent of their true values.

If the value of $N$ which is obtained from (14) is substituted in (11), the result is

$$R = 2\pi\sqrt{10^{-9}\rho f}\left[\frac{L^{1/2}D^{1/2}(102S + 45)^{1/2}}{d} + \frac{2dL^{3/2}(102S + 45)^{3/2}}{S^2D^{5/2}}\right] \tag{15}$$

To find the optimum wire size for fixed values of $L$, $S$, and $D$, (15) can be differentiated and the result equated to zero; that is, take

$$\frac{\partial R}{\partial d} = 0$$

If this operation is performed, the result obtained, for the optimum wire size to give minimum resistance, is

$$d_0 = b\sqrt{\frac{D}{2L(102S + 45)}} \tag{16}$$

If the value of $L$ from (14) is substituted in this equation, the particularly simple relation

$$d_0 = \frac{b}{\sqrt{2N}} \tag{17}$$

is obtained. Differentiating (11) would yield this result directly. These results can be substituted in (15) for $d$ to give the resistance of a coil, when the wire size is always optimum,

$$R_m = 4\pi\sqrt{2 \times 10^{-9}\rho f}\left[\frac{L(102b + 45D)}{Db}\right] \tag{18}$$

or

$$R_m = 4\pi\sqrt{2 \times 10^{-9}\rho f}\,\frac{N^2}{S} \tag{19}$$

These equations may be applied directly to the prediction of $Q$, as well as of $R$. Substituting the value of $R$ from (11) into

$$Q = \frac{X}{R}$$

gives, for any wire size,

$$Q = \frac{f^{1/2}LdS^2D}{10^{9/2}\rho^{1/2}[S^2D^2N + 2N^3d^2]} \tag{20}$$

The use of (15) yields

$$Q = \frac{f^{1/2}L^{1/2}S^2D^{5/2}}{10^{9/2}\rho^{1/2}[S^2D^3(102S + 45)^{1/2} + 2d^2L(102S + 45)^{3/2}]} \tag{21}$$

In the same way, the value of the figure of merit when the optimum

wire size is employed, $Q_m$, is, from (18),

$$Q_m = \frac{f^{1/2}\ Db}{20^{3/2}\rho^{1/2}(102b + 45D)} \tag{22}$$

or, from (19),

$$Q_m = \frac{f^{1/2}LS}{20^{3/2}\rho^{1/2}N^2} \tag{23}$$

Equation 15 may also be differentiated with respect to $D$, holding $L$, $S$, and $d$ constant, giving, for the optimum diameter

$$D_0 = \sqrt[3]{\frac{10d^2L(102S + 45)}{S^2}} \tag{24}$$

Note that the equations for the optimum wire size, (16) and (17), are not consistent with (24), because a different set of variables is assumed in each case. (24) is useful, practically, only because it affords an opportunity for an added experimental check on the analysis.

# Matrices in Engineering

By LOUIS A. PIPES
ASSOCIATE AIEE

## I. Summary

IT IS THE purpose of this paper to develop in a concise and simple manner the theory of matrix algebra from the foundations, and to emphasize the use of this powerful method in engineering problems.

It appears not to be a well-known fact among engineers that the matrix is not only a convenient notation that summarizes in a natural and convenient form whole groups of operations but that it is actually possible to solve the sets of differential or algebraic equations written in matrix form in a most convenient manner.

The method by which this is done is one of the utmost simplicity but makes use of some fundamental theorems on matrices not usually found in texts. The theory is scattered throughout the mathematical literature. It has, therefore, been considered worth while in the interest of unity and simplicity to build the subject from the foundations. It thus requires no previous knowledge of matrix algebra for the understanding of this paper.

The recent work of Kron, Sah, and others using the notation of tensors and dyadics in studying the behavior of circuits and machinery suggests the power and flexibility of more advanced mathematical methods in expressing the behavior of physical systems.

A perusal of this paper will illustrate that the matrix appears to be a natural tool to employ in the solution of certain classes of problems.

In the matrix notation we can actually solve the differential or algebraic equations involved without first unscrambling the variables and then proceeding in the conventional manner. The only restrictions on the differential equations is that they be linear and homogeneous. However, they may have variable or constant coefficients.

## II. The Fundamentals of Matrix Algebra

### 1. Definition of a Matrix

By a matrix is meant a system of $mn$ quantities arranged in a rectangular array of $m$ rows and $n$ columns. A matrix is usually denoted as:

$$\begin{bmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & a_{22} & \dots & a_{2n} \\ \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots \\ a_{m1} & a_{m2} & \dots & a_{mn} \end{bmatrix} = [a]$$

A paper recommended for publication by the AIEE committee on basic sciences. Manuscript submitted December 11, 1936; released for publication July 9, 1937.

LOUIS A. PIPES is a research fellow at the University of Wisconsin, Madison. The author wishes to acknowledge the helpful suggestions of Professor R. W. Sorensen, of the California Institute of Technology, and J. S. Waters, of The Rice Institute.

1. For all numbered references, see list at end of paper.

The subscript $m$ refers to the row and the subscript $n$ refers to the column.

The quantities $a_{ij}$ are called the elements of the matrix, they may be constants or functions of a variable.

This arrangement appears similar to that of a determinant. However, a matrix is not a determinant. A determinant has a certain definite value. A matrix, on the other hand, as we shall see, represents a set of operations that involve the elements of the matrix.

We note here that $n$ may differ from $m$. If $m = n$, we have a square matrix of order $n$. The square matrix is, as we shall see, the fundamental matrix. A rectangular matrix may be regarded as a square matrix whose missing rows or columns may be filled with elements whose value is zero.

### 2. Equality of Matrices

The question now arises, when may it be said that the matrix $[a] = [b]$? It is usual to define 2 things as equal when they cannot be distinguished from each other. We adopt this procedure in this case and define 2 matrices as equal when they have the same number of rows and of columns and if they have corresponding elements identical.

That is, if $a_{ij} = b_{ij}$ then, by definition $[a] = [b]$.

### 3. The Zero and Unit Matrices

We define a matrix $[a]$ to be a zero matrix denoted by $[0]$ if all of its elements $a_{ij} = 0$. That is, by definition if $a_{ij} = 0$ then $[a] = [0]$.

We define the square matrix $[I]$ all of whose elements are zero except those in the principal diagonal which are all unity as the unit matrix. As an example, for a third order matrix:

$$|I| = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

We shall see that the unit matrix plays the same rôle in matrix algebra that unity plays in ordinary algebra.

### 4. Square Matrix, the Fundamental Matrix

Suppose we have a matrix $[a]$ of $m$ rows and $n$ columns. For preciseness, let us say that $m > n$. If this condition holds, then our matrix $[a]$ is a rectangular matrix. We can, however, consider $[a]$ as a square matrix whose lacking columns are filled with elements of value zero.

As an example consider $m = 3$, $n = 2$, then:

$$[a] = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \\ a_{31} & a_{32} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & 0 \\ a_{21} & a_{22} & 0 \\ a_{31} & a_{32} & 0 \end{bmatrix}$$

We can, therefore, confine our discussion to square matrices. If $m < n$, the lacking rows would be filled with zeros.

## 5. The Fundamental Operations

### A. Addition and Subtraction

By definition $[a] + [b] = [c]$ provided that $c_{ij} = a_{ij} + b_{ij}$.

That is, the sum of the matrices $[a]$ and $[b]$ is defined as a new matrix $[c]$ whose elements are the sums of the corresponding elements of $[a]$ and $[b]$.

Similarly by definition $[a] - [b] = [c]$ provided that $c_{ij} = a_{ij} - b_{ij}$. Subtraction is merely a special case of addition.

### B. Multiplication

In matrix algebra an ordinary number or function is called a scalar in order to distinguish it from a matrix. If $[a]$ is a matrix and $k$ is some scalar quantity, we define $k[a] = [b]$ if $b_{ij} = ka_{ij}$.

That is, multiplication of a matrix by a scalar yields a new matrix whose elements are $k$ times the elements of the original matrix.

We have now to define the multiplication of one matrix by another. It must be realized that we are at liberty to define multiplication of matrices in any manner we please. However, of all possible methods of defining multiplication we select one because of its usefulness, as we shall see.

We define the multiplication of the two matrices $[a]$ and $[b]$ as being a matrix $[c]$ whose elements $c_{ij}$ are specified in a certain manner.

That is

$$[a][b] = [c]$$

if

$$c_{ij} = \sum_{k=1}^{n} a_{ik}b_{kj}$$

That is, if

$$[a] = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}$$

and

$$[b] = \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{bmatrix}$$

then

$$[a][b] = \begin{bmatrix} (a_{11}b_{11} + a_{12}b_{21}) & (a_{11}b_{12} + a_{12}b_{22}) \\ (a_{21}b_{11} + a_{22}b_{21}) & (a_{21}b_{12} + a_{22}b_{22}) \end{bmatrix}$$

The rule is very simple. In words: "The product $[a]$ $[b]$ of 2 square matrices is a matrix $[c]$ in which the element which lies in the $i$th row and $j$th column is obtained by multiplying each element of the $i$th row of $[a]$ by the corresponding element of the $j$th column of $[b]$ and adding the results.

This rule is not as formidable as it looks. It can best be grasped by studying the example above. As a special case multiplication by the unit matrix $[I]$ gives $[a]$ $[I]$ = $[a] = [I]$ $[a]$. From this it is seen that the behavior of the unit matrix in multiplication is as if it were the number one in ordinary algebra.

Multiplication is not commutative in general. That is, $[a]$ $[b] \neq [b]$ $[a]$ in general.

This is obvious because

$$\sum_{n=1}^{n} b_{in}a_{nj} \neq \sum_{n=1}^{n} a_{in}b_{nj}$$

in general.

## The Singular Matrix

A matrix is said to be singular if the determinant of its elements is zero. If the determinant formed from the elements of a matrix does not vanish, the matrix is said to be a nonsingular matrix.

### C. The Inverse of a Matrix

If $[a]$ $[b] = [I]$, then, by definition, $[a]$ is called the inverse of $[b]$, and similarly $[b]$ the inverse of $[a]$. It is usual to denote the inverse of a matrix $[a]$ by $[a]^{-1}$. That is $[a]$ $[a]^{-1} = [I]$ and $[a]^{-1}$ $[a] = [I]$, the unit matrix. By actually multiplying out we arrive at the following rule for determining the elements of the inverse of a matrix $[a]$. The rule is analytically as follows:

Let $[b] = [a]^{-1}$, then the elements $b_{ij}$ of the matrix $[b]$ are given by $b_{ij} = A_{ji}/|A|$ where $|A|$ is the determinant formed from the elements of the matrix $[a]$ and $A_{ij}$ is the cofactor, or the minor with the appropriate sign of the element $a_{ij}$ in the determinant $|A|$. Since in order for $b_{ij}$ to have any values which are finite it is necessary that $|A| \neq 0$, it can be seen that only a nonsingular matrix has an inverse.

### D. Division of Matrices

Division is defined as the inverse of multiplication. However, since multiplication is not commutative, there are 2 kinds of division. That is, if $[c]$ $[b] = [b]$ $[d]$, we cannot infer that in general $[d] = [c]$. From the principles discussed so far, we can prove the following theorem: If $[a]$ is any matrix and $[b]$ is any nonsingular matrix, there exists only one matrix $[x]$ which satisfies $[a] = [b]$ $[x]$. The proof of this is as follows: Let us multiply both sides of the equation $[a] = [b]$ $[x]$ by $[b]^{-1}$ the inverse of $[b]$. Then we have $[b]^{-1}$ $[a] = [b]^{-1}$ $[b]$ $[x] = [I]$ $[x] = [x]$ since multiplication by the unit matrix always gives us back our matrix. We have thus found $[x] = [b]^{-1}$ $[a]$. However, if we had started with the relation $[x]$ $[b] = [a]$ then a similar process would have given $[x] = [a]$ $[b]^{-1}$. Since, in general $[a]$ $[b]^{-1} \neq [b]^{-1}$ $[a]$, we see that from $[c]$ $[b] = [b]$ $[d]$ we cannot infer that $[c] = [d]$. The order of multiplication in matrix algebra cannot be interchanged in general. In the case where it can be interchanged, that is if $[a]$ $[b] = [b]$ $[a]$, the matrices are called symmetric.

### E. The Vanishing of a Product of Matrices

If $[a] \cdot [b] = [0]$ that is, if the product of 2 matrices yields the zero matrix there are 3 possibilities. Either the

matrix $[a] = [0]$ or $[b] = [0]$ or if neither the matrix $[a]$ or $[b]$ is a zero matrix, the rule for multiplication tells us that

$$\sum_{n=1}^{n} a_{in}b_{nj} = 0$$

for all values of $i$ and $j$.

By expanding this set of equations out and making some elementary manipulations it is easily shown that the elements of the various rows of $[a]$ or of $[b]$ are proportional to the elements of the top row. As a special case let us consider $[a]$ and $[b]$ as matrices of the third order then on the supposition that neither is a zero matrix we can say that

$$[a] = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ \beta a_{11} & \beta a_{12} & \beta a_{13} \\ \omega a_{11} & \omega a_{12} & \omega a_{13} \end{bmatrix}$$

or

$$[b] = \begin{bmatrix} b_{11} & b_{12} & b_{13} \\ mb_{11} & mb_{12} & mb_{13} \\ nb_{11} & nb_{12} & nb_{13} \end{bmatrix}$$

where $\beta$, $\omega$, $m$, and $n$ are constants. That is, the elements of the lower rows are proportional to the elements of the top row.

This result, as we shall see, is of extreme usefulness.

### F. Powers of Matrices

We define powers of matrices in the following manner

Positive integral powers $[a]^p = [a][a] \ldots [a]$ to $p$ factors

Negative integral powers $[a]^{-p} = ([a]^{-1})^p$

$[a]^0 = [I]$ = the unit matrix

## 6. The Laws of Matrix Algebra

We see now with the exception that multiplication is not in general commutative, that is:

$$[a][b] \neq [b][a]$$

That our matrix algebra is similar to ordinary algebra, that is:

$$[a] + [b] = [b] + [a]$$
$$[a] + ([b] + [c]) + [c] = ([a] + [b]) + [c]$$

If $k$ is a scalar and $l$ is a scalar

$$k[a] + k[b] = k([a] + [b])$$
$$k[a] + l[a] = (k + l)[a]$$

If $[c]$ is a matrix and $[d]$ is a matrix

$$[c][a] + [c][b] = [c]([a] + [b])$$
$$[c][a] + [d][a] = ([c] + [d])[a]$$

The only precaution is that $[a]\,[b] \neq [b]\,[a]$ in general

## 7. The Characteristic Matrix of a Matrix

Let $[a]$ be a matrix whose elements are constants.

Then the matrix $[A] = \mu[I] - [a]$, where $\mu$ is a parameter and $[I]$ = the unit matrix, is called the characteristic matrix of $[a]$

## 8. The Characteristic Function of a Matrix [a]

Let $[A]$ be the characteristic matrix of $[a]$, then the determinant of the elements of the matrix $[A]$ $|A|$ is called the characteristic function of $[a]$

## 9. The Latent Roots of a Matrix [a]

Let $|A|$ = the characteristic function of $[a]$

$$\therefore |A| = \alpha(\mu)$$

Then the equation $|A| = 0$ is the characteristic equation of the matrix $[a]$

Now since

$$[A] = \mu[I] - [a]$$

The characteristic equation $|A| = 0$ is in general an equation of the $n$th degree in $\mu$ where $n$ is the degree of the matrix $[a]$.

The $n$ roots $\mu_1, \mu_2, \ldots . \mu_n$ of the characteristic equation are called the latent roots of the matrix $[a]$.

As an example consider

$$[a] = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}$$

The characteristic matrix is $[A] = \mu[I] - [a]$ or

$$[A] = \begin{bmatrix} (\mu - a_{11}) & -a_{12} \\ -a_{21} & (\mu - a_{22}) \end{bmatrix} = \text{characteristic matrix of } [a]$$

$$\begin{vmatrix} (\mu - a_{11}) & -a_{12} \\ -a_{21} & (\mu - a_{22}) \end{vmatrix} = 0$$

is the characteristic equation of $[a]$ or

$$\mu^2 - \mu(a_{11} + a_{22}) + (a_{11}a_{22} - a_{21}a_{12}) = 0$$

The roots of the equation

$$\mu_1 = \alpha_1 + jB$$
$$\mu_2 = \alpha_1 - jB$$

are the latent roots of $[a]$

## 10. The Cayley-Hamilton Theorem

This theorem, as we shall see, provides us with our most potent weapon in the solution of differential equations and circuit problems. The theorem: If $[a]$ is a matrix of constant elements and $\alpha(\mu) = 0$ is the characteristic equation of $[a]$, then $\alpha([a]) = [0]$ where $[0]$ is the zero matrix. In other words a matrix satisfies its own characteristic equation in a matrix sense. Example: As we have just seen if

$$[a] = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}$$

then

$$\alpha(\mu) = \mu^2 - \mu(a_{11} + a_{22}) + (a_{11}a_{22} - a_{21}a_{12}) = 0$$

is the characteristic equation of $[a]$. Then the Cayley-Hamilton theorem states that

$$\alpha([a]) = [a]^2 - [a](a_{11} + a_{22}) + [I](a_{11}a_{22} - a_{21}a_{12}) = 0$$

For a proof of this powerful theorem, see reference 2.

## 11. Functions of Matrices

How are we to define functions of the matrix $[a]$? In analysis, it is customary to define a function of $Z$ such as $\log Z$, $e^z$, sine $Z$, etc., in certain regions of the complex $Z$ plane by their power series expansions. In matrix algebra we shall adopt a similar procedure.

Consider a function of $Z$ $\alpha(Z)$ such as $e^z$, $\log Z$, sine $Z$, etc., which is definable as a power series in $Z$. That is:

$$\alpha(Z) = \sum_{n=0}^{n} C_n Z^n$$

Similarly we define a function of a matrix $[a]$ as

$$\alpha([a]) = \sum_{n=0}^{n} C_n [a]^n$$

with the proviso that $C_0 = C_0[I]$. From the fundamental definition, it is possible by repeated applications of the Cayley-Hamilton theorem to arrive at a simpler form for $\alpha([a])$.

It may be shown, see Duncan and Collar "Solution of Oscillation Problems by Matrices," *Philosophical Magazine*, volume 17, series 7, page 900, that the above definition reduces to the following one:

$$\alpha[a] = \sum_{r=1}^{n} \alpha(\mu_r)[Z_r]$$

where

$$[Z_r] = \frac{\prod_{s \neq r} (\mu_s[I] - [a])}{\prod_{s \neq r} (\mu_s - \mu_r)}$$

where $\mu_1 \ldots \mu_2 \ldots \mu_n$ are the latent roots of the matrix $[a]$.

This theorem is valid only if $[a]$ is a matrix of constant elements.

Professor H. F. Baker has given an alternative form which is sometimes more convenient in practice.[5] Baker's form is:

$$\alpha[a] = \frac{D_{n-1}}{D}[a]^{n-1} + \frac{D_{n-2}}{D} + [a]^{n-2} + \ldots + \frac{D_1}{D}[a] + \frac{D_0}{D}[I]$$

where $\mu_1, \mu_2, \ldots \mu_n$ are the latent roots of $[a]$

$$D = \begin{vmatrix} 1 & 1 & \ldots & 1 \\ \mu_1 & \mu_2 & \ldots & \mu_n \\ \ldots & \ldots & \ldots & \ldots \\ \mu_1^{n-1} & \mu_2^{n-1} & \ldots & \mu_n^{n-1} \end{vmatrix}$$

and $D_{r-1}$ is the determinant derived from $D$ by replacing the elements of the $r$th row by

$$\alpha(\mu_1) \ldots \alpha(\mu_2) \ldots \alpha(\mu_n)$$

Both forms are useful, as we shall see.

*Example:* Let it be required to find

$$e^{[n]} \text{ where } [n] = \begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix}$$

The characteristic equation of $[n]$ is

$$\alpha(\mu) = \begin{vmatrix} (\mu - 1) & 0 \\ 0 & (\mu - 2) \end{vmatrix} = (\mu - 1)(\mu - 2) = \mu^2 - 3\mu + 2 = 0$$

The latent roots, are therefore, $\mu_1 = 1$, $\mu_2 = 2$

Now

$$D = \begin{vmatrix} 1 & 1 \\ \mu_1 & \mu_2 \end{vmatrix} = \begin{vmatrix} 1 & 1 \\ 1 & 2 \end{vmatrix} = 1$$

$$D_1 = \begin{vmatrix} 1 & 1 \\ e & e^2 \end{vmatrix} = e^2 - e$$

$$D_0 = \begin{vmatrix} e & e^2 \\ 1 & 2 \end{vmatrix} = 2e - e^2$$

$$e^{[n]} = \frac{D_1}{D}[n] + \frac{D_0}{D}[I] = (e^2 - e)\begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix} +$$

$$(2e - e^2)\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} = \begin{bmatrix} e & 0 \\ 0 & e^2 \end{bmatrix} \qquad e^{\left[\begin{smallmatrix} 1 & 0 \\ 0 & 2 \end{smallmatrix}\right]} = \begin{bmatrix} e & 0 \\ 0 & e^2 \end{bmatrix}$$

another matrix.

## 12. The Limiting Form of a Matrix When Raised to a Very High Power

A very useful result may be obtained from the above formulas if $\mu([a])$ is placed equal to $[a]^m$.

Let us substitute this in the above, then

$$[a]^m = \sum_{r=1}^{n} \mu_r{}^m [Z_r]$$

where $\mu_1 \ldots . \mu_n$ are the latent roots of $[a]$ arranged in descending order of magnitude. Let us suppose all roots are unequal. Now

$$[Z_r] = \frac{\prod_{s \neq r} (\mu_s[I] - [a])}{\prod_{s \neq r} (\mu_s - \mu_r)}$$

We see from this that $[Z_r]$ is independent of $m$.

Now if $m$ is very large and $\mu_1$ is the largest root, then

$$\lim_{m \to \infty} \sum_{r=1}^{n} \mu_1{}^m [Z_1] = \mu_1{}^m [Z_r]$$

This is true because $\mu_1$, being the largest of the roots, when it is raised to a very high power the term containing $\mu_1{}^m$ is much greater than the other terms and hence the other terms may be neglected in comparison with it. Therefore

$$\lim_{m \to \infty} [a]^m = \frac{\mu_1{}^m (\mu_2[I] - [a])(\mu_3[I] - [a]) \ldots (\mu_n[I] - [a])}{(\mu_2 - \mu_1)(\mu_3 - \mu_1) \ldots (\mu_n - \mu_1)}$$

*Example:* What is

$$\begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix} ?$$

Here as before $\mu_1 = 2$, $\mu_1 = 1$

$$\begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix}^{238} = \frac{2^{238}([I] - [a])}{-1}$$

$$= -2^{238}\left(\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} - \begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix}\right)$$

$$= -2^{238}\begin{bmatrix} 0 & 0 \\ 0 & -1 \end{bmatrix} \qquad = 2^{238}\begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}$$

This theorem is of extreme importance in raising matrices to high powers. It is valid only when the latent

roots are different. If the difference between the latent roots is great, the formula gives accurate answers even for rather small powers of a matrix.

## 13. The Differentiation of a Matrix

Suppose we have a matrix $[u]$ whose elements are functions of the variable $t$; that is, $u_{ij} = u_{ij}(t)$. We define

$$\frac{d}{dt}[u] = \begin{bmatrix} \frac{du_{11}}{dt} & \frac{du_{12}}{dt} & \cdots & \frac{du_{1n}}{dt} \\ \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots \\ \frac{du_{n1}}{dt} & \cdots & \cdots & \frac{du_{nn}}{dt} \end{bmatrix}$$

That is, if we let $D = \frac{d}{dt}$, then

$$D[u] = [Du]$$

## 14. Integration of a Matrix

Let $[u]$ be a matrix whose elements are functions of the variable $t$, that is, $\mu_{ij} = \mu_{ij}(t)$

Let

$$Q = \int_{t_0}^{t} (\,)dt$$

stand for the integral operator. We define

$$\int_{t_0}^{t} [u]dt = Q[u] = \begin{bmatrix} Qu_{11} & \cdots & Qu_{1n} \\ \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots \\ Qu_{n1} & \cdots & Qu_{nn} \end{bmatrix}$$

that is, $Q[u] = [Qu]$ or the integral of a matrix is a matrix whose elements are the integrals of the elements of the original matrix.

If $u_{ij}$ are constants, then

$$Q[u] = (t - t_0)[u]$$

## 15. Linear Transformation

Consider a set of variables $(e_1 \ldots e_n)$ related linearly to a set $(i_1 \ldots i_n)$ by the equations.

$$\begin{aligned} e_1 &= Z_{11}i_1 + Z_{12}i_2 + \ldots + Z_{1n}i_n \\ e_2 &= Z_{21}i_1 + Z_{22}i_2 + \ldots + Z_{2n}i_n \\ &\ldots\ldots\ldots\ldots\ldots\ldots\ldots \\ &\ldots\ldots\ldots\ldots\ldots\ldots\ldots \\ e_n &= Z_{n1}i_1 + Z_{n2}i_2 + \ldots + Z_{nn}i_n \end{aligned}$$

In matrix notation

$$[e] = [Z][i]$$

where

$$[e] = \begin{bmatrix} e_1 \\ \cdots \\ \cdots \\ \cdots \\ e_n \end{bmatrix} \qquad [i] = \begin{bmatrix} i_1 \\ \cdots \\ \cdots \\ \cdots \\ \cdots \\ i_n \end{bmatrix}$$

$$[Z] = \begin{bmatrix} Z_{11} \ldots Z_{1n} \\ \ldots\ldots\ldots \\ \ldots\ldots\ldots \\ Z_{n1} \ldots Z_{nn} \end{bmatrix}$$

That is, by our matrix notation, we may concisely write the above system of equations in the matrix form.

## III. The Most General Linear Network

If in the above linear transformation we allow the variables $(e_1 \ldots e_n)$ to represent the alternating voltages impressed in the various meshes of an $n$-mesh network and $[Z]$ and $[i]$ represent the impedance and current matrices, respectively, of the network, then the equation $[e] = [Z]\,[i]$ represents the matrix equation characterizing the behavior of the most general possible linear network.

If the voltages are alternating of angular frequency $\omega$, then

$$Z_{ij} = J\omega L_{ij} + R_{ij} - \frac{J}{\omega C_{ij}} \qquad J = \sqrt{-1}$$

As we shall see, in case we desire the solution for the transient state we may still use matrices.

In general $Z_{ij} = Z_{ji}$. Let us solve the matrix equation for the current. Let us multiply $[Z]\,[i] = [e]$ by $[Z]^{-1}$ the inverse of $[Z]$

$$[Z]^{-1}[Z][i] = [Z]^{-1}[e]$$
$$[i] = [Z]^{-1}[e]$$

where $[Z]^{-1} = [Y]$ the admittance matrix from II part 5c. The elements of $[Y]$ are given by

$$Y_{ij} = \frac{A_{ji}}{|Z|}$$

$A_{ij}$ is the cofactor of the element $Z_{ij}$ of the matrix $[Z]$.

Having determined the elements of the admittance matrix $[Y]$, we calculate the matrix

$$[i] = [Y][e]$$

The various elements of the current matrix $[i]$ give the various currents in the several branches.

Because $Z_{ij} = Z_{ji}$, therefore $A_{ij} = A_{ji}$, consequently, we have immediately the familiar reciprocity theorem as well as the superposition theorem directly from the equation

$$[i] = [Y][e]$$

## IV. Traveling Waves on Multiconductors

Suppose we have $n$ parallel conductors with electrostatic and electromagnetic coupling between them.

We may write the 2 matrix equations for the currents and voltages

$$-\frac{\partial}{\partial x}[e] = [Z][i] \quad \text{and} \quad -\frac{\partial}{\partial x}[i] = [Y][e]$$

Where the elements of the matrix $[e]$ represent the various voltages between the lines and the elements of the matrix $[i]$ represent the currents in the $n$ lines. The matrix

$$[Z] = \begin{bmatrix} Z_{11} & Z_{12} & \cdots & Z_{1n} \\ Z_{21} & Z_{22} & \cdots & Z_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ Z_{n1} & \cdots & \cdots & Z_{nn} \end{bmatrix}$$

$$Z_{ii} = R_{ii} + L_{ii}\frac{d}{dt} \qquad Z_{ij} = M_{ij}\frac{d}{dt} \qquad i \neq j$$

$R_{ii}$ represents the resistances per unit length of the conductors, $L_{ii}$ the inductances per unit length of the conductors, and $M_{ij}$ represents the mutual inductance per unit length of the various conductors. The matrix

$$[Y] = \begin{bmatrix} Y_{11} & \dots & Y_{1n} \\ \dots & \dots & \dots \\ Y_{n1} & \dots & Y_{nn} \end{bmatrix}$$

$$Y_{ij} = G_{ij} + C_{ij}\frac{d}{dt} \qquad i \neq j$$

$G_{ij}$ = the leakage coefficient per unit length

$C_{ij}$ = mutual capacitance per unit length

$$\frac{-\delta^2[e]}{\delta x^2} = \frac{\delta}{\delta x}[Z][i] = [Z]\frac{\delta}{\delta x}[i]$$

Since $[Z]$ is a constant matrix

$$\frac{-\delta^2}{\delta x^2}[i] = [Y]\frac{\delta}{\delta x}[e]$$

Substituting in the original equation we obtain the fundamental equations for the voltages and currents

$$\frac{\delta^2}{\delta x^2}[e] = [Z][Y][e]$$

$$\frac{\delta^2}{\delta x^2}[i] = [Y][Z][i]$$

As we shall see, we can proceed to the solution of the actual differential equations in matrix form.[9]

## V. The 4-Terminal Network

From the general theory discussed in part III, it can be easily shown that for the case of a linear, passive, bilateral 4-terminal network shown diagrammatically as in figure 1.

$$E_1 = E_2A + BI_2$$
$$I_1 = E_2C + DI_2$$

where $AD - BC = 1$ or in the matrix form

$$\begin{bmatrix} E_1 \\ I_1 \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \cdot \begin{bmatrix} E_2 \\ I_2 \end{bmatrix}$$

Assume that 2 such circuits are connected in series as in figure 2.

If the 2 networks are identical, we have,

$$\begin{bmatrix} E_2 \\ I_2 \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \cdot \begin{bmatrix} E_3 \\ I_3 \end{bmatrix}$$

$$\begin{bmatrix} E_1 \\ I_1 \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \cdot \begin{bmatrix} A & B \\ C & D \end{bmatrix} \cdot \begin{bmatrix} E_3 \\ I_3 \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix}^2 \begin{bmatrix} E_3 \\ I_3 \end{bmatrix}$$

If there are $n$ such circuits in series,

$$\begin{bmatrix} E_1 \\ I_1 \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix}^n \begin{bmatrix} E_{n+1} \\ I_{n+1} \end{bmatrix}$$

If we wish to get the $(n + 1)$ currents and voltages in terms of the initial values, we have

$$E_2 = DE_1 - BI_1$$
$$I_2 = -CE_1 + AI_1$$

or

$$\begin{bmatrix} E_2 \\ I_2 \end{bmatrix} = \begin{bmatrix} D & -B \\ -C & A \end{bmatrix} \cdot \begin{bmatrix} E_1 \\ I_1 \end{bmatrix}$$

If we have $n$ identical networks in series then

$$\begin{bmatrix} E_{n+1} \\ I_{n+1} \end{bmatrix} = \begin{bmatrix} D & -B \\ -C & A \end{bmatrix}^n \cdot \begin{bmatrix} E_1 \\ I_1 \end{bmatrix}$$

If $n$ is very large, we may use the formula for raising a matrix to a very high power.

Because of the natural way in which matrix algebra enters into linear transformations, their application to circuit theory are seen to be unlimited.

## VI. The Solution of Differential Equations

The brief examples which are given above and obvious other applications are rather well known to some communication engineers. However, the powerful use which may be made of matrices in the actual *solution* of linear differential equations is not well known.

### 1. The Differential Equation in Matrix Form

In modern electrical and mechanical engineering there are a great class of problems in circuits, vibrations, etc., which lead either to linear equations of high order or to systems of linear equations. These equations may have either variable or constant coefficients.

Any differential equation or a set of differential equations can be changed into another involving only first order differential coefficients by writing the highest order coefficient as the differential coefficient of a new dependent variable.

All the other differential coefficients are regarded as separate dependent variables, and, for each new variable introduced, another equation must be added to the set.

These added equations are merely the mathematical statement that each new variable is the differential coefficient of the variable that represents the next differential coefficient of lower order. In this way the most general homogeneous linear equation or set of linear homogeneous equations with either constant or variable coefficients may be written as:

$$\frac{dx_1}{dt} = u_{11}x_1 + u_{12}x_2 + \dots + u_{1n}x_n$$
$$\frac{dx_2}{dt} = u_{21}x_1 \dots\dots\dots\dots + u_{2n}x_n$$
$$\dots\dots\dots\dots\dots\dots\dots\dots$$
$$\frac{dx_n}{dt} = u_{n1}x_1 \dots\dots\dots\dots + u_{nn}x_1$$

In matrix form: if $D = \frac{d}{dt}$

$$[Dx] = [u][x]$$

or

$$\frac{d}{dt}[x] = [u][x]$$

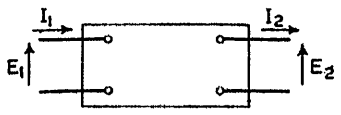

Figure 1

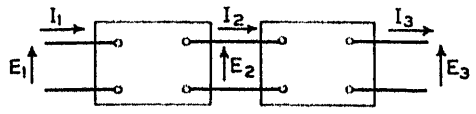

Figure 2

As a preliminary to the integration of this matrix differential equation let us consider the integration of the ordinary differential equation

$$\frac{dy}{dt} = \mu y \qquad \mu = \mu(t)$$

subject to $y = y_0$ at $t = t_0$ the boundary condition.

If we integrate, we obtain, on introducing the boundary conditions.

$$y = y_0 + \int_{t_0}^{t} \mu(t)\, y dt$$

This is an integral equation. We will solve it by successive approximations. Let $Q$ be the operator defined by

$$Q = \int_{t_0}^{t} (\,)\, dt$$

Then

$$y = y_0 + Q\mu y$$

Substitute $y$ in the second member and we obtain

$$y = y_0 + Q\mu[y_0 + Q\mu y] = y_0 + y_0 Q\mu + Q\mu Q\mu y$$

Repeating the process,

$$y = y_0(1 + Q\mu + Q\mu Q\mu + Q\mu Q\mu Q\mu + \ldots)$$

This series is very rapidly convergent.

### The Matrix Equation

We return now to our matrix equation

$$\frac{d}{dt}[x] = [u][x]$$

Let us require as a boundary condition that $[x] = [x^0]$ at $t = t_0$

Then carrying out the above process on the matrix equation, we obtain the matrix integral equation

$$[x(t)] = [x^0] + \int_{t_0}^{t} [u(t)][x(t)]dt$$

This may be solved by successive approximations.

$$[x(t)] = ([I] + Q[u] + Q[u]Q[u] + \ldots + \ldots)[x_0]$$

$[I]$ = unit matrix

$Q = \int_{t_0}^{t} (\,)dt$ operator

## 2. The Matrizant

We denote

$$\Omega^{t_0,t}[u] = ([I] + \int_{t_0}^{t} [u]dt + \int_{t_0}^{t} [u]dt \int_{t_0}^{t} [u]dt + \ldots)$$

and the solution of the equation is

$$[x(t)] = \Omega^{t_0,t}[u][x^0]$$

by the name of the "matrizant" of $[u]$.[3 4]

### Fundamental Properties of the Matrizant $\Omega^{t_0,t}[u]$

1. $\Omega^{t_0,t_0}[u] = [I]$
2. $\frac{d}{dt}\Omega^{t_0,t}[u] = [u]\Omega^{t_0,t}[u]$
3. If $[u]$ is a matrix of constant elements, then

$\Omega^{t_0,t}[u] = [I]e^{[u](t-t_0)}$

or, if we let $T = t - t_0$

$[I]$ = unit matrix

then,

$\Omega^{t_0-t}[u] = [I]e^{[u]T}$

$e$ = base of natural logarithms

These fundamental properties may all easily be deduced from the above definition of

$$\Omega^{t_0-t}[u] = ([I] + \int_{t_0}^{t} [u]dt + \int_{t_0}^{t} [u]dt \int_{t_0}^{t} [u]dt + +)$$

For a further set of properties, the above paper by Doctor Baker may be consulted.

## 3. Linear Equations With Constant Coefficients

As an example, let us consider the system:

$$dx_1/dt = u_{11}x_1 + u_{12}x_2$$
$$dx_2/dt = u_{21}x_1 + u_{22}x_2$$

where $u_{ij}$ are constants

Or in the short matrix form:

$$D[x] = [u][x]$$

Let the solution be subject to the boundary conditions that:

$x_1 = x_1^0$ and $x_2 = x_2^0$ at $t = t_0$

(Note: The superscripts here must not be confused with exponents, they are merely a convenient notation used to denote the initial values of $x_1$ and $x_2$ and, since the place for subscripts is already taken it is convenient to use superscripts.) By the foregoing theory, the solution under these initial conditions is:

$$[x] = \Omega^{t_0,t}[u][x^0]$$

In this case, since $[u]$ is a matrix of constants,

$$\Omega^{t_0,t}[u] = [I]e^{[u]T}$$

where $T = t - t_0$.

We must now compute the matrix function $e^{[u]T}$ by the rule given in part II, section 11. Following the procedure given there, we first compute the latent roots of $[u]$. The characteristic equation is:

$$|\mu I - u| = 0 \quad \text{or} \quad \begin{vmatrix} (\mu - u_{11}) & -u_{12} \\ (-u_{21}) & (\mu - u_{22}) \end{vmatrix} = 0$$

Or, expanding the determinant,

$$\mu^2 - \mu(u_{11} + u_{22}) + (u_{11}u_{22} - u_{12}u_{21}) = 0$$

Let us call the 2 roots of this equation $\mu_1$ and $\mu_2$. In general, the 2 roots will be complex numbers.
We can, therefore, in general denote the 2 roots as:

$$\mu_1 = \alpha + \beta \quad \text{and} \quad \mu_2 = \alpha - \beta$$

Computing $e^{[u]t}$ by Baker's rule (part II, section 11) we first must compute:

$$D = \begin{vmatrix} 1 & 1 \\ (\alpha+\beta) & (\alpha-\beta) \end{vmatrix} = (\alpha-\beta) - (\alpha+\beta) = -2\beta$$

$$D_1 = \begin{vmatrix} 1 & 1 \\ e^{\alpha T+\beta T} & e^{\alpha T-\beta T} \end{vmatrix} = -2e^{\alpha T}\sinh \beta T$$

$$D_0 = \begin{vmatrix} e^{\alpha t+\beta T} & e^{\alpha T-\beta T} \\ \alpha+\beta & \alpha-\beta \end{vmatrix} = 2e^{\alpha T}(\alpha \sinh \beta T - \beta \cosh \beta T)$$

We note that, by definition $[u]^0 = [I]$. We have, therefore, by Baker's rule:

$$e^{[u]T} = e^{\alpha T}\sinh \beta T \begin{bmatrix} u_{11} & u_{12} \\ u_{21} & u_{22} \end{bmatrix} - e^{\alpha T}/\beta\,(\alpha \sinh \beta T - \beta \cosh \beta T)[I]$$

Or, therefore, the matrizant, in this case is:

$$\Omega^{t_0,t}[u] = e^{\alpha T}\begin{bmatrix} (u_{11}-\alpha)/\beta \sinh \beta T + \cosh \beta T) & (u_{12}/\beta \sinh \beta T) \\ (u_{21}/\beta \sinh \beta T)\left(\dfrac{u_{22}-\alpha}{\beta}\right) & \sinh \beta T + \cosh \beta T) \end{bmatrix}$$

Therefore, the equation has the solution:

$$[x] = \Omega^{t_0,t}[u][x^0]$$

If we write

$$\Omega^{t_0,t}[u] = \begin{bmatrix} \Omega_{11} & \Omega_{12} \\ \Omega_{21} & \Omega_{22} \end{bmatrix}$$

$$\Omega^{t_0,t}[u] = e^{\alpha T}\begin{bmatrix} \left(\dfrac{u_{11}-\alpha}{\beta}\sinh \beta T + \cosh \beta T\right)\left(\dfrac{u_{12}}{\beta}\sinh \beta T\right) \\ \left(\dfrac{u_{21}}{\beta}\sinh \beta T\right)\left(\dfrac{u_{22}-\alpha}{\beta}\sinh \beta T + \cosh \beta T\right) \end{bmatrix}$$

where

$$\Omega_{11} = \left\{\frac{(u_{11}-\alpha)}{\beta}\sinh \beta T + \cosh \beta T\right\}e^{\alpha T}$$

$$\Omega_{12} = (u_{12}/\beta e)^{\alpha T}\sinh \beta T$$

$$\Omega_{21} = (u_{21}/\beta e)^{\alpha T}\sinh \beta T$$

$$\Omega_{22} = [(u_{22}-\alpha)/\beta \sinh] \beta T + \cosh \beta T)e^{\alpha T}$$

$$T = t - t_0$$

If $\beta$ is imaginary, sinh $\beta T$ and cosh $\beta T$ must be replaced by sine $\beta T$ and cos $\beta T$, respectively. If $\beta = 0$, we must obtain the limiting forms from these equations by the usual L'Hospital's rule of differentiation. We have now, the dependent variables in terms of the initial conditions.

## 4. Linear Equations With Variable Coefficients

The method of matrices is particularly well adapted to the solution of equations whose coefficients are functions of the independent variable $t$. The only restrictions on the variables is that they be finite and single valued functions of $t$ throughout the range of integration. This limitation is met by physical equations.

Let us consider the most general homogeneous linear differential equation with variable coefficients. This equation may be written:

$$Dx^n + a_1(t)Dx^{n-1} + \ldots + a_{n-1}(t)x = 0$$

where $D$ is the operator $d/dt$ and the coefficients $a_i(t)$ are single-valued analytic functions of $t$. That is, they do not become infinite in any part of the range for which we desire a solution.

As in the previous case with constant coefficients, we first break up the equation into a set of $n$ homogeneous equations of the first order. This is done by calling successive derivatives new variables. That is, we let $x = x_1$, $Dx = x_2$ and so forth. Our equation is then replaced by:

$$dx_1/dt = u_{11}x_1 + u_{12}x_2 + \ldots\ldots + u_{1n}x_n$$
$$\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots$$
$$\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots$$
$$dx_n/dt = u_{n1}x_1 + \ldots\ldots\ldots\ldots + u_{nn}x_n$$

where now the coefficients of $u_{ij}$ are functions of $t$.
In matrix form, we write this set of equations as before: $D[x] = [u][x]$. If we know the initial value of $x$ and the initial value of $(n-1)$th derivatives we denote them by $x_1^0$, $x_2^0$, etc., these initial values at $t = t_0$. Our solution is as before:

$$[x] = \Omega^{t_0-t}[u][x^0]$$

Where, unfortunately $\Omega^{t_0-t}[u]$ does not have the simple form it had when the elements of the matrix $[u]$ were constants instead of functions of $t$. In this case

$$\Omega^{t_0-t}[u] = ([I] + \int_{t_0}^{t}[u]dt + \int_{t_0}^{t}[u]dt\int_{t_0}^{t}[u]dt + + )$$

from the fundamental defining equation. It is most laborious to use this form to compute the matrizant. However we note that if $[u]$ is a matrix of constants, then

$$\Omega^{t_0-t}[u] = [I]e^{[u]T}$$

where $e$ is the base of the natural logarithms. This suggests that the following procedure be followed. Let the interval of time over which the equation is to be solved be broken up into $s$ small time intervals. The procedure may be more easily followed by the consideration of the following diagram:

| 1 | 2 | | 3 | 4 | | | | $s$ | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| $t_0$ | $t_1$ | $t_2$ | | | | | $t_{s-1}$ | $t_s$ | | | | | |

Let us assume that during the time interval from $t_0$ to $t_1$ the elements of the matrix $[u]$ are approximately constant and have the average value that they assume throughout the interval. Let us denote this matrix by $[u(1)]$. Let in general $[u(s)]$ represent the matrix whose elements are given the average values which they assume in the $s$th interval from $t = t_{s-1}$ to $t = t_s$. We may then proceed to the solution of our actual equation with variable coefficients by a sort of chain process. That is, assuming that throughout the first interval the elements of the matrix $[u]$ are constant and denoting the matrix of these constant values by $[u(1)]$, we may say that at the end of the first interval the solution is:

$$[x(t_1)] = [I]e^{[u]T}[x^0]$$

where

$$T = t_1 - t_0$$

This is the value that the variables have assumed at the end of the first interval, and hence these values provide the initial conditions for the second interval. That is, the initial conditions for the second interval are $[x(t_1)]$ instead of $[x^0]$. If the intervals are all equal let us call them $T$; that is

$$t_s - t_{s-1} = T$$

then

$$[x(t_1)] = [I]e^{[u(1)]T}[x^0]$$

and, at the end of the second interval, the solution is:

$$[x(t_2)] = [I]e^{[u(2)]T}[x(t_1)]$$

Since, however, we know $[x(t_1)]$, we can compute $[x(t_2)]$ by a matrix multiplication. The solution for the $s$th interval can be obtained similarly by a repeated chain of multiplication of the various values of the preceding intervals. The procedure appears laborious, but it is in reality quite simple. It may be noted that the intervals do not have to be of the same length $T$. It is usually more convenient to choose short intervals where the variations of the elements of the matrix $[u]$ is great and to choose larger intervals where the elements of $[u]$ are more or less constant.

## Illustration

This method may perhaps be brought out more clearly by means of an illustration. The example worked out by Frazer[6] will be given. It is particularly good as an illustration since it tests the method to the utmost in that the variables fluctuate widely and the values obtained may be compared with the exact solution.

Let us consider the motion of a pendulum of variable stiffness whose equation of motion may be taken as:

$$D^{2\alpha} + (16\pi^2 e^{-2t} - 1/4)\,\alpha = 0$$

It is easy to solve this equation in exact terms.

The exact solution is:

$$\theta = e^{t/2}\cos(4\pi e^{-t})$$

for the boundary conditions that $\alpha = 1.0$ and $d\alpha/dt = 0.5$ at $t = 0$. To solve this equation in the matrix form we place $\alpha = x_1$ and $d\alpha/dt = x_2$. Then the matrix equation is:

$$D[x] \begin{Vmatrix} 0 & 1 \\ u_{21} & 0 \end{Vmatrix} [x] = [u][x]$$

where

$$u_{21} = 1/4 - 16\pi^2 e^{-2t}$$

Let $u_{21}(s)$ be the average value of $^1/_4 - 16\pi^2 e^{-2t}$ for the $s$th interval from $t = t_{s-1}$ to $t = t_s$. Then, for that interval:

$$D[x] = \begin{bmatrix} 0 & 1 \\ u_{21}(s) & 0 \end{bmatrix} \cdot [x]$$

The characteristic equation is:

$$\begin{vmatrix} \mu & -1 \\ -u_{21}(s) & \mu \end{vmatrix} = 0$$

and the latent roots are:

$$\alpha_s = 0 \qquad \beta_s = \sqrt{u_{21}(S)}$$

The matrizant relation is as in VI part 3.

$$[x] = \begin{bmatrix} \cosh(\beta_s T) & \sinh(\beta_s T) \\ \dfrac{u_{21}(s)\sinh(\beta_s T)}{\beta_s} & \cosh(\beta_s T) \end{bmatrix} [x^{s-1}]$$

if $\beta_s$ is real. If, however, $\beta_s$ is imaginary, then circular functions must replace the above hyperbolic functions. The numerical values of the elements of $\Omega^{t_s - 1^{t_s}}$ are given in the table I.

The matrizant $\Omega^{t_{s-1},t_s}[u]$ is formed for each interval from the values given in the above table. From the value of the matrizant for the first interval and the initial conditions, the values of the dependent variables at the end of that interval and hence the initial conditions for the next interval can be found.

For example, the product $\Omega^{t_0,t_1}[x^0]$ may be carried out in table form. That is, the square matrix $\Omega t_0, t_1$ is multiplied by the line matrix $[x^0]$. This gives a line matrix

**Table I**

| Start of Interval t= | $u_{21}(s)$ | $\beta$ | $\cos \beta T$ $\cosh \beta T$ | $\sin \beta T$ $\sinh \beta T$ | $\sin \beta T/\beta$ $\sinh \beta T/\beta$ | $u_{21}(s)\sin \beta T/\beta$ $u_{21}(s)\sinh \beta T/\beta$ |

| $t = 3.0$ | $+0.0808$ | $0.284$ | $1.0405$ | $0.2880$ | $1.015$ | $+0.0819$ |

**Table II**

| Initial Value of t | The Matrizant $\Omega^{t_s - 1^{t_s}}$ | | Initial Conditions $\alpha$ and $D\alpha$ Stepped Solution | Exact Solution |
|---|---|---|---|---|
| 0 | $-0.6504$ | $0.0666$ | $1.0000$ | $1.0000$ |
| | $-8.650$ | $-0.6504$ | $0.5000$ | $0.5000$ |
| 0.2 | $-0.2900$ | $0.1026$ | $-0.6171$ | $-0.725$ |
| | $-8.926$ | $-0.2900$ | $-8.975$ | $-9.243$ |
| 0.4 | $0.0448$ | $0.1309$ | $-0.7419$ | $-0.657$ |
| | $-7.623$ | $0.0448$ | $+8.111$ | $+9.008$ |
| 0.6 | $0.3172$ | $0.1519$ | $1.0285$ | $1.11$ |
| | $-5.918$ | $-0.3172$ | $6.019$ | $5.855$ |
| 0.8 | $0.5233$ | $0.1670$ | $1.2405$ | $1.20$ |
| | $-4.346$ | $0.5233$ | $-4.1775$ | $-4.43$ |
| 1.0 | $-0.2636$ | $0.2626$ | $-0.0487$ | $-0.172$ |
| | $-3.546$ | $-0.2636$ | $-7.577$ | $-7.646$ |
| 1.5 | $-0.4915$ | $0.4120$ | $-1.977$ | $-1.99$ |
| | $-1.841$ | $0.4915$ | $+2.170$ | $+3.005$ |
| 2.0 | $0.5403$ | $0.8415$ | $-0.0776$ | $-0.35$ |
| | $-0.8415$ | $0.5403$ | $+4.706$ | $+4.745$ |
| 3.0 | $1.0405$ | $1.015$ | $3.918$ | $3.64$ |
| | $0.0819$ | $1.0405$ | $2.608$ | $3.46$ |
| 4.0 | | | $6.724$ | $7.19$ |
| | | | $3.035$ | $3.984$ |

which provides the initial conditions for the next interval. The same procedure is carried out for the next interval and repeated to the end of the range in $t$.

The process may be written symbolically as follows:

$$[x(t_n)] = \Omega^{t_{n-1},\, t_n}\Omega^{t_{n-2},t_{n-1}} \ldots \Omega^{t_0,t_1}[x^0]$$

or more briefly:

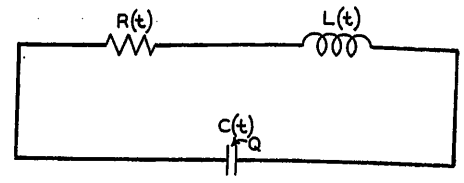
$$[x(t_n)] = \Omega^{t_{r-1},t_r}[x^0]$$

This is shown in table II.

It may be remarked that the approximate stepped solution differs quite considerably from the exact solution. However, in the example the variable stiffness fluctuates tremendously during the first interval.

The time intervals at the beginning of the solution should have been chosen shorter. Where the coefficients of the matrix $[u]$ vary considerably shorter time intervals must be taken.

The method here presented is only an approximate one and will give good results only in case the number of intervals during which the variable coefficients are to be considered constant is taken to be great. In the case of second order systems this method provides a rather quick method of arriving at the trend of the solution. In the example given here it is of course needless to calculate the process to 4 significant figures as has been done. It must be realized that the coefficient $(16\pi^2 e^{-2t} - 1/4)$ changes tremendously in the neighborhood of $t = 0$, and more accurate results would have been obtained had the number of intervals at the start of the solution been chosen in a different manner.



The method here presented is of particular value in second order differential equations whose coefficients do not vary greatly. It is true that when $t$ becomes large, errors will accumulate. Since, however, in most problems the variation of the dependent variable for small values of the independent variable $t$, is sought this method gives rather quickly the required information.

## VII. Variable Networks

The above-mentioned method enables one to obtain the solution for the free oscillations of a network whose parameters vary with the time. The solution may be made as accurate as desired by the correct choice of the time intervals $t_s - t_{s-1}$.

It is now proposed to discuss the transient solution of networks whose parameters vary with the time in a periodic manner. An example of this type of network is the alternator with the mutual inductance varying as a sine function of $t$. Another example is the telephone transmitter with internal resistance that varies periodically with the time. The condenser microphone is another example of this class of circuit. There are a host of important technical problems of this class. In the field of mechanical engineering the situation is the same. The torsional vibrations of the side-rods of electric locomotives and even the noisy vibrations of small synchronous clock motors may be brought under the heading of systems with periodically varying parameters. For other mechanical problems of this class the reader is referred to "Mechanical Vibrations," a book by Den Hartog. A most extensive bibliography of this class of problems is given by Van der Pol and Strutt.[8]

**Figure 3**

### 1. Free Oscillations of a Variable Network

The method will be illustrated by the use of a special case which is of great importance in electrical and mechanical engineering.

For definiteness, let us consider the most general possible series circuit containing a variable resistance, inductance, and capacitance. The circuit is shown in figure 3.

Suppose that at $t = t_0$ a charge is placed on the condenser and we inquire the subsequent behavior of the system. We specify that all the variable elements are periodic in time with the same frequency. That is,

$$R(t + T) = R(t)$$
$$C(T + t) = C(t)$$

and

$$L(t + T) = L(t)$$

where $T$ is the period of the variation. Let

$$R(t) = R_0 + r(t)$$
$$L(t) = L_0 + l(t)$$
$$R/C(t) = S(t) = S_0 + s(t)$$

where $S(t)$, the reciprocal of the capacitance is the elastance. $R_0$, $L_0$, and $S_0$ are the fixed constant resistance, inductance, and elastance of the circuit about which the circuit varies. $r(t)$, $l(t)$, and $s(t)$, are the variable elements of resistance, inductance, and elastance of the circuit. Let us suppose that the variations in the various elements is always smaller than the fixed portion of the various elements. That is,

$$|s| < R_0 \qquad |l| < L_0 \qquad \text{and} \qquad |s| < S_0$$

that is, the absolute values of the variable elements are always less than the fixed components. This is usually the case in actual physical systems.

The fundamental equation of the circuit is:

$$\frac{d^2Q}{dt^2} + \frac{dQ}{dt}\left(R + \frac{dL}{dt}\right)\frac{1}{L} + \frac{S(t)}{L(t)}\,Q = 0$$

where

$$D = d/dt$$

and $Q$ is the charge on the condenser in coulombs. Let

$$A(t) = \left(R + \frac{dL}{dt}\right)\frac{1}{L_0 + l(t)} \quad \text{and} \quad B(t) = \frac{S_0 + s(t)}{L_0 + l(t)}$$

In the above equation let us substitute

$$Q = e^{-1/2\int A(t)dt}y(t) \text{ for } Q$$

On making this substitution for $Q$ in the above differential equation we find that $y(t)$ must satisfy the uation $D^2y + (B - {}^1/_2DA - {}^1/_4A^2)y = 0$, if we call $- {}^1/_2DA - {}^1/_4A^2) = b^2 + \alpha(t)$; that is, we separate is expression into 2 parts, one a constant term and the ier a variable term. Our problem now reduces to the ution of $D^2y + [b^2 + \alpha(t)]y = 0$

It may be here noted that because of the periodicity of the rameters we must have: $\alpha(t + T) = \alpha(t)$

The above equation in $y$ is the equation of Hill. It has ceived extensive treatment particularly in astronomical nnections. All the methods published deal with the ution of the equation in series or contour integrals. ese solutions are most unsatisfactory from the practical int of view. A theorem will now be established which ll show the ease with which this equation may be solved nerically by the matrix method.

## The Stability of Hill's Equation

The following analysis is a general discussion on the de-rmination of the stability of the physical system whose havior is described by Hill's equation.

Consider Hill's equation:

$$y + [b^2 + \alpha(t)]y = 0$$

Now let $g_1(t)$ and $g_2(t)$ be 2 linearly independent solutions the differential equation. The general solution will en be a linear combination of $g_1$ and $g_2$ and may be ritten as:

$$= c_1g_1 + c_2g_2$$

here $c_1$ and $c_2$ are constants.

Let us write $y = x_1$ and $dy/dt = x_2$. We may then rite the matrix:

$$\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} g_1 & g_2 \\ Dg_1 & Dg_2 \end{bmatrix} \cdot \begin{bmatrix} c_1 \\ c_2 \end{bmatrix}$$

here $D = d/dt$ at $t = t_0$. Let

$$] = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = [x^0]$$

we now let

$$(t)] = \begin{bmatrix} g_1(t) & g_2(t) \\ Dg_1(t) & Dg_2(t) \end{bmatrix}$$

nd

$$] = \begin{bmatrix} c_1 \\ c_2 \end{bmatrix}$$

e may write the matrix relation $[x] = [A(t)]\,[c]$. Now determine the arbitrary constants we have,

$$^0] = [A(t_0)][c]$$

nd hence

$$] = [A(t_0)]^{-1}[x^0]$$

nd hence the solution becomes:

$$] = [A(t)][A(t_0)]^{-1}[x^0]$$

ow because of the periodicity of the variable coefficient $(t)$, that is, $\alpha(t + T) = \alpha(t)$, we may assume $[x(t_0 + T)] = k[x^0]$, where $k$ is some constant to be determined. But $[x(t_0 + T)] = [A(t_0 + T)]\,[A(t_0)]^{-1}[x^0]$, and hence substituting into the above equation we obtain:

$$k[x^0] = [A(t_0 + T)][A(t_0)]^{-1}[x^0]$$

If we let $[M] = [A(t_0 + T)]\,[A(t_0)]^{-1}$, then we have:

$$k[x^0] = [M][x^0]$$

or

$$[kI - M] = [0]$$

and the constant $k$ depends upon the 2 characteristic roots of the matrix $[M]$. That is if,

$$[M] = \begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix}$$

then $k$ is given by the 2 roots of the equation

$$k^2 - k(M_{11} + M_{22}) + (M_{11}M_{22} - M_{12}M_{21}) = 0$$

Now if $|k_1| < 0$ and $|k_2| < 0$ the motion is stable while if $|k_1| > 0$ or $|k_2| > 0$, the motion is unstable.

By subdividing the interval from $t_0$ to $t_0 + T$ into small intervals throughout which the variable $v(t)$ may be assumed to have its mean value it is possible to arrive at a numerical value for the matrix $[M]$ and hence to compute the stability of the system. This method has recently been employed by the author to a simple system. The results are to appear in the *Journal* of the Franklin Institute shortly.

## 3. The Matrix Solution of Hill's Equation

It would be easy to give a numerical example. However, it is best to consider the general case.

We are to solve $D^2y + [b^2 + \alpha(t)]y = 0$ with the initial conditions of $y$ and $dy/dt$ known. Let $y = x_1$ and $dy/dt = x_2$. Our equation reduces to the system.

$$Dx_1 = x_2$$
$$Dx_2 = -[b^2 + \alpha(t)]x_1$$

Let $F(t) = -[b^2 + \alpha(t)]$

The equation in matrix form becomes,

$$D[x] = \begin{bmatrix} 0 & 1 \\ u_{21} & 0 \end{bmatrix} \cdot [x] \qquad u_{21} = F(t)$$

The solution is carried out as in the example of section VI, part 4. The time $T$ for one cycle of variation of $\alpha(t)$ is divided into several intervals of length $\Delta t$ and the various matrizants calculated.

The solution at the $n$th interval is given by

$$[x(t_n)] = \prod_{r=1}^{n} \Omega^{t_r - t_{r-1}}[x^0]$$

where, as before, $[x^0]$ is the matrix of the initial values of $y$ and $dy/dt$. If at the end of time $t = T$ or at the end of the completion of one cycle of variation of $\alpha(t)$ the variables $x_1$ and $x_2$ have increased to $kx_1^0$ and $kx_2^0$ or, in matrix form $[x(T)] = k[x^0]$, then we have solved the equation for any value of $t$ by the use of the formula $y(t + T) = ky(t)$. The important thing particularly in mechanical problems

is that we have determined the stability coefficient $k$ and can now predict whether the motion will increase and hence be unstable or die out or keep on without any increase or decrease. The author is in the process of applying this method to several special cases.

Having determined $y$, $Q$, the charge on the condenser is obtained from

$$Q = e^{-1/2\int(A_i)dt}y(t)$$

Whether $Q$ builds up or not depends on the relative magnitudes of the decrement factor

$$e^{-1/2\int A(t)dt}$$

and the value of $k$. In the absence of resistance, $A(t) = 0$. The behavior of $Q$ depends entirely on $k$ in such a case.

## VIII. The Solution of Oscillatory Networks

If in the most general linear bilateral network with lumped parameters discussed in part III, we place the resistance elements $R_{ij} = 0$. That is, the resistance in the various branches is negligible, we call the network an oscillatory network. In the conventional solution of such a network for the resonance frequencies and amplitudes it is necessary to solve a set of algebraic equations of high order. A method will now be given by which through the employment of matrices we do not have to solve any algebraic equations whatsoever. The method to be given here is a modification of a method developed by Duncan and Collar in treating mechanical problems.[7]

The fundamental equations for such a circuit in matrix form are:

$$[e] = [Z][i] \qquad \text{(See part III)}$$

where

$$Z_{ij} = J(\omega L_{ij} - 1/\omega C_{ij}) \qquad J = \sqrt{-1}$$

putting $R_{ij} = 0$.

Now, if we are interested in the various resonant frequencies, we place $[e] = [0]$.

Our matrix equation reduces to: $[0] = [Z]\ [i]$ or $[0] = (\omega[L] - 1/\omega[1/C])\ [i]$. The matrix

$$[L] = \begin{bmatrix} L_{11}\ldots L_{12}\ldots\ldots L_{1n} \\ \ldots\ldots\ldots\ldots\ldots \\ \ldots\ldots\ldots\ldots\ldots \\ L_{n1}\ldots L_{n2}\ldots\ldots L_{nn} \end{bmatrix}$$

may be termed the inductance matrix. The inductance matrix includes all the self-inductances ($L_{11}, L_{22}, \ldots L_{jj}$) and all the mutual inductances ($L_{ij}$ where $i \neq j$). The matrix

$$[1/C] = \begin{bmatrix} 1/C_{11}\ldots 1/C_{12} \quad \ldots\ldots 1/C_{1n} \\ \ldots\ldots\ldots\ldots\ldots\ldots \\ \ldots\ldots\ldots\ldots\ldots\ldots \\ 1/C_{n1}\ldots 1/C_{n2}\ldots\ldots 1/C_{nn} \end{bmatrix}$$

may be termed the elastance matrix. It includes the self- and mutual-elastances of the system.

If we multiply both sides of our above matrix equation by the scalar $\omega$, the angular frequency, we obtain:

$$(\omega^2[L] - [1/C])[i] = [0]$$

Multiplying by $[L]^{-1}$, the inverse of $[L]$ gives us,

$$(\omega^2[I] - [L]^{-1}[1/C])[i] = [0]$$

where $[I]$ is the unit matrix.

This may be considered as the generalization of the equation

$$(\omega^2 - 1/LC)i = 0$$

for the resonant frequency of a simple series circuit having an inductance $L$ and a capacitance $C$. In this simple case, the well-known solution for the angular resonant frequency is $\omega = 1/\sqrt{LC}$.

## 3. The Solution of the Matrix Equation

We must now solve the matrix equation:

$$(\omega^2[I] - [L]^{-1}[1/C])[i] = 0$$

For simplicity, let $\mu = \omega^2$ and $[M] = [L]^{-1}[1/C]$. Our equation now reduces to $[\mu I - M]\ [I] = [0]$. We note here (part II, section 7) that the matrix $[\mu I - M]$ is the characteristic matrix of the matrix $[M]$.

The latent roots $\mu_j$ of the matrix $[M]$ are related therefore, to the resonant frequencies by the equation

$$f_j = 1/2\pi\sqrt{\mu_j}$$

where the $f_j$ are the resonant frequencies.

We could, of course, evaluate these roots by finding the roots of the characteristic function

$$|\mu I - M| = 0$$

however, this is essentially the conventional procedure which one employs without the use of matrices. We are then confronted with an equation of degree $n$ for $\mu$. It is now proposed to give another method which avoids the solution of the algebraic equation.

Let us consider the matrix $[M]$ raised to a very high power. See part II, section 12. We have the equation

$$\lim_{n\to\infty}[M]^n = \frac{\mu_1{}^n\,[M_1]}{(\mu_2 - \mu_1)(\mu_3 - \mu_1)\ldots(\mu_n - \mu_1)}$$

where $\mu_1$ is the greatest of the latent roots of $[M]$, and $[M_1] = [\mu_2 - M]\ [\mu_3 - M]\ \ldots\ldots [\mu_n - M]$. We note that $[M_1]$ is the product in the Cayley-Hamilton relation with $[\mu_1 - M]$ absent. Therefore, by the Cayley-Hamilton theorem (part II, section 10), we have $[\mu_1 - M]\ [M_1] = [0]$

We now make use of the theorem on the vanishing of a product of matrices (part II, section $e$). Therefore

$$[M_1] = \begin{bmatrix} a_1A_1\ldots a_2A_2\ldots\ldots a_1A_n \\ \ldots\ldots\ldots\ldots\ldots\ldots \\ \ldots\ldots\ldots\ldots\ldots\ldots \\ a_nA_1 \quad a_nA_2\ldots\ldots a_nA_n \end{bmatrix}$$

That is, the matrix $[M_1]$ is such that the elements of any row are proportional to the corresponding elements of the top row of $[M_1]$. Therefore

$$\lim [M]^n = \frac{\mu_1{}^n}{\prod_{r\neq 1}(\mu_r - \mu_1)} \begin{bmatrix} a_1A_1\ldots\ldots\ldots a_1A_n \\ \ldots\ldots\ldots\ldots \\ \ldots\ldots\ldots\ldots \\ a_nA_1\ldots\ldots\ldots a_nA_n \end{bmatrix}$$

Now consider *any* line matrix $[X]$ and form the product

$$[M]^n[X] = \frac{{\mu_1}^n}{\prod_{r\neq 1}(\mu_r - \mu_1)} \begin{bmatrix} a_1A_1 \ldots\ldots a_1A_n \\ \ldots\ldots\ldots\ldots \\ \ldots\ldots\ldots\ldots \\ a_nA_1 \ldots\ldots a_nA_n \end{bmatrix} \begin{bmatrix} X_1 \\ X_2 \\ \ldots \\ X_n \end{bmatrix} =$$

$$\frac{{\mu_1}^n}{\prod_{r\neq 1}(\mu_r - \mu_1)} \begin{bmatrix} a_1R \\ a_2R \\ \ldots \\ a_nR \end{bmatrix}$$

where

$$R = A_1X_1 + A_2X_2 + \ldots + A_nX_n$$

If the values of $X_1, X_2 \ldots\ldots\ldots X_n$ are chosen so that $R$ is not zero, it follows that $[M]^{n+1}[X] = \mu_1[M]^n[X]$ that is, raising the power of the matrix $[M]$ from $n$ to $n+1$, gives a resulting matrix that is the same as before except that it is multiplied by $\mu_1$. Therefore, to obtain the fundamental frequency, any series of values are assumed for $X_1 \ldots\ldots X_n$ and, by continually multiplying $[M]^{n+1}[X]$ is obtained. After $n$ has reached a certain value, a limiting form is obtained when the ratio of successive multiplications is equal to $\mu_1$. When $\mu_1$ has been obtained, the fundamental frequency is obtained from

$$f_1 = 1/2\pi\sqrt{\mu_1}$$

It remains now to find the relative amplitude of the currents in the various meshes when the system is oscillating in its fundamental mode. We return to

$$[\mu I - M][i] = [0]$$

and

$$[\mu_1 - M][M_1] = [0]$$

Let $(i_1^0\ i_2^0 \ldots\ldots\ldots i_n^0)$ be the amplitudes of the currents corresponding to the fundamental mode $\mu_1$. Then

$$[\mu_1 - M][i^0] = [0]$$
$$[\mu_1 - M][M_1] = [0]$$

hence $[i^0] = K_1[M_1]$, where $K_1$ is some constant; or, therefore,

$$[i^0] = K_2 \begin{bmatrix} a_1R_1 \\ a_2R_2 \\ \ldots \\ \ldots \\ a_nR \end{bmatrix}$$

Therefore the amplitudes of the various currents are proportional to the quantities $a_1, a_2, \ldots\ldots\ldots a_n$. The method will be illustrated by means of a numerical example.

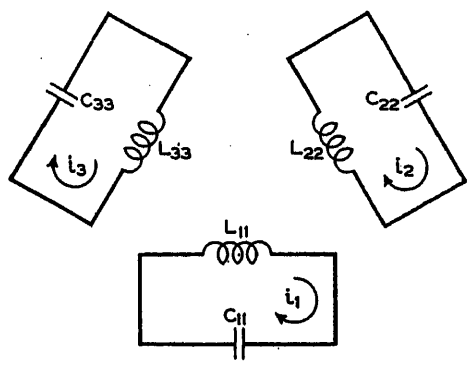


**Figure 4**

## 4. Example, Free Vibrations of a Coupled Circuit

The method will be made clear by the following example. Consider the coupled circuit shown in figure 4. In the circuit, let $C_{11} = C_{22} = C_{33} = 10^{-6}$ farads. Let $C_{ij} = 0$ if $i \neq j$. Let $L_{11} = {}^5/_6H$, $L_{22} = {}^1/_2H$, $L_{33} = {}^1/_6H$, $L_{12} = -{}^1/_3H = L_{21}$, $L_{31} = 0 = L_{13}$, $L_{23} = -{}^1/_3H = L_{32}$. In matrix form

$$[L] = \begin{bmatrix} 5/6 & -1/3 & 0 \\ -1/3 & 1/2 & -1/6 \\ 0 & -1/6 & 1/6 \end{bmatrix}$$

$$[1/C] = 10^6 \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} = 10^6[I]$$

We first calculate $[M] = [L]^{-1}[1/C]$

$$[L] = 1/36 \begin{bmatrix} 30 & -12 & 0 \\ -12 & 18 & -6 \\ 0 & -6 & 6 \end{bmatrix}$$

$$[L]^{-1} = \begin{bmatrix} 2 & 2 & 2 \\ 2 & 5 & 5 \\ 2 & 5 & 11 \end{bmatrix}$$

$$[M] = 10^6 \begin{bmatrix} 2 & 2 & 2 \\ 2 & 5 & 5 \\ 2 & 5 & 11 \end{bmatrix}$$

We choose

$$[X] = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}$$

for simplicity. Therefore

$$[M][X] = 10^6 \begin{bmatrix} 2 & 2 & 2 \\ 2 & 5 & 5 \\ 2 & 5 & 11 \end{bmatrix} \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} = 10^6 \begin{bmatrix} 6 \\ 12 \\ 18 \end{bmatrix} = 18 \times 10^6 \begin{bmatrix} 1/3 \\ 2/3 \\ 1 \end{bmatrix}$$

$$[M]^2[X] = 18 \times 10^{12} \begin{bmatrix} 2 & 2 & 2 \\ 2 & 5 & 5 \\ 2 & 5 & 11 \end{bmatrix} \begin{bmatrix} 1/3 \\ 2/3 \\ 1 \end{bmatrix} = (18)(15)(10^{12}) \begin{bmatrix} 4/15 \\ 9/15 \\ 1 \end{bmatrix}$$

It may be noted that since we are only interested in the ratio of successive multiplications we may dispense with the numerical factors in front of the matrix. Continuing the process we soon reach:

$$\begin{bmatrix} 4/15 \\ 9/15 \\ 1 \end{bmatrix} \begin{bmatrix} 2 & 2 & 2 \\ 2 & 5 & 5 \\ 2 & 5 & 11 \end{bmatrix} = 14.533 \begin{bmatrix} 0.256{,}881 \\ 0.584{,}762 \\ 1 \end{bmatrix}$$

and

$$\begin{bmatrix} 2 & 2 & 2 \\ 2 & 5 & 5 \\ 2 & 5 & 11 \end{bmatrix} \begin{bmatrix} 0.256{,}881 \\ 0.584{,}762 \\ 1 \end{bmatrix} = 14.4495 \begin{bmatrix} 0.255{,}238 \\ 0.584{,}762 \\ 1 \end{bmatrix}$$

The ratio is settling down to a number nearly equal to 14.45. By continuing further it is found that the value of $\mu_1 = 14.431 \times 10^6$ and the ratios of the amplitudes of the currents for the fundamental oscillation are about 0.255, 0.584, and 1.000 as given by the final matrix. A similar mechanical problem is discussed by Duncan and Collar in the above-mentioned paper in the *Philosophical Magazine.*

It is seen that the convergency of the process is very high and the calculations are easily made with a comptometer. The results are

$\mu_1 = 14.431(10^6)$

hence

$_1 = 1/2\pi\sqrt{\mu_1} = 607$ cycles per second

This is the fundamental frequency. When the system is oscillating at the fundamental frequency the ratios of the currents are $i_1 = 0.225$, $i_2 = 0.584$, and $i_3 = 1.000$; that is, with respect to $i_3$ as unity the other currents have the above values.

For a more complete discussion of this method in similar mechanical problems the reader is referred to "Solution of Oscillation Problems by Matrices" by Duncan and Collar. In this paper a method of obtaining the higher resonant frequencies is also given. The author is working on some more applications of the method.

It must be noted that the method here given while it avoids the direct solution of the detrimental equation makes use of a process which is related to the well-known root-squaring method of Graeffe. Graeffe's method has been shown to be equivalent to the method of Daniel Bernoulli. An excellent discussion and an extension of Bernoulli's method which may be reduced to the method here presented may be found in A. C. Aitken's paper "On Bernoulli's Numerical Solution of Algebraic Equations" Proceedings of the Royal Society, Edinburgh, volume 46, page 289, 1926.

## X. Conclusion

It has been the purpose of this paper to show the inherent simplicity and power of the matrix method once the fundamental operations have been grasped.

The theory of matrices as presented in part II has been the result of searching the international literature and it is hoped that the concise presentation may give an impetus to the use of this method. The author is at present attacking the problem of simultaneous partial differential equations by this method and the results thus far show that the matrix method will be more powerful in this connection (See reference 9).

# The Next 50 Years

IN THE 50-year period before us there will be an accelerated advance in the accomplishments of engineering, which, broadly speaking, is the application of science. New discoveries in science, and their use by means of new inventions, will follow one another with ever increasing rapidity. Often one discovery will reveal a score or more of new opportunities which speedily will be developed and made useful to man.

This acceleration in the speed of engineering advancement will be due in part to the increase in the number of workers in this field, made available through the competition of engineering colleges to gain students, and especially through the growing conviction among parents, whether well-founded or not, that an engineering education carries with it an improved economic and social status. The public has become "engineering minded."

No one can foretell with accuracy what specific results will ensue from this intensified development along engineering lines; but a few accomplishments are clearly evident:

1. Space, already so greatly reduced, will, practically speaking, be well nigh eliminated by the conquest of the air.

2. Mass-production will be extended to far more industries.

3. Agriculture will yield more and more to combination-control and mechanization. With the aid of new methods of processing and the discovery of synthetic foods, the necessary agricultural products for a unit of population will be provided with a fraction of the labor and land now used.

4. Automatic control of production and operation will further greatly reduce the need for manual control.

5. New scientific discoveries, new sources of power, and the development of new processes and inventions, will make necessities and many luxuries more generally available.

Such changes will inevitably shorten the work-time required to satisfy the demands of the public. In Canada and the States it has been reduced $^1/_3$ during the last 50 years. Is it not probable that an equal reduction will result in the next 50 years? If so, the required work-time will become only half what it is at present. Probably 20 hours a week is a conservative estimate.

Whatever this reduction may be, it will result largely from the activities of the engineer. Credit for lightening the human burden, however, will be accompanied by liability for any unfortunate results which may ensue, and the public will look to the engineer to provide the means to avoid them.

From an address by the late Harrison P. Eddy, past-president of the American Society of Civil Engineers, prepared for presentation at the recent semicentennial celebration of the Engineering Institute of Canada, upon which occasion Mr. Eddy was to have been made an honorary member of that society. The address was posthumously delivered at a luncheon meeting on June 16, and was published in the August 1937 issue of *Civil Engineering*, pages 545–6.

# Short-Circuit Protection of Distribution Networks by the Use of Limiters

By C. P. XENIS
MEMBER AIEE

A LARGE PERCENTAGE of secondary cable faults in distribution networks "burn clear" rapidly. In such cases, the short-circuit current to the fault has not persisted for a sufficiently long period of time to raise the temperature of the cable conductor on either side of the fault to a high enough temperature to fuse, or permanently damage adjacent cable insulation. However, not even the most optimistic treatises on "burnoff" have ever asserted that all secondary cable faults are of this accommodating type. Furthermore, the fault consists of an electric arc between a number of energized copper conductors confined in the small space of the duct, surrounded by masses of molten metal and with water frequently present. Under such a combination of conditions, who can contend that the fault can be depended upon to always clear in time to protect the insulation of cables supplying the fault current?

Companies operating extensive distribution networks have experienced cases of cable failure "spreading" beyond the initial point of fault, and the prevention of extensive damage in such cases depends on the prompt arrival of the operating crews who cut network cables "around" the faulted area. This type of fault is frequently accompanied by fires and explosions for apparent reasons.

This problem is not new, and the development of noncombustible cable insulation represents one angle of attack. The development of cable joining connectors, lugs, etc., which incorporate fusible elements, so that in addition to their normal splicing functions, they provide adequate fuse protection to the cables to which they are attached, represents another angle of attack to the problem. Undoubtedly other solutions will present themselves in the future.

## The Limiter

The limiter consists of a reduced metallic section incorporated in a connector, lug, or other connecting device used in normal cable installation procedure. It has a time-current characteristic calculated to protect the cable to which it is connected over a wide range of short-circuit currents, by interrupting the faulty circuit before the cable insulation reaches the "roasting" point; in other words, the limiter selects with cable insulation. It is so designed as to form an integral part of the joint or cable terminal without the necessity of the additional enclosures, terminal blocks, packing glands, etc. that conventional underground fusing systems require. In short, it is a fuse made into an inconspicuous part of the cable it is intended to protect.

Figure 1 step number 1 shows a connector-type limiter used for protecting number 4/0 nonleaded cables on the distribution systems of the Consolidated Edison Company of New York, Incorporated. This limiter is made from a single piece of copper tubing by flattening the middle portion of the tube and punching out the excess metal, thus leaving the desired fusible section. Step number 2 shows the ends of the number 4/0 cables inserted in the tubular ends of the limiter, while step number 3 shows the assembly after the tubular ends are indented to form a permanent connection between the cables. Step number 4 shows the fireproofing shells assembled around the limiter, while step number 5 shows the limiter installation completed by covering the assembly with a rubber sleeve and taping the ends to the cable insulation. Figure 2 gives the corresponding steps taken in installing a limiter lug on the end of a 500,000-circular-mil nonleaded cable. Note that in this case no rubber covering is provided over the fireproofing shells on the lug since it is used for indoor installations. The limiter lug is also constructed from a single piece of

A paper presented at the Edison Electric Institute transmission and distribution committee meeting, Chicago, Ill., May 5, 1937, and recommended for publication by the AIEE committee on power transmission and distribution. Manuscript submitted May 21, 1937; released for publication July 9, 1937.

C. P. XENIS is division engineer, distribution development division, Consolidated Edison Company of New York, Inc., New York, N. Y.

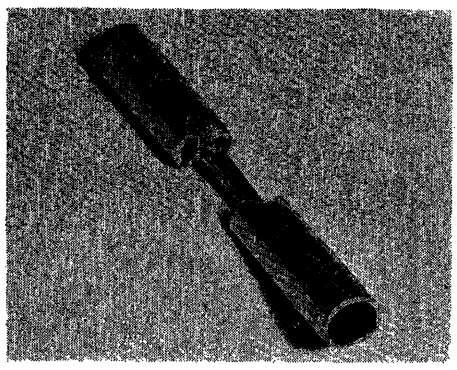

**Figure 1A. Connector type limiter**

copper tubing, a portion of which has been flattened, bent, and punched out to form the lug and fusible section.

The fireproofing shell (figure 3) plays an important part in the proper operation of the limiter by providing the means of confining the arc developed during the interruption of the circuit. It is molded from a noncombustible dry mixture of asbestos and cement. Note the barriers which further tend to confine the arc and keep it from striking across the large cylindrical portions of the limiter. With the limiter assembly as described, it is possible to interrupt short-circuit currents met in practice without any external indication of arc or flame.

In connecting the above limiters to cables, it should be noted that compression-type mechanical connections were used. Various types of powder driven, hydraulically operated, and screw-type devices are now available which make satisfactory connections. Solder must be avoided in the proximity of limiters because of its low melting point. While in the above illustrations we have indicated the use of limiters on nonleaded cables, their application to rubber-insulated lead-covered cables is equally practical and lead sleeves may be installed over the limiters if desired. However, the use of limiters on paper-insulated lead-covered cables becomes relatively difficult since it is necessary to take additional steps to keep the impregnating oil from entering the fuse chamber of the limiter.

The use of limiters at multiple points of a network system results in the protection of each cable section between such points. The cable fault shown in figure 4 draws its supply of short-circuit current from 3 directions at each multiple point. However, the total short-circuit current from each multiple point must pass through the limiter which is connected to the faulty cable. In other words by installing limiters of the same type at each multiple point of a network system, the selection between limiters is automatically secured, and since the faulty section is equipped with limiters at both extremities, it will be isolated from the rest of the network. This presumes that the limiter is designed so that it will blow at the minimum values of short-circuit current encountered in that network.

## Limiter Characteristics

The limiter, like any other type of fuse, has a time current characteristic which defines its performance at various overloads. From previous discussions, it is evident that the ideal characteristic for a limiter is one slightly faster than the insulation damage characteristic of the cable it is intended to protect. In other words, the limiters on the faulted section should fuse before the insulation of the cables feeding the short-circuit reaches a dangerous condition as the result of the total heat generated by all cables in the duct. It therefore follows that limiter design should be preceded by the determination of cable damage characteristics. This has been done experimentally using various rubber-insulated cables, for a single cable in open air and again for a set of main cables installed in concrete duct. Figures 5, 6, and 7 show time-temperature characteristics for various types of cable installations encountered in the network distribution systems of the Consolidated Edison Company of New York, Incorporated. It will be noticed that after the copper conductor reaches a temperature of approximately 265 degrees centigrade the rubber reaches the point of permanent visible damage. Although tests were made on cables insulated with 2 types of rubber base compounds, namely, intermediate rubber compound, ASTM performance rubber compound, some lead-covered, others not, it was found that the slight differences in the results obtained did not justify separate treatment in this report and therefore one set of curves have been plotted. It will also be noted that in cases of rapid temperature rise in the copper conductor, somewhat higher copper temperatures are necessary to cause the same extent of damage to cable insulation. This is the result of the lag in the temperature

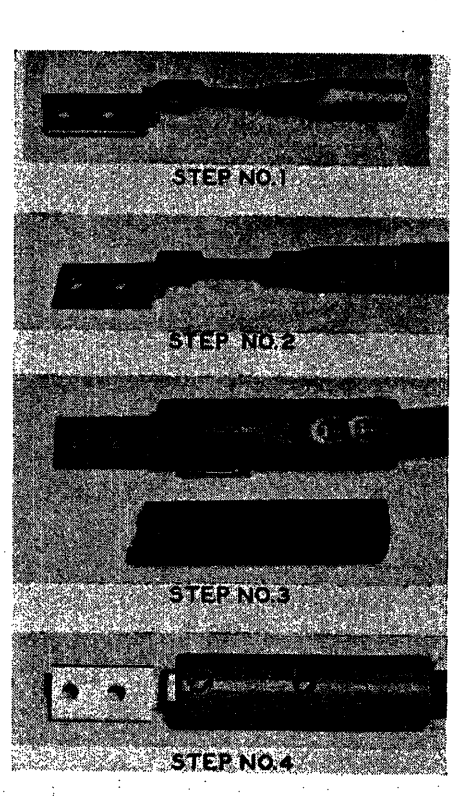

**Figure 2. Installation of lug type limiter**

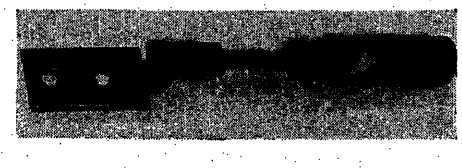

**Figure 2A. Lug type limiter**

rise of the insulation behind the rise of copper temperature. Figure 8 summarizes the cable damage characteristics for rubber insulation in a more convenient form for comparison with limiter characteristics.

In figures 9 and 10 we have shown cable damage characteristics together with the characteristics of limiters of types illustrated in the first part of this paper. The intersection of the limiter characteristic with the cable damage characteristic indicates the value of current below which the limiter offers no protection to cable insulation. However, if this critical current is below the minimum value of short-circuit current obtainable in the network, this limitation loses all practical importance. A wide range of limiter characteristics is possible by varying the cross section and the length of the fusible section. This phase of the limiter design problem is not much different than that of general fuse link design and therefore, no useful purpose can be served here by going into detail. On figure 9, 2 limiter characteristics have been shown to illustrate possible variations in design.

An additional point to be kept in mind in selecting or designing limiters is that the limiter generates heat at a higher rate than the cable conductor and therefore some of this heat is conducted to the cable to which it is attached. This presents a problem only for currents near the minimum at which the limiter is designed to fuse. Higher currents fuse the limiter before the heat generated has time to affect the adjacent cable insulation. Substantially lower currents (than the minimum fusing values for the limiter) do not generate a sufficient amount of heat to affect the adjacent cable insulation. It is therefore desirable that this particular point be investigated as the last step of design to insure that no overheating of the cable insulation adjacent to the limiter results from heat conducted from the limiter. By judicious change of the length and cross section of the fusible section and by proper selection of the minimum blowing point of the limiter, this condition can be overcome. In this connection the fact that the limiter and adjacent cable insulation are located in the manhole where ambient temperatures are substantially lower than those in the duct in which the overloaded cables are located, assists in arriving at the desired thermal balance. At rated loads the temperature of the fusible section (located within the asbestos shell) is approximately 5 degrees centigrade higher than that of the cable conductor.

With the aid of the above analysis and reference to the data presented in curve form, it is possible to design limiters which will properly select with the cable insulation. In the a-c distribution system of the Consolidated Edison Company of New York, Incorporated, limiter type *AC-2R* has been used extensively for protecting number 4/0 nonleaded network cables in Manhattan and the

Bronx. Their use is now being extended to other sizes of cables and at other points of the distribution networks.

## Selectivity Between Limiters and Network Protector Fuses

Our discussion heretofore has been confined to the proper protection of network cables by means of limiters installed at multiple points. Where the multiple point happens to be also a supply point, 2 additional considerations for the proper design of the system must receive attention:

(*a*) The supply cables (connecting the network protector to the street mains) may be protected by means of limiters.

(*b*) The network protector fuse should properly select with the combination of limiters on the supply cables and those on the network mains at the multiple point.

With reference to consideration (*a*) the desirability of protecting supply cables varies with the type of installation. If, for example, the supply cables represent a very short run between a network protector installed in an underground manhole and the multiple point, the need for protecting the supply cables is questionable. If, however, the supply cables are of considerable length as in the case of transformer banks installed within customer's buildings, the protection of such supply cables and secondary ties is of considerable importance since a serious case of cable failure within the customer's premises is liable to entail unpleasant consequences. This protection can be accomplished in accordance with the methods previously explained. Where the cable terminates at a bus, as would be the case where secondary ties connect to the customer's bus, limiter lugs are used for the purpose. Figure 11 is a schematic diagram representing a network completely equipped with limiters at multiple points and with supply cables protected at both extremities. Figure 12 shows a transformer vault installation with secondary ties, as well as cables connecting the transformer secondary side to the network switch, completely protected by means of limiters. This type of protection has been recently adopted by the Consolidated Edison Company of New York, Incorporated.

Figure 12 also serves to illustrate the problem of obtaining the proper selection between network protector fuse and associated limiters. In the event of a high-voltage feeder failure, if the network protector fails to open because of some defect, it is desirable to have the circuit interrupted by the network protector fuse because of the relative ease of replacement of the latter, in comparison with the replacement of limiters. Hence, it is necessary to consider the characteristic of the network protector fuse in conjunction with that of the associated limiters, taking into consideration the fact that a number

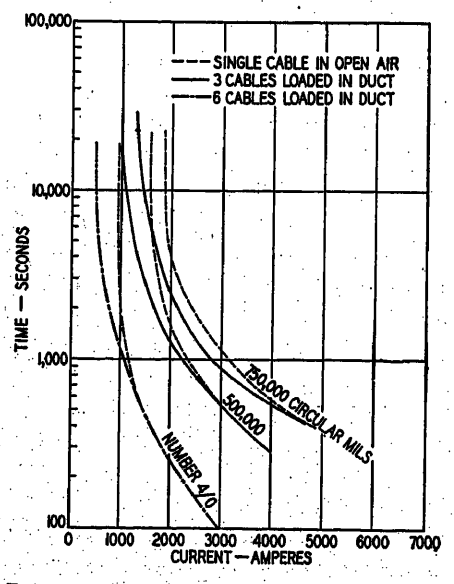

**Figure 8. Cable insulation damage characteristics, rubber-insulated cables**

Note: Visible damage occurs at points on and above each characteristic curve

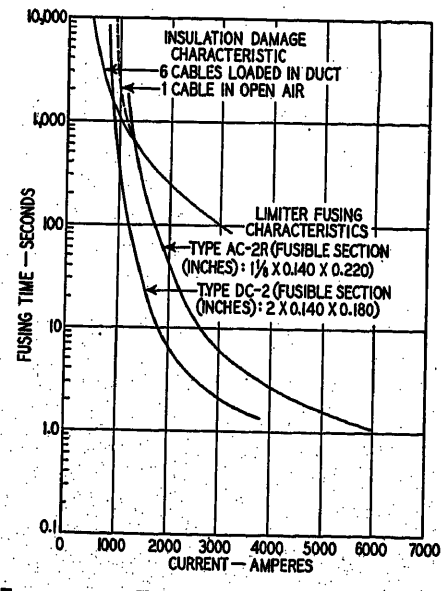

**Figure 9. Time-current characteristic, 4/0 cable limiter**

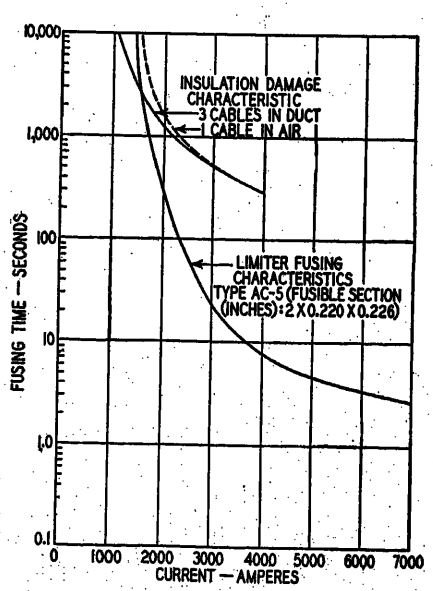

**Figure 10. Time-current characteristic, 500,000-circular-mil cable limiter**

of limiters in parallel (4 per phase in the case of figure 12) divide the total current flowing through each network protector fuse. Because of differences in length between the street ties and variations in the network layout, it is possible that in the case of backfeed the 4 street ties shown in figure 12 may not equally divide the total backfeed current. It has therefore been decided that the proper selection should be obtained even when one of the 4 secondary ties carries as much as 40 per cent of the total backfeed current. An unbalance of this magnitude is extremely unlikely to occur on the system. Figure 13 shows the characteristic of network protector fuse type $Z$-25 and that of limiter type $AC$-5 when carrying various percentages of the total fuse current. It will be noticed that even when a limiter on one of the secondary ties carries as much as 40 per cent of the total backfeed current, a comfortable margin of selectivity is obtained. The characteristic of the limiter considered on figure 13 ($AC$-5) is shown on figure 10. With a range of selection such as indicated above, the network protector fuse continues to be the weakest link in the chain of network protection.

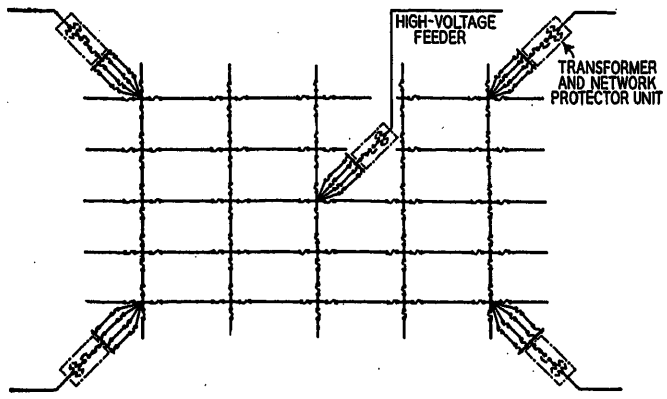

**Figure 11. Schematic diagram of distribution network completely equipped with limiters**

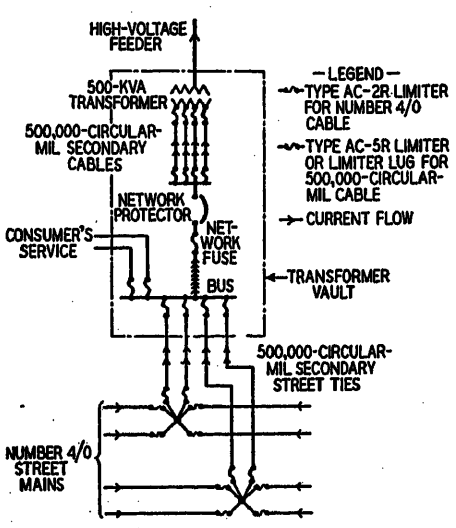

**Figure 12. Schematic current distribution diagram under condition of backfeed**

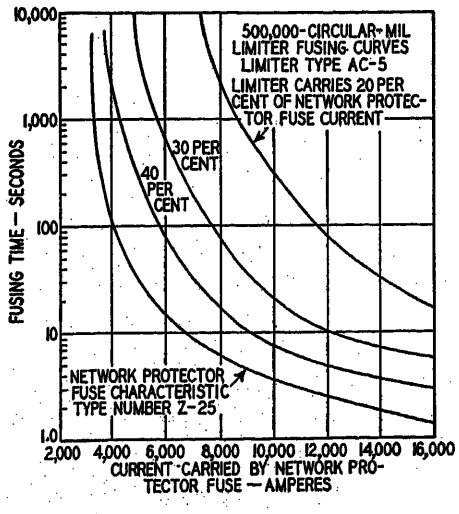

**Figure 13. Selectivity between network protector fuse and associated limiters**

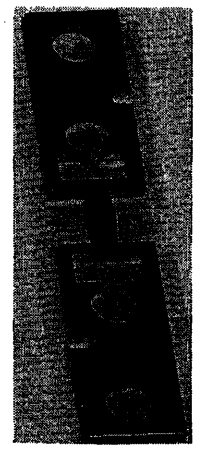

**Figure 14 (above). Type Z network protector fuse**

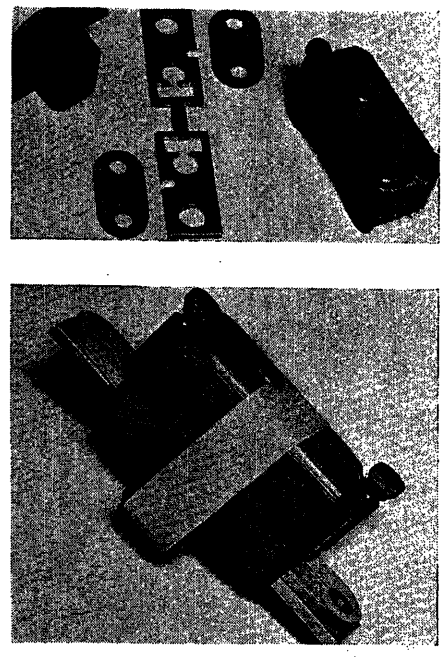

**Figure 15 (right). Details of type Z network protector fuse and enclosure (top) and assembly of type Z network protector fuse and enclosure (bottom)**

Since the network protector fuse is in series with a group of limiters which are in parallel, the 2 types of devices must necessarily possess time-current characteristics of the same general shape. Hence it was decided to review network fuse design and bring it in line with limiter design so as to obtain the desired selection. The result of this work was a copper fuse, illustrated on figure 14, which provides proper selection with limiters, protects the transformer over a broader range of overload currents than other conventional network protector fuses, and is of a type that can be readily punched out of flat sheet copper. An individual fireproof arc-suppressing enclosure (see figure 15) is provided with each fuse. These enclosures serve to protect men who may happen to be standing in front of an open network protector when the fuse blows, and to prevent damage to equipment and communication of trouble. These fuse assemblies have successfully interrupted currents of the order of 30,000 amperes at full restoration voltage with no restriking, and with the arc sufficiently confined to protect workmen in the immediate vicinity. The fuse characteristic on figure 13 is that of a fuse of this type, and of the size used with a 500-kva bank.

The development outlined in this paper may be briefly summarized as an attempt to revise cable splicing procedure so as to incorporate fuse protection for the large amounts of cable insulation exposed to high copper temperature in the vicinity of short-circuited distribution-

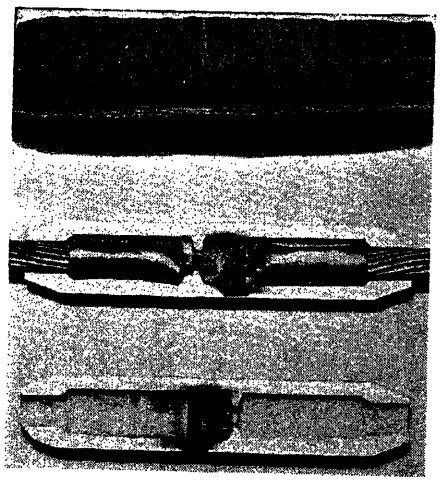

**Figure 16. Kerite and friction tape covering (top) and limiter fusing with separation of 1/4 inch (bottom)**

network mains. With such a system, those faults which "burn clear" in less time than that required to clear the limiter (see limiter characteristic) will continue to "burn clear" as heretofore. The faults which do not "burn clear" very readily are the ones that endanger insulation on cables supplying the fault current. Such faults will be cleared by limiter action.

The selection of the proper limiter for any distribution system should be based on a study of conditions obtaining in that system, with particular reference to (*a*) insulation damage characteristic of network cables, (*b*) minimum short circuit current, (*c*) selection with network protector fuses. Standardization in limiter design must necessarily be preceded by standardization in distribution network design.

The Consolidated Edison Company of New York, Incorporated, has installed 16,000 limiters in the past year. During this period there have been 2 cases of faults on cables equipped with limiters (35th Street and Sixth Avenue and 40th Street and Sixth Avenue). Both cases were caused by cables being "bull-pointed" by subway construction contractors. In each case the limiters properly cleared and protected the cables to which they were attached. Figure 16 shows a limiter which has blown in the field and cleared a short-circuit.

## Pooling Power in a Large Industrial Center

A PROBLEM of The Detroit (Mich.) Edison Company incident to the provision of reserve capacity against the exigencies of power plant operation and against outages occasioned by routine maintenance, and the provision of excess capacity to meet the unpredictable and sudden demands of a vigorously expanding industrial community, was discussed in a paper presented at the semiannual meeting of The American Society of Mechanical Engineers, Detroit, Mich., May 17–21, 1937, by J. W. Parker and R. E. Greene (A'26) respectively, vice-president and member of the engineering division of the company. The paper was published in *Mechanical Engineering* for May 1937, pages 335–9.

Diversity in time of use constitutes the major advantage in pooling the power requirements of any community, inasmuch as the peak load of residential and commercial users does not occur at the same hour as the peak industrial load. If each wholesale user of power operated its own isolated power plant, the installed capacity required would be much greater than is needed if all plants in an area are interconnected. Reserve capacity in a large system can be less than the aggregate reserve capacity in a series of isolated plants for the same load, where one spare unit may be a relatively large part of the total capacity.

In the Detroit system, reserve capacity in machines running and on the line is maintained at least equal to the capacity of the largest machine on the line. In case a machine must be shut down in an emergency, the running reserve should be restored at once, and, therefore, a second large machine is kept standing ready for an immediate start.

Pooling of power resources benefits the community because freedom is allowed in the choice of sites for manufacturing establishments, inasmuch as large quantities of water for condensers may be obtained by locating central stations on rivers, rather than requiring all manufacturers to build plants on the rivers. Such concentration in large stations, however, requires considerable investment in a transmission and distribution system, amounting in the Detroit system to approximately 56.6 per cent of the total property. The territory served is divided into 4 areas, each with a major generating station. Interconnection may be described as "loose linked," for limited-capacity ties are provided which may or may not normally carry load but which are sufficient in capacity to compensate for any losses in generating capacity which can be reasonably anticipated. If an uncontrollable fault develops in one area, the remainder of the system cuts clear.

The authors conclude that: "With all its advantages of both reliability and economy, the central system cannot, under certain circumstances, compete with certain types of load. Combining electric generation with a supply of steam required in some industrial process, produces power as a by-product at a much lower cost than can be attained by the best of condensing turbines. Seldom, however, does the requirement of steam for process work and building heating coincide with the manufacturer's own use of power. Paralleling such by-product generation with the central system may be, and often is, good economy rather than providing spare capacity against breakdown or being compelled to generate power under costly conditions in periods when no corresponding demand for steam exists. In a sense, the central system becomes a broker ready to sell or buy power as the circumstances of the moment may dictate."

# Extension of 2-Reaction Theory to Multiphase Synchronous Machines

By Y. H. KU
MEMBER AIEE

An extension of the 2-reaction theory of synchronous machines as developed by R. H. Park is given in this paper for machines with any number of phases.

AT THE 1929 AIEE winter convention, Park[1] and Ku[2] presented simultaneously 2 papers on the analysis of 3-phase synchronous machines. While Ku's method was based on Heaviside's operational calculus and Stokvis-Fortescue's symmetrical components, Park generalized the work of Blondel, Dreyfus, Doherty, and Nickle and gave a complete analysis of the salient-pole machine with any number of rotor circuits. Ku's work has since been extended to the salient-pole case with inductive and capacitive load[3] and also to the asynchronous operation[4] of synchronous machines. The 2-reaction theory has been further extended by Park[5] to the consideration of synchronizing and damping torque during continuous and transient oscillations. The 2-reaction operational impedances of machines with field collars are given by Waring and Crary,[6] and, more recently, the effect of condenser load is considered by Crary.[7] The present paper is a further extension of the 2-reaction theory as developed by Park to the general case of $n$-phase salient-pole synchronous machines. It may be pointed out that the 2-reaction components can also be simply related to the symmetrical components[8,9] and a similar extension based on operational calculus and symmetrical components[10] may serve as a good comparison between the 2 methods of attack.

## Fundamental Circuit Equations

Consider an ideal synchronous machine with $n$ phases, and let

$i_A, i_B, i_C \ldots i_N$ = per-unit instantaneous phase currents
$e_A, e_B, e_C \ldots e_N$ = per-unit instantaneous phase voltages
$\psi_A, \psi_B, \psi_C \ldots \psi_N$ = per-unit instantaneous phase linkages
$t$ = time in electrical radians
$p$ = $d/dt$

Then there is

$$\left.\begin{aligned} e_A &= p\psi_A - ri_A \\ e_B &= p\psi_B - ri_B \\ e_C &= p\psi_C - ri_C \\ &\cdots\cdots \\ e_N &= p\psi_N - ri_N \end{aligned}\right\} \quad (1)$$

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted June 2, 1937; released for publication July 22, 1937.

Y. H. KU is dean of engineering at National Tsing Hua University, Peiping, China.

1. For all numbered references, see list at end of paper.

The phase linkages of an $n$-phase salient-pole synchronous machine may be given as follows (see appendix I):

$$\psi_A = I_d \cos\theta - I_q \sin\theta - x_0 i_A + \left[x_0 - \left(\frac{x_d + x_q}{2}\right)\right]\left(\frac{2}{n}\right) \times [i_A + i_B \cos\theta_0 + i_C \cos 2\theta_0 + \ldots + i_N \cos\{(n-1)\theta_0\}] - \left(\frac{x_d - x_q}{2}\right)\left(\frac{2}{n}\right)[i_A \cos 2\theta + i_B \cos(2\theta - \theta_0) + i_C \cos(2\theta - 2\theta_0) + \ldots + i_N \cos\{2\theta - (n-1)\theta_0\}]$$

$$\psi_B = I_d \cos(\theta - \theta_0) - I_q \sin(\theta - \theta_0) - x_0 i_B + \left[x_0 - \left(\frac{x_d + x_q}{2}\right)\right]\left(\frac{2}{n}\right)\left[i_A \cos\theta_0 + i_B + i_C \cos\theta_0 + \ldots + i_N \cos(n-2)\theta_0\right] - \left(\frac{x_d - x_q}{2}\right)\left(\frac{2}{n}\right) \times [i_A \cos(2\theta - \theta_0) + i_B \cos(2\theta - 2\theta_0) + i_C \cos(2\theta - 3\theta_0) + \ldots + i_N \cos(2\theta)]$$

$$\cdots\cdots\cdots\cdots$$

$$\psi_N = I_d \cos\{\theta - (n-1)\theta_0\} - I_q \sin\{\theta - (n-1)\theta_0\} - x_0 i_N + \left[x_0 - \left(\frac{x_d + x_q}{2}\right)\right]\left(\frac{2}{n}\right)[i_A \cos(n-1)\theta_0 + i_B \cos(n-2)\theta_0 + i_C \cos(n-3)\theta_0 + \ldots + i_N] - \left(\frac{x_d - x_q}{2}\right)\left(\frac{2}{n}\right)[i_A \cos\{2\theta - (n-1)\theta_0\} + i_B \cos 2\theta + i_C \cos\{2\theta - (n+1)\theta_0\} + \ldots + i_N \cos\{2\theta - (n-2)\theta_0\}] \quad (2)$$

where $\theta$ = position of rotor axis in electrical radians measured from the axis of phase $A$, and $\theta_0 = 2\pi/n$. Let the transformations from the phase quantities to 2-reaction components be given by the following (see appendix II):

$$f_d = \frac{2}{n}[f_A \cos\theta + f_B \cos(\theta - \theta_0) + f_C \cos(\theta - 2\theta_0) + \ldots + f_N \cos\{\theta - (n-1)\theta_0\}] \quad (3)$$

$$f_q = -\frac{2}{n}[f_A \sin\theta + f_B \sin(\theta - \theta_0) + f_C \sin(\theta - 2\theta_0) + \ldots + f_N \cos\{\theta - (n-1)\theta_0\}] \quad (4)$$

where $f$ may stand for $e$, $i$, or $\psi$. It may be verified that

$$\psi_d = I_d - x_d i_d \quad (5)$$

$$\psi_q = I_q - x_q i_q \quad (6)$$

From previous work of Park,[1] Waring and Crary,[6] and others,[9] we know that $I_d$ can be expressed in terms of $E_d$ and $i_d$, and, similarly, $I_q$ can be expressed in terms of $E_q$ and $i_q$. Hence by extending to the $n$-phase case, we have

$$\psi_d = G_d(p)E_d - x_d(p)i_d \quad (5a)$$

$$\psi_q = G_q(p)E_q - x_q(p)i_q \quad (6a)$$

Let also

$$f_0 = \frac{1}{n}[f_A + f_B + f_C + \ldots + f_N] \quad (7)$$

Then

$$\psi_0 = -x_0 i_0 \quad (8)$$

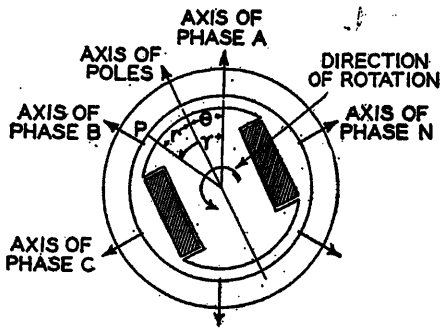

Figure 1

For the transformation of other variables, we have in general,

$$f_{u(k)} = \frac{2}{n}\,[f_A + f_B \cos(k+1)\theta_0 + f_C \cos\{2(k+1)\theta_0\} + \ldots + f_N \cos(k+1)\theta_0] \quad (9)$$

$$f_{v(k)} = \frac{2}{n}\,[0 + f_B \sin(k+1)\theta_0 + f_C \sin\{2(k+1)\theta_0\} + \ldots - f_N \sin(k+1)\theta_0] \quad (10)$$

where $(k)$ has the values from one to $(n-3)/2$ for $n$ odd and to $(n-4)/2$ for $n$ even. For $n$ even, we have also

$$f_w = \frac{1}{n}\,[f_A - f_B + f_C - \ldots - f_N] \quad (11)$$

Then it can be shown that

$$\psi_{u(k)} = -x_{0i} i_{u(k)} \quad (12)$$

$$\psi_{v(k)} = -x_{0i} i_{v(k)} \quad (13)$$

$$\psi_w = -x_{0i} i_w \quad (14)$$

The equations for the phase voltages can now be transformed to the following:

$$e_d = p\psi_d - r i_d - \psi_q p\theta \quad (15)$$

$$e_q = p\psi_d - r i_q + \psi_d p\theta \quad (16)$$

$$e_0 = p\psi_0 - r i_0 \quad (17)$$

$$e_{u(k)} = p\psi_{u(k)} - r i_{u(k)} \quad (18)$$

$$e_{v(k)} = p\psi_{v(k)} - r i_{v(k)} \quad (19)$$

$$e_w = p\psi_w - r i_w \quad (20)$$

Notice that since $\psi_d$ and $\psi_q$ only involve the current components $i_d$ and $i_q$, $i_d$ and $i_q$ can be obtained by solving 15 and 16 simultaneously. Equations 17 to 20 are even simpler as linkages are functions of their own current components, hence each equation only contains one current component corresponding to the voltage component, and the common impedance function is $z_0(p) = r + x_0 p$.

The reverse transformations from the "2-reaction" components to the phase quantities are as follows:

$$f_A = f_d \cos\theta - f_q \sin\theta + f_{u(1)} + 0 + \ldots + f_w$$

$$f_B = f_d \cos(\theta - \theta_0) - f_q \sin(\theta - \theta_0) + f_{u(1)} \cos 2\theta_0 + f_{v(1)} \sin 2\theta_0 + \ldots - f_w$$

$$f_C = f_d \cos(\theta - 2\theta_0) - f_q \sin(\theta - 2\theta_0) + f_{u(1)} \cos 4\theta_0 + f_{v(1)} \sin 4\theta_0 + \ldots + f_w$$

$$\cdots\cdots\cdots\cdots$$

$$f_N = f_d \cos(\theta + \theta_0) - f_q \sin(\theta + \theta_0) + f_{u(1)} \cos 2\theta_0 - f_{v(1)} \sin 2\theta_0 \quad (21)$$

## Appendix I. Armature Flux Linkages

The machine will be assumed to be "ideal" as defined by Park.[11] The no-load per-unit space fundamental flux density at the armature surface will be (see figure 1)

$$\beta_0 = I_d \cos\Gamma + I_q \sin\Gamma \quad (1)$$

where

$\Gamma$ = angle along the armature surface measured in electrical radians from the rotor axis

$I_d$ = per-unit rotor excitation or rotor current in direct axis

$I_q$ = per-unit rotor excitation or rotor current in quadrature axis magnetizing ahead of the poles

The per-unit magnetomotive force due to armature phase currents $i_A, i_B, i_C \ldots i_N$ will be

$$A = -\frac{2}{n}\,[i_A \cos(\Gamma+\theta) + i_B \cos(\Gamma+\theta-\theta_0) + i_C \cos(\Gamma+\theta-2\theta_0) + \ldots + i_N \cos(\Gamma+\theta+\theta_0)]$$

$$= -\frac{2}{n}\cos\Gamma\,[i_A\cos\theta + i_B\cos(\theta-\theta_0) + i_C\cos(\theta-2\theta_0) + \ldots + i_N\cos(\theta+\theta_0)] + \frac{2}{n}\sin\Gamma\,[i_A\sin\theta + i_B\sin(\theta-\theta_0) + i_C\sin(\theta-2\theta_0) \times + \ldots + i_N\sin(\theta+\theta_0)] \quad (2)$$

where $\theta$ is the position of rotor axis measured from the axis of phase $A$, $\theta_0 = 2\pi/n$, $n$ = number of phases.

As the armature linkages for all space harmonics are assumed to be zero for the ideal machine, we have for the wave of per-unit flux,

$$\beta = I_d \cos\Gamma + I_q \sin\Gamma - \frac{2}{n} p_d \cos\Gamma\,[i_A\cos\theta + i_B\cos(\theta-\theta_0) + i_C\cos(\theta-2\theta_0) + \ldots + i_N\cos(\theta+\theta_0)] + \frac{2}{n} p_q \sin\Gamma\,[i_A\sin\theta + i_B\sin(\theta-\theta_0) + i_C\sin(\theta-2\theta_0) + \ldots + i_N\cos(\theta+\theta_0)] \quad (3)$$

The per-unit linkages in phase $A$ due to the flux are equal to the value of $\beta$ at $\gamma = \Gamma + \theta = 0$ or $\Gamma = -\theta$, i.e.,

$$\psi_{A(\beta)} = I_d\cos\theta - I_q\sin\theta - \frac{p_d+p_q}{n}\,[i_A + i_B\cos\theta_0 + i_C\cos 2\theta_0 + \ldots i_N\cos\theta_0] - \frac{p_d-p_q}{n}[i_A\cos 2\theta + i_B\cos(2\theta-\theta_0) + i_C\cos(2\theta-2\theta_0) + \ldots + i_N\cos(2\theta+\theta_0)] \quad (4)$$

The total per-unit linkages in phase $A$ are then

$$\psi_A = I_d\cos\theta - I_q\sin\theta - x_{l\sigma} i_A - x_m'\,[i_B\cos\theta_0 + i_C\cos 2\theta_0 + \ldots + i_N\cos\theta_0] - \frac{p_d+p_q}{n}\,[i_A + i_B\cos\theta_0 + i_C\cos 2\theta_0 + \ldots + i_N\cos\theta_0] - \frac{p_d-p_q}{n}\,[i_A\cos 2\theta + i_B\cos(2\theta-\theta_0) + i_C\cos(2\theta-2\theta_0) \times + \ldots + i_N\cos(2\theta+\theta_0)] \quad (5)$$

where

$x_{l\sigma}$ = per-unit self leakage reactance of any phase

$x_m'$ = maximum possible value of per-unit mutual leakage reactance between the phases. When $n$ is even, this is equal to the actual value between diametrically opposite phases. For 3-phase case, this is equal to twice the actual value between any 2 phases

Under balanced conditions of operation with normal armature current flowing, there is

$$i_A = \cos t$$
$$i_B = \cos (t - \theta_0)$$
$$i_C = \cos (t - 2\theta_0)$$
$$\cdots\cdots$$
$$i_N = \cos (t + \theta_0)$$
$$\theta = t + t_0$$

where $t_0$ = the value of $\theta$ at $t = 0$.
Then, for $I_d = I_q = 0$ there is

$$\psi_A = -\left[x_{l\sigma} + x_m'\left(\frac{n}{2} - 1\right) + \frac{p_d + p_q}{2}\right]\cos t - \left[\frac{p_d - p_q}{2}\right]\cos (t + 2t_0) \quad (6)$$

When $t_0 = 0$ there is

$$\psi_A = -(x_{l\sigma} + x_m + p_d)\cos t = -x_d \cos t \quad (7)$$

where

$$x_m = x_m'\left(\frac{n}{2} - 1\right)$$

$x_d$ = direct synchronous reactance[11,12]

When $t_0 = \pi/2$ there is

$$\psi_A = -(x_{l\sigma} + x_m + p_q)\cos t = -x_q \cos t \quad (8)$$

where $x_q$ = quadrature synchronous reactance
With zero phase-sequence currents impressed there is

$$i_A = i_B = i_C \ldots = i_N$$
$$\psi_A = -(x_{l\sigma} - x_m')i_A = -x_0 i_A \quad (9)$$

where $x_0$ = zero-sequence reactance
Thus we have obtained the following relations:

$$x_{l\sigma} + x_m + p_d = x_d$$
$$x_{l\sigma} + x_m + p_q = x_q$$
$$x_{l\sigma} - x_m' = x_0$$
$$p_d - p_q = x_d - x_q$$
$$p_d + p_q + 2(x_{l\sigma} + x_m) = x_d + x_q$$

Equation 5 can now be rewritten in the form

$$\psi_A = I_d \cos\theta - I_q \sin\theta - x_0 i_A - \left[\left(\frac{x_d + x_q}{2}\right) - x_0\right] \times \left(\frac{2}{n}\right)[i_A + i_B \cos\theta_0 + i_C \cos 2\theta_0 + \ldots + i_N \cos\theta_0] - \left(\frac{x_d - x_q}{2}\right)\left(\frac{2}{n}\right)[i_A \cos 2\theta + i_B \cos (2\theta - \theta_0) + i_C \cos (2\theta - 2\theta_0) + \ldots + i_N \cos (2\theta + \theta_0)] \quad (10)$$

Similarly we can write down the equations for the other phases.

## Appendix II. Transformation of Variables

The transformations between the phase quantities and the 2-reaction components will be given in the form of matrices as below:

$C_d{}^A =$

| | $A$ | $B$ | $C$ | $D$ | ..... | $N$ |
|---|---|---|---|---|---|---|
| 0 | $\frac{1}{n}$ | $\frac{1}{n}$ | $\frac{1}{n}$ | $\frac{1}{n}$ | ..... | $\frac{1}{n}$ |
| $d$ | $\frac{2}{n}\cos\theta$ | $\frac{2}{n}\cos(\theta - \theta_0)$ | $\frac{2}{n}\cos(\theta - 2\theta_0)$ | $\frac{2}{n}\cos(\theta - 3\theta_0)$ | ..... | $\frac{2}{n}\cos(\theta + \theta_0)$ |
| $q$ | $(-)\frac{2}{n}\sin\theta$ | $(-)\frac{2}{n}\sin(\theta - \theta_0)$ | $(-)\frac{2}{n}\sin(\theta - 2\theta_0)$ | $(-)\frac{2}{n}\sin(\theta - 3\theta_0)$ | ..... | $(-)\frac{2}{n}\sin(\theta + \theta_0)$ |
| $u_1$ | $\frac{2}{n}$ | $\frac{2}{n}\cos 2\theta_0$ | $\frac{2}{n}\cos 4\theta_0$ | $\frac{2}{n}\cos 6\theta_0$ | ..... | $\frac{2}{n}\cos 2\theta_0$ |
| $v_1$ | 0 | $\frac{2}{n}\sin 2\theta_0$ | $\frac{2}{n}\sin 4\theta_0$ | $\frac{2}{n}\sin 6\theta_0$ | ..... | $(-)\frac{2}{n}\sin 2\theta_0$ |
| : | : | : | : | : | ..... | ..... |
| : | : | : | : | : | ..... | ..... |
| $w$ | $\frac{1}{n}$ | $-\frac{1}{n}$ | $\frac{1}{n}$ | $-\frac{1}{n}$ | ..... | ..... |

For example, from the first row, we have $i_0 = \frac{1}{n}(i_A + i_B + i_C + i_D + \ldots + i_N)$

$C_A{}^d =$

| | 0 | $d$ | $q$ | $u_1$ | $v_1$ | ..... | $w$ |
|---|---|---|---|---|---|---|---|
| $A$ | 1 | $\cos\theta$ | $-\sin\theta$ | 1 | 0 | .... | 1 |
| $B$ | 1 | $\cos(\theta - \theta_0)$ | $-\sin(\theta - \theta_0)$ | $\cos 2\theta_0$ | $\sin 2\theta_0$ | ..... | $-1$ |
| $C$ | 1 | $\cos(\theta - 2\theta_0)$ | $-\sin(\theta - 2\theta_0)$ | $\cos 4\theta_0$ | $\sin 4\theta_0$ | ..... | 1 |
| $D$ | 1 | $\cos(\theta - 3\theta_0)$ | $-\sin(\theta - 3\theta_0)$ | $\cos 6\theta_0$ | $\sin 6\theta_0$ | ..... | $-1$ |
| : | : | : | : | : | : | ..... | ... |
| : | : | : | : | : | : | ..... | ... |
| $N$ | 1 | $\cos(\theta + \theta_0)$ | $-\sin(\theta + \theta_0)$ | $\cos 2\theta_0$ | $-\sin 2\theta_0$ | ..... | ... |

For $n$ odd, row $w$ or column $w$ should be omitted.
As a check, we have

$$C_A{}^d C_d{}^A = 1$$

The foregoing transformations may be derived in another way as follows:

According to the method of symmetrical components, we have

$C_1^A =$

| | $A$ | $B$ | $C$ | $D$ | ... | $N$ |
|---|---|---|---|---|---|---|
| 0 | $\frac{1}{n}$ | $\frac{1}{n}$ | $\frac{1}{n}$ | $\frac{1}{n}$ | ... | $\frac{1}{n}$ |
| 1 | $\frac{1}{n}$ | $\frac{a}{n}$ | $\frac{a^2}{n}$ | $\frac{a^3}{n}$ | ... | $\frac{a^{-1}}{n}$ |
| 2 | $\frac{1}{n}$ | $\frac{a^2}{n}$ | $\frac{a^4}{n}$ | $\frac{a^6}{n}$ | ... | $\frac{a^{-2}}{n}$ |
| ⋮ | ⋮ | ⋮ | ⋮ | ⋮ | ... | ... |
| $\frac{n}{2}$ | $\frac{1}{n}$ | $-\frac{1}{n}$ | $\frac{1}{n}$ | $-\frac{1}{n}$ | ... | ... |
| ⋮ | ⋮ | ⋮ | ⋮ | ⋮ | ... | ... |
| $n-2$ | $\frac{1}{n}$ | $\frac{a^{-2}}{n}$ | $\frac{a^{-4}}{n}$ | $\frac{a^{-6}}{n}$ | ... | $\frac{a^2}{n}$ |
| $n-1$ | $\frac{1}{n}$ | $\frac{a^{-1}}{n}$ | $\frac{a^{-2}}{n}$ | $\frac{a^{-3}}{n}$ | ... | $\frac{a}{n}$ |

$a = e^{j\theta_0}$ where $\theta_0 = \frac{2\pi}{n}$

For $n$ odd, row $n/2$ should be omitted.
The reverse transformation is

$C_A^1 =$

| | 0 | 1 | 2 | ... | $\frac{n}{2}$ | ... | $n-2$ | $n-1$ |
|---|---|---|---|---|---|---|---|---|
| $A$ | 1 | 1 | 1 | ... | 1 | ... | 1 | 1 |
| $B$ | 1 | $a^{-1}$ | $a^{-2}$ | ... | $-1$ | ... | $a^2$ | $a$ |
| $C$ | 1 | $a^{-2}$ | $a^{-4}$ | ... | 1 | ... | $a^4$ | $a^2$ |
| $D$ | 1 | $a^{-3}$ | $a^{-6}$ | ... | $-1$ | ... | $a^6$ | $a^3$ |
| : | : | : | : | : | : | : | : | : |
| : | : | : | : | : | : | : | : | : |
| $N$ | 1 | $a$ | $a^2$ | ... | ... | ... | $a^{-2}$ | $a^{-1}$ |

For $n$ odd, column $n/2$ should be omitted.

The correlation between the symmetrical components and the 2-reaction components are as follows:[9,10]

$C_d^1 =$

| | 0 | 1 | 2 | .... | $\frac{n}{2}$ | .... | $n-2$ | $n-1$ |
|---|---|---|---|---|---|---|---|---|
| 0 | 1 | | | | | | | |
| $d$ | | $\epsilon^{-j\theta}$ | | | | | | $\epsilon^{j\theta}$ |
| $q$ | | $-j\epsilon^{-j\theta}$ | | | | | | $j\epsilon^{j\theta}$ |
| $u_1$ | | | 1 | | | | 1 | |
| $v_1$ | | | $-j$ | | | | $j$ | |
| ⋮ | | | | ⋮ | | ⋮ | | |
| $w$ | | | | | 1 | | | |

All the empty spaces should be indicated by 0. For $n$ odd, column $n/2$ and row $w$ should be omitted.

$C_1^d =$

| | 0 | $d$ | $q$ | $u_1$ | $v_1$ | ..... | $w$ |
|---|---|---|---|---|---|---|---|
| 0 | 1 | | | | | | |
| 1 | | $\frac{1}{2}\epsilon^{j\theta}$ | $j\frac{1}{2}\epsilon^{j\theta}$ | | | | |
| 2 | | | | $\frac{1}{2}$ | $j\frac{1}{2}$ | | |
| ⋮ | | | | | | ... | |
| $\frac{n}{2}$ | | | | | | | 1 |
| ⋮ | | | | | | ... | |
| $n-2$ | | | | $\frac{1}{2}$ | $-j\frac{1}{2}$ | | |
| $n-1$ | | $\frac{1}{2}\epsilon^{-j\theta}$ | $-j\frac{1}{2}\epsilon^{-j\theta}$ | | | | |

All the empty spaces should be indicated by 0. For $n$ odd, column $w$ and row $n/2$ should be omitted.

Then we can get $C_A^d$ and $C_d^A$ from the relations:

$$C_A^d = C_A^1 C_1^d$$
$$C_d^A = C_d^1 C_1^A$$

Notice that $C_1^d$ and $C_d^1$ are of very simple form, and, since $C_A^1$ and $C_1^A$ are well known from the method of symmetrical components, $C_A^d$ and $C_d^A$ can be written down very simply without going through the details of matrix algebra.

## Appendix III. Derivation of 2-Reaction Flux Linkages

Substituting equation 2 into equations 3 and 4, we can derive the expressions for $\psi_d$ and $\psi_q$ as follows:
Consider $\psi_d$ first. From equation 3, we have

$$\psi_d = \frac{2}{n}[\psi_A \cos\theta + \psi_B \cos(\theta - \theta_0) + \psi_C \cos \times (\theta - 2\theta_0) + \ldots + \psi_N \cos\theta - (n-1)\theta_0]$$

Let us examine the different components of the phase flux linkages separately. The first component is $I_d \cos\theta$. Hence

$$\psi_{d(1)} = \frac{2}{n} I_d[\cos\theta\cos\theta + \cos(\theta - \theta_0)\cos(\theta - \theta_0) + \cos(\theta - 2\theta_0)\cos(\theta - 2\theta_0) + \ldots] = I_d$$

Similarly, for the second component $-I_q \sin\theta$, we get

$$\psi_{d(2)} = -\frac{2}{n} I_q [\sin\theta\cos\theta + \sin(\theta - \theta_0)\cos(\theta - \theta_0) + \sin(\theta - 2\theta_0)\cos(\theta - 2\theta_0) + \ldots] = 0$$

For the third component, $-x_0 i_A$, we have

$$\psi_{d(3)} = -\frac{2}{n} x_0 [i_A \cos\theta + i_B \cos(\theta - \theta_0) + i_C \cos(\theta - 2\theta_0) + \ldots]$$
$$= -x_0 i_d$$

The fourth component is as follows:

$$\psi_{d(4)} = \frac{2}{n}\left[x_0 - \left(\frac{x_d + x_q}{2}\right)\right]\left(\frac{2}{n}\right)[\{i_A + i_B\cos\theta_0 + i_C\cos 2\theta_0 + \ldots\}\cos\theta + \{i_A\cos\theta_0 + i_B + i_C\cos\theta_0 + \ldots\}\cos(\theta - \theta_0) + \{i_A\cos 2\theta_0 + i_B\cos\theta_0 + i_C + \ldots\}\cos(\theta - 2\theta_0) + \ldots]$$

Now we may combine the terms into the following groups:

$$\left(\frac{2}{n}\right)[i_A\cos\theta + i_A\cos\theta_0\cos(\theta - \theta_0) + i_A\cos 2\theta_0\cos(\theta - 2\theta_0) + \ldots] = i_A\cos\theta$$

$$\left(\frac{2}{n}\right)[i_B\cos(\theta - \theta_0) + i_B\cos\theta_0\cos(\theta - 2\theta_0) + \ldots + i_B\cos\theta_0\cos\theta] = i_B\cos(\theta - \theta_0)$$

So we get

$$\psi_{d(4)} = \frac{2}{n}\left[x_0 - \left(\frac{x_d + x_q}{2}\right)\right][i_A\cos\theta + i_B\cos(\theta - \theta_0) + i_C\cos(\theta - 2\theta_0) + \ldots]$$
$$= x_0 i_d - \left(\frac{x_d + x_q}{2}\right) i_d$$

For the fifth component, we have

$$\psi_{d(5)} = -\frac{2}{n}\left(\frac{x_d - x_q}{2}\right)\left(\frac{2}{n}\right)[\{i_A\cos 2\theta\, i_B\cos(2\theta - \theta_0) + i_C\cos(2\theta - 2\theta_0) + \ldots\}\cos\theta \{i_A\cos(2\theta - \theta_0) + i_B\cos(2\theta - 2\theta_0) + i_C\cos(2\theta - 3\theta_0) + \ldots + \ldots\}\cos(\theta - \theta_0) \{i_A\cos(2\theta - 2\theta_0) + i_B\cos(2\theta - 3\theta_0) + i_C\cos(2\theta - 4\theta_0) + \ldots\}\cos(\theta - 2\theta_0) + \ldots]$$

Grouping the terms together, there is

$$\left(\frac{2}{n}\right)[i_A\cos 2\theta\cos\theta + i_A\cos(2\theta-\theta_0)\cos(\theta-\theta_0) + i_A\cos(2\theta-2\theta_0)\cos(\theta-2\theta_0)+\ldots] = i_A\cos\theta$$

$$\left(\frac{2}{n}\right)[i_B\cos(2\theta-2\theta_0)\cos(\theta-\theta_0) + i_B\cos(2\theta-3\theta_0)\times\cos(\theta-2\theta_0)+\ldots+i_B\cos(2\theta-\theta_0)\cos\theta] = i_B\cos(\theta-\theta_0)$$

So we have

$$\psi_{d(5)} = -\frac{2}{n}\left(\frac{x_d-x_q}{2}\right)[i_A\cos\theta + i_B\cos(\theta-\theta_0) + i_C\cos(\theta-2\theta_0)+\ldots] = -\left(\frac{x_d-x_q}{2}\right)i_d$$

The sum of 5 components gives

$$\psi_d = I_d - x_d i_d$$

For the quadrature flux linkages, we can derive the expression in a similar manner. The different components will be

$$\psi_{q(1)} = -\frac{2}{n}I_d[\cos\theta\sin\theta + \cos(\theta-\theta_0)\sin(\theta-\theta_0)+\ldots] = 0$$

$$\psi_{q(2)} = \frac{2}{n}I_q[\sin^2\theta + \sin^2(\theta-\theta_0)+\ldots] = I_q$$

$$\psi_{q(3)} = \frac{2}{n}x_0[i_A\sin\theta + i_B\sin(\theta-\theta_0)+\ldots] = -x_0 i_q$$

$$\psi_{q(4)} = -\frac{2}{n}\left[x_0-\left(\frac{x_d+x_q}{2}\right)\right][i_A\sin\theta + i_B\sin(\theta-\theta_0)+\ldots] = x_0 i_q - \left(\frac{x_d+x_q}{2}\right)i_q$$

$$\psi_{q(5)} = -\frac{2}{n}\left(\frac{x_d-x_q}{2}\right)[i_A\sin\theta + i_B\sin(\theta-\theta_0)+\ldots] = \left(\frac{x_d-x_q}{2}\right)i_q$$

The sum of the above 5 components will then give

$$\psi_q = I_q - x_q i_q$$

# Fuels of Tomorrow

FUELS of today and tomorrow were discussed by A. C. Fieldner, retiring president, American Society for Testing Materials, in his presidential address at the annual meeting of the society held in New York, N. Y., June 28–July 2, 1937. Doctor Fieldner first covered fuels of today, including such topics as the search for oil, developments in refining petroleum, displacement of coal by fuel oil, rise of natural gas, and coal production and utilization. After discussing fuels of today and outlining national fuel reserves, he discussed fuels of tomorrow, indicating that gas, oil, and coal are available today in abundance. There is coal enough for hundreds, and possibly thousands of years; but natural gas and oil obtainable by present methods may be exhausted in less than 100 years, and a shortage of our domestic supply may begin within 10 or 20 years.

He indicated that coal will continue to be the principal fuel used for the generation of public utility and major industrial power. Technologic improvements and new hydroelectric power will tend to reduce the consumption of coal; on the other hand, an increasing demand for energy and a decreasing supply of cheap residual oil will increase the amount of coal consumed for power purposes. No material change is expected in either direction in the near future, but in 10 or 15 years the trend will favor increased consumption of coal. Tomorrow's power and central heating plant will burn any kind of coal completely and efficiently.

The convenience and uniformity of automatic heating of homes with gas or oil will continue to attract more users, even at higher costs than those prevailing today. The insulation of houses has been improved greatly, and future homes will permit higher unit cost of fuel without increasing the total heating bill.

Referring to railroad and marine fuels he indicated that further improvements in the over-all efficiency of the steam locomotive and a gradual increase of electrification will retain the use of coal for freight traffic throughout the age of oil and natural gas, and that the convenience and economy of Diesel-engine drive for ships and boats is such that its use will continue even after declining production of petroleum requires the production of Diesel fuel from shale or coal.

In discussing the motor fuel supply, one of the most interesting questions, he pointed to the prediction of Snider and Brooks that by 1945 there is the probability of considerable shortage of domestic petroleum. Doctor Fieldner said that from the very beginning of the automobile industry, recurring threats of shortage of gasoline were met—in the field by finding new pools and improving production technique, and in the refinery by increasing yields and making a more efficient product. "The end has not been reached. We are just beginning to use scientific methods in extracting oil from the sands, and catalytic polymerization and hydrogenation eventually will furnish the means for complete conversion of volatile liquids and heavy petroleum to gasoline."

# Discussions

## Of AIEE Papers—as Recommended for Publication by Technical Committees

ON THIS and the following 2 pages appear all remaining discussions submitted for publication, and approved by the technical committees, on papers presented at the 1937 AIEE winter convention, New York, N. Y., January 25–29. Discussions of papers presented at the sessions on general power applications, vibration and balance, communication and research, power transmission, education, power generation and electrical machinery, instruments and measurements, insulation co-ordination, and lightning protective equipment at the 1937 AIEE summer convention, Milwaukee, Wis., June 21–25, now are being reviewed by the technical committees, and will appear in ELECTRICAL ENGINEERING as they are released for publication.

Members anywhere are encouraged to submit written discussion of any paper published in ELECTRICAL ENGINEERING, which discussion will be reviewed by the proper technical committee and considered for possible publication in a subsequent issue. Discussions of papers scheduled for presentation at any AIEE meeting or convention are closed 2 weeks after presentation.

## Watt-Hour Meter Bearings

**Discussion and authors' closure of a paper by I. F. Kinnard and J. H. Goss published in the January 1937 issue, pages 129–37, and presented for oral discussion at the instruments and measurements session of the winter convention, New York, N. Y., January 28, 1937.**

**F. C. Holtz** (Sangamo Electric Company, Springfield, Ill.): To me, there are few subjects which offer greater possibilities for scientific adventure and speculation than the study of watt-hour meter bearings. No branch of physics or chemistry seems able to escape being involved in this problem in at least one form or another. It offers a challenge to the best we have in modern scientific technique, in the fine structure and architecture of solids and it plays with stresses seldom considered in modern machinery. Any familiarity with the problem reveals that the great mass of knowledge is still to be gained from carefully planned investigation.

One cannot help but be impressed by the long list of references which is only one indication of the great commercial importance attached to the problem and the desire to further improve what for a time seemed incapable of improvement. Beginning with the work of Shotter and others, it was quite evident that practical improvement lay in the direction of materials rather than of form and the present work is without question a valuable and important contribution.

I trust, in commenting on the present paper, it will not be out of order to draw on the experience of others and to relate certain conclusions which we are able to draw from our own observations.

The success of any bearing system must be judged from the results obtained in the field under all possible conditions of installation and use.

Because of the wide variation in these conditions the application of statistical methods are very helpful in determining the success of any particular arrangement and from this point of view we, as manufacturers, are very grateful for the friendly co-operation and assistance which we received from the public utilities in the form of data on the many millions of meters scattered throughout the country. All experimental data should be examined in its relation to the practical aspects of the problem.

The present paper is for the most part a record of laboratory experiment and from that standpoint is extremely interesting and satisfying to the user of meters in pointing out the care and consideration which is given to the problem before a commercial arrangement is arrived at.

Figure 2 is extremely interesting in showing how the friction varies with pivot radius; however, it should be pointed out that it is also a function of the jewel radius. Strictly speaking, it is probably a function of the order of contact between the 2 surfaces and from this point of view it would be interesting to know how this friction varies as the jewel radius approaches that of the pivot. The values indicated by the authors are very close to what might be considered an average throughout the industry. They are somewhat smaller than the values chosen a few years ago due to the lighter weight moving systems, higher expected values of overload, which together with higher torque gives a greater tendency for the pivot to ride on top of the jewel. While other means are provided to prevent it, the deeper and smaller radius cup is the ideal arrangement.

While the curve of figure 3 is extremely interesting, it is to be noted that in watt-hour meter practice meter pivots are seldom worn at the point. This, as is well known, is due to the fact that both driving and damping torques act to force the pivot up the side of the meter jewel until the forces are balanced, leaving the point of contact at some suitable distance from the axis of the pivot. At light load this is near the stationary position, but in this case the speed of rotation is small, hence no great amount of wear is to be expected. In some respects this is fortunate for if wear results at the higher loads the corresponding friction does not appreciably alter the meter registration; yet during periods of light load the pivot returns to put into contact areas which are little affected and which again has little effect on the initial accuracy. I should like at this time to refer to the curves of figure 7 which, in the light of past experience seems to be an anomalous behavior of materials. It is generally agreed that the pivot-and-cup type of bearing is improved by oiling and that its life is correspondingly increased. The work of Stott, Shotter, and others points very clearly to this conclusion and I am sure that it has been thoroughly supported by field observation. It certainly must be true for a great variety of materials, if not all. Why, then, does the oiled cobalt-tungsten pivot wear as rapidly as dry steel in the beginning and then slow down to that of dry cobalt tungsten at 10,000,000 revolutions, and then less with advancing revolutions?

It would be interesting also to know something of the performance of the oiled steel pivot drawn to the same scale for comparative purposes.

Figure 7 is apt to give the impression that a pivot begins to wear the instant it begins rotation. This may be true of some alloys and even steel in the dry state, but it is not necessarily true of an oiled steel pivot. I have tried to form an opinion based on the great mass of evidence supplied by the operating companies. There is ample evidence in support of the contention that wear begins with some unfortunate accident to the bearing system, the nature of which is, as yet, not fully understood. We know, for example, that some pivots will apparently operate for millions of revolutions without showing more than a trace of wear and then without warning increase rapidly at a fairly uniform rate somewhat as shown in figure 7. It is as if Mr. Kinnard's curves did not all start in the same place but chose to distribute themselves out along the axis of revolutions in some quite arbitrary manner. This type of action is hinted at in Shotter's paper, but so far as I know it has not been recorded in the form of a curve. If this were not true, we could readily predict the exact number of revolutions which a meter should make before changing bearings. I believe that I have the support of the meter man in the above statement based on a systematic and careful examination of meter pivots removed at the time of periodic test. It would be extremely interesting to carefully measure the radius of worn areas on a relatively large number (say 1,000) of meter pivots and plot these results in terms of meter revolutions. This will require that the work be followed in a territory where conditions are fairly uniform both as to loads, methods of handling, etc.

The impact tests are extremely interest-

ing in pointing out the manner in which jewels and pivots may be damaged by short circuit conditions. We conducted tests some years ago to determine the relative susceptibility of jewels of various types and orientation to damage by impact. To eliminate certain types of errors and render the results more uniform and dependable, the arrangement provided for applying the impact at the center and thinnest section of the jewel. To do this the jewel was mounted on a relatively massive iron anvil. A small steel ball was placed in the jewel which combination then received the impact from a small hardened steel cylinder dropped through a small tube from varying heights. In this case the impacts were repeated on the same jewel from varying heights until microscopic examination revealed that the jewel had been damaged.

The results show clearly that to obtain consistent results considerable care is necessary in properly mounting the jewel and that the results are influenced by the nature of the back surface of the jewel.

The subject of pivot materials is in itself a most interesting one, and I should like to discuss it according to the 6 qualities laid down by the present authors:

1. *Noncorrosive.* The question of corrosion resistance is, so I am told, tied up with 2 different properties of the metal or alloy. The first assumes that the metals are relatively inert as to forming chemical combinations with the compounds with which they may be in contact. Gold, platinum, osmium, tungsten, and other noble metals belong to this group. They achieve their corrosion resistances through their extreme stability and refusal to readily form compounds.

The second group are those which are relatively active, chemically, and readily form oxide layers over their surfaces which in themselves are chemically inactive. Aluminum and stainless steels belong to this class.

It should be quite obvious that materials of the second class should not be considered acceptable for meter pivots since the abrasive action of the jewel and pivot in contact will remove this oxide covering and expose the under layer to further corrosion. This explains why, under certain conditions a stainless steel pivot will show considerable quantities of red iron oxide after having operated dry in a meter bearing. All such oxides are invariably hard, brittle, and therefore quite abrasive.

2. *Nonabrasive.* A careful examination of the abraded material also raises an interesting question: Are the products of abrasion dependent upon the abrasive qualities of the constituent alloys or do the oxides of such alloys have qualities which are independent of them?

If they depend upon the individual constituents, it would be an easy matter to say which metals should and which should not form a satisfactory combination for a meter pivot. The problem is not so simple for the abrasive qualities of the material removed frequently does not resemble any of its constituents. The former is, nevertheless, a safe guide to follow. Oxides of tungsten and cobalt are each relatively mild abrasives and so far as we know the oxide of the alloy is also. Shotter, in his paper, comments very favorably on tungsten which has been verified by further test, but it requires very careful preparation.

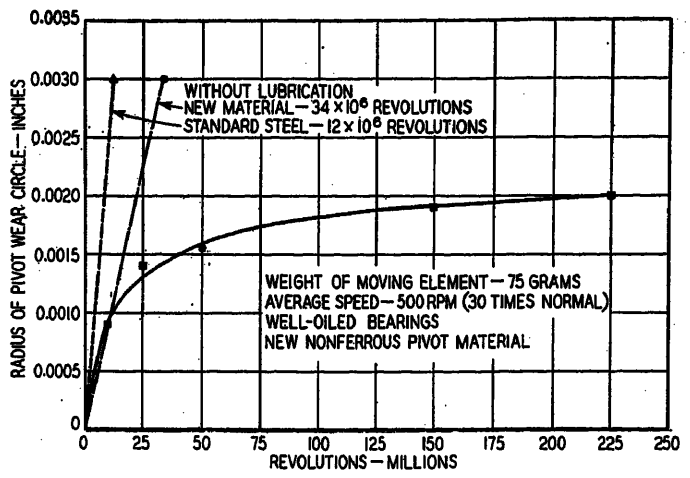
3. *Shock Resistance.* There are some extremely interesting things about the alloys suitable for pivot materials. In addition to the corrosion resistance already referred to, there is the property of hardness.

I am inclined to feel from numerous tests that extreme hardness is essential to abrasion resistance. This follows from a consideration of diamond and sapphire as jewel materials and it is equally true in pivot materials. It may, however, be possible for a pivot material to be so hard as to resist wear, and when used against sapphire, wear the latter.

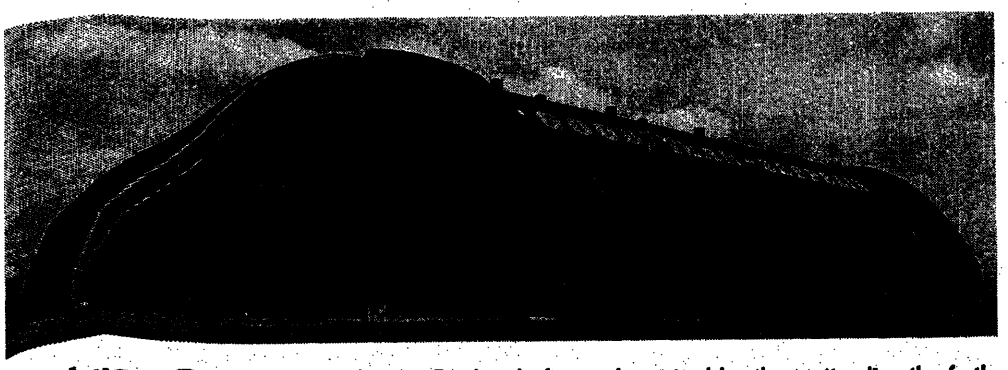
In most cases the reverse is true, but in some cases such as in alloys containing comparatively large percentages of iridium the pivot will actually cut the jewel, especially when run dry.

Frequently the presence of minute inclusions of foreign matter in the pivot material may damage the jewel. It is extremely necessary, therefore, to watch alloys for the appearance of minute inclusions in any series of experiments to determine a suitable material.

The present paper refers to cobalt-tungsten alloy as being softer than steel. In one sense this is true and in another it is not. Cobalt-tungsten alloy as with other alloys, especially precipitation hardening alloys, comprises a series of hard crystals in a matrix of softer material. For this reason the material is soft from the standpoint of deformation and hard from the standpoint of wear. This property of the structure is shown when determining superficial hardness. A perfectly conical diamond penetrator will frequently leave a triangular shaped depression showing that the hard crystals are moved about as a body in a matrix of softer material.



No comment will be made on the last 2 properties; namely, low friction and workability, since this in itself involves a consideration of many materials. I should, however, remark that certain alloys of osmium, rhodium, and platinum show great promise as pivot materials and it is hoped that the cost can be brought within permissible figures.



In pointing to the possibility of operating the cobalt-tungsten pivot without oil, no mention is made of the relative friction in each case and the variation in friction over long periods of operation. It would be interesting to know something of this.

4. *Lubrication.* With the rapidly growing tendency toward outdoor meter installations, the matter of lubrication is extremely important and the qualities outlined by the authors is an excellent guide in the selection of a suitable lubricant. In general the mineral oils have a somewhat greater tendency to creep but this can be reduced by suitably applying to the surfaces a mixture known to the watchmaking industry as "epilame." Its essential ingredients are steric acid in toluene, and when applied its thickness is of molecular dimensions.

In addition to chemical tests, certain simple mechanical tests are extremely useful in detecting any undesirable qualities. A small quantity of the oil is placed in a hemispherical cup which is alternately rotated and stopped in the presence of warm

**Figure 7. Accelerated life test wear curves**

The huge Goodyear Zeppelin Air Dock, which may be visited by those attending the forthcoming AIEE Middle Eastern District meeting to be held at Akron, Ohio

air or oxygen. Centrifugal action drives the oil over the surface in a thin layer and then allows it to settle to the bottom. This test will quickly reveal any tendency toward gumming and frequently reveals conditions which cannot be detected by chemical tests. It corresponds to an accelerated service test and is therefore of considerable value.

**I. F. Kinnard and J. H. Goss:** The discussion of the paper, especially by Mr. S. Green, Mr. F. C. Holtz, and Professor M. W. Pullen has brought out much information of interest to users and designers of watt-hour meters. Some of the points raised require further discussion by the authors.

Mr. F. C. Holtz has referred to the effect of the radius of the jewel cup on the value of friction torque between the pivot or ball and the jewel cup. Mr. V. Stott (reference 2 of the bibliography) has shown by a mathematical analysis that a negligibly small error is introduced if the radius of the jewel cup is assumed to be infinite over the small area of contact of a new bearing within the range of radii for pivots, balls, and jewels which are used commercially.

Figure 7, which Mr. Holtz questions, was plotted in error and the authors are pleased to include in this discussion a corrected figure. It will be noted that the oiled cobalt-tungsten bearing follows almost exactly the same wear curve as the dry for the first few million revolutions. A possible explanation for this behavior is that due to the extremely high bearing pressures during this period, little or no lubrication is present under the contact area. As the bearing wears, the pressure drops until the oil film is eventually able to support the load.

There is no question but that many bearings have been operated for long periods without showing appreciable wear. The phenomena of just what initiates wear is difficult to understand. It has been the aim of the authors to present data to permit a logical explanation of the major factors that influence watthour meter bearing life. At this time it appears to be impossible to fully explain every case.

Mr. Holtz suggests it would have been worth while to publish the wear curve for a well oiled steel pivot along with the curve of cobalt-tungsten shown in figure 7. Such a curve was published in a previous article (reference 1 of the bibliography) and for that reason was omitted.

Professor Pullen brings up the point of preforming the radius of the pivot contact area to match the jewel. There has been no change in pivot manufacturing methods to allow the exact matching of the pivot and jewel radius.

The radius of a pivot can be quite accurately ground while somewhat greater variations are found in sapphire jewel cups.

The hardness of boron carbide, figure 5, was plotted in error and should be 19.7 instead of 29.

Figure 10 showing the oxidation of oils should show a total range of acidity of 1.0 per cent instead of 10 per cent. The ordinates should be tenths of a per cent, the decimal points being omitted.

The authors wish to express their appreciation for the favorable discussion of their paper by Doctor H. B. Brooks and by Mr. E. W. Allen.

# First Report of Power System Stability

**Closure of a report of the AIEE subcommittee on interconnection and stability factors published in the February 1937 issue, pages 261–82, and presented for oral discussion at the power transmission session of the winter convention, New York, N. Y., January 26, 1937. Previous discussions and closure appeared in the May 1937 issue, pages 632–4.**

**R. D. Evans:** Raymond Bailey, H. K. Sels, and Nicholas Stahl have called to our attention the fact that table III contains certain discrepancies as applied to the Pennsylvania-New Jersey interconnection. It is believed that these can best be clarified by republishing part of the table. The accompanying tabulation supersedes item I for the Pennsylvania Power & Light Company and the next 5 columns headed "Pennsylvania and New Jersey Interconnection."

Mr. Bailey has also pointed out certain errors in table III as applying to the Philadelphia Electric Company's system. Under item I for the Conowingo-Plymouth Meeting circuit, line *B*-5 should show "H.T." bus at both sending and receiving ends; and line *E*-2 should show:

Phase: High-speed differential induction impedance.

Ground: High-speed differential and high-speed overcurrent.

Under item II for the Plymouth Meeting-Westmoreland circuit, line *B*-5 should also show "H.T." bus at both sending and receiving ends; and under line *B*-2 should show:

Phase: Induction impedance.
Ground: High-speed directional overcurrent.

## Of Institute and Related Activities

# Middle Eastern District Meeting and Student Branch Convention

AKRON, OHIO, will be host to a 3-day meeting of the Middle Eastern District of the AIEE, October 13–15, 1937. The meeting headquarters will be in the Mayflower Hotel. The local committees have arranged an attractive technical program which consists of 6 sessions and a student session to be held during the mornings and have planned for the afternoons and evenings interesting inspection trips, entertainment, and a banquet. In addition, a special program has been arranged for the women, who are especially urged to attend the meeting.

Akron is called "The City of Opportunity." It is a prosperous, enterprising industrial community with a population of 255,000, ranking thirty-fifth in the United States as to population, but twelfth in the value of its manufactures. It is the world's largest rubber manufacturing center and the dirigible-airship-manufacturing center of the United States. The committee has taken full cognizance of these industries in the arrangement of inspection trips.

### Technical Program

A special effort has been made by the meetings and papers committee to arrange a technical program of a sufficiently diversified nature to offer general appeal to those in the electrical engineering profession. To accomplish this, parallel sessions will be held each morning, as shown in the program.

On Friday morning the student technical session will parallel the other 2 meetings. This session will be followed by a luncheon meeting in the Mayflower Hotel of Branch counselors and student chairmen. It is hoped that a minimum of conflict will occur on the part of those attending any particular series of sessions.

### Inspection Trips

Those attending the Middle Eastern District meeting will have an opportunity to see a representative cross section of the manufacturing and points of interest in Akron and vicinity. Transportation on all inspection trips by bus will be available at a nominal cost for those who desire it.

In addition to the scheduled inspection trips appearing on the program, a visit to the Goodyear Air Dock and the Goodyear Museum can be arranged for those interested by consulting a member of the registration committee in the hotel lobby.

Trips that are desired should be indicated at the time of registration at the meeting.

**Babcock & Wilcox Company**

The manufacturing operations of the Barberton plant to be seen will include the complete central station and industrial plant, high- and low-pressure steam boilers, pulverized coal equipment, economizers, air heaters, etc. To those interested in power plant equipment this trip offers an unusual opportunity to see the fabrication processes involved in a wide field of manufacture.

**B. F. Goodrich Company**

Those choosing this trip will see those manufacturing processes which characterize Akron as being "The Rubber City." Starting with the crude rubber as it is received from the native plantation, it will be followed through the various stages of cutting, plastication, mixing, milling, tubing, and curing to become a finished product in the form of a tire or tube.

**Nela Park**

An extensive tour has been arranged to be made through Nela Park, Cleveland, for those registered at the District meeting. The laboratory trip is scheduled to begin at 3:00 p.m. and will show the methods of development and manufacture of lamps. Following the tour through the laboratory there will be a discussion on lamp development and lighting research after which an inspection of the General Electric Lighting Institute will be made. Dinner will be given to guests at 6:30 and followed by an evening of popular entertainment.

Because of the many interesting displays of home applications this trip should be of equal interest to the ladies and has been arranged with this in mind.

**Ohio Brass Company**

An inspection of the Barberton plant of the Ohio Brass Company will be made starting from the main office building and will include inspection of the processes, production methods, and routine testing in the manufacture of high-voltage porcelain insulators for both station and line use. The plant inspection will be followed by a demonstration of normal-frequency and impulse tests on various insulator equipment. These tests will be made in the electrical testing laboratory.

**Daniel Guggenheim Airship Institute**

One of the main test stands of the Daniel Guggenheim Airship Institute is the vertical wind tunnel. It provides a uniform open air stream 6½ feet in diameter. Wind velocity can be regulated in small steps from zero to 125 miles per hour. This wind tunnel is driven by a 225-horsepower d-c motor and propeller-type fan, the electrical system being provided with various automatic and hand regulators and safety devices. This wind tunnel was built primarily for lighter-than-air testing, but is now being used also for airplane and various other industrial tests, for example, for testing the wind resistance of buildings and radio towers, the streamlining of trains, ventilating and cooling, etc. Some of the models used in such testing will be demonstrated.

The whirling arm is a unique apparatus, being the only one now in use in the United States for aeronautical testing. It is an arm 32 feet in length, turning at a height of 10 feet above the ground with

**Electrical testing laboratory of the Ohio Brass Company, Barberton, a few miles southwest of Akron. An inspection trip to this plant has been included on the program of the AIEE Middle Eastern District meeting to be held in Akron, October 13-15**

# Program

Eastern Standard Time

In this program, reference to the issue and, in so far as possible, to the page in ELECTRICAL ENGINEERING, is given for all papers.

## Wednesday, October 13

### 9:00 a.m.—Registration

### 9:45 a.m.—Opening of meeting

Address of Welcome: Lee D. Schroy, mayor of Akron

Response: I. Melville Stein, vice-president of Middle Eastern District

### 10:15 a.m.—Selected Subjects

Presiding: I. Melville Stein

A REVIEW OF RADIO INTERFERENCE INVESTIGATION, Frank Sanford and Willard Weise, Cincinnati Gas and Electric Company.
Scheduled for October issue

*NOTES ON RADIO INTERFERENCE, Grover Lapp, Lapp Insulator Company, Inc.

*RADIO DISTURBANCE MEASUREMENTS. W. S. Jennens and C. J. Miller, Jr., Ohio Brass Company.

*IMPROVEMENTS IN MINE VENTILATION, Theodore Troller, Guggenheim Airship Institute.

### 10:15 a.m.—Protective Devices

Presiding: Russell Krammes

*USE OF ELECTRONIC TUBES FOR RELAY PURPOSES, E. E. George, Tennessee Electric Power Company.

*THE ADVANCE IN INDUSTRIAL SWITCHGEAR, R. Paxton and F. E. Fairman, General Electric Company.

*THE DESIGN AND TEST OF A HIGH-SPEED HIGH-INTERRUPTING-CAPACITY RAILWAY CIRCUIT BREAKER, W. F. Skeats and H. E. Strong, General Electric Company.

### 2:00 p.m.—Inspection Trips

1. Babcock & Wilcox Company, Barberton, or
2. B. F. Goodrich Company, Akron

### 7:30 p.m.—Inspection Trip

Daniel Guggenheim Airship Institute

* These papers are scheduled for presentation, but at the time of going to press they have not been accepted for publication.

## Thursday, October 14

### 9:30 a.m.—Electrical Machinery

Presiding: A. M. MacCutcheon

*TRENDS IN THE DESIGN OF POWER TRANSFORMERS, L. H. Hill, Allis-Chalmers Manufacturing Company.

SINGLE-PHASE INDUCTION-MOTOR PERFORMANCE, A. F. Puchstein and T. C. Lloyd, Robbins and Myers, Inc. Scheduled for October issue

*5,000-KW. EXTRACTION TURBINE, W. S. Kramer, Westinghouse Electric & Manufacturing Company.

*ELECTRICAL APPLICATION IN RUBBER MILLS, John Grotzinger, R. S. Ferguson, and W. A. Brown, Goodyear Tire and Rubber Company.

### 9:30 a.m.—Electronics

Presiding: J. R. Martin

LOW-CURRENT IGNITORS, A. H. Toepfer, Westinghouse Electric & Manufacturing Company.
July, pages 810–12

REGULATION OF GRID-CONTROLLED RECTIFIERS, L. A. Kilgore and J. H. Cox, Westinghouse Electric & Manufacturing Company.
September, pages 1134–40

*THE IGNITER-TYPE MERCURY ARC RECTIFIER AS A POWER CONVERSION UNIT, A. Lee Barrett, Pittsburgh Coal Company.

*MERCURY ARC RECTIFIERS IN CHLORINE PRODUCTION, L. J. Rimlinger, Pittsburgh Plate Glass Co.

### 1:30 p.m.—Inspection Trip to Nela Park, Cleveland

### 6:30 p.m.—Dinner at Nela Park

### 8:00 p.m.—Popular Entertainment, Nela Park

## Friday, October 15

### 9:30 a.m.—Iron and Steel

Presiding: Wray Dudley

SOME HIGH LIGHTS IN THE USE OF ELECTRICITY IN STEEL MILLS, E. G. Fox, Freyn Engineering Company. September, pages 1115–23

CARBON BRUSHES FOR STEEL MILL EQUIPMENT, W. C. Kalb, National Carbon Company, Inc.
September, pages 1165–8

TENSION MEASUREMENT AND CONTROL IN COLD STRIP ROLLING, C. M. Hathaway and F. Mohler, General Electric Company.
September, pages 1141–4

### 9:30 a.m.—Power Transmission and Distribution

Presiding: F. W. Funk

*LIGHTNING-PROOF TRANSMISSION LINES, E. Hansson and A. F. Bang, Pennsylvania Water and Power Company.

LIGHTNING STROKES IN FIELD AND LABORATORY—II, P. L. Bellaschi, Westinghouse Electric and Manufacturing Company.
Scheduled for October issue

*PENNSYLVANIA RAILROAD ELECTRIFICATION, H. C. Griffith, Pennsylvania Railroad Company.

*POSSIBILITIES OF DIRECT CURRENT POWER TRANSMISSION USING ELECTRICALLY-CONTROLLED RECTIFIERS AND INVERTERS, O. K. Marti, Allis-Chalmers Mfg. Co.

*CROSS CATENARY TRANSMISSION LINES FOR LIGHTNING AND FOG CONDITIONS, A. O. Austin, Consulting and Manufacturing Engineer.

### 9:30 a.m.—Student Technical Session and Conference

Papers to be presented by students from each of the following schools:

Case School of Applied Science
Ohio University
Johns Hopkins University
West Virginia University
The University of Akron

### 12:00 noon—Luncheon Meeting of Branch Counselors and Student Chairmen

### 2:00 p.m.—Inspection Trip to Ohio Brass Company, Barberton

### 7:00 p.m.—Banquet

Presiding: Doctor W. E. Wickenden, president, Case School of Applied Science.

A message from President W. H. Harrison

Lighter-than-air craft will be discussed by Commander Rosendahl of the United States Naval Air Station, Lakehurst, N. J.

---

a top speed up to 200 miles per hour. Airplane or airship models are attached to the end of this arm and their behavior in curved flight can be investigated and the air forces determined by means of suitable instruments. A wind tunnel used in connection with this whirling arm makes it possible to duplicate the effect of atmospheric gusts on aircraft, when the model attached to the arm is made to traverse the open jet of this tunnel. The air forces in this case are recorded by means of diamonds scratching on glass cylinders.

Another test stand, just now in development, is a water tank, in which the free movement of an airship under the influence of gusts is imitated. Water is used to obtain kinematic and dynamic similarity. The airship model in this tank may be seen describing a path similar to that of an airship in flight in gusty weather.

Among the instruments to be demonstrated is a hot-wire anemometer, which is used for the measurement of rapid fluctuations of air velocity in magnitude and direction. This hot-wire anemometer, consisting essentially of thin platinum wires in a Wheatstone bridge, heated electrically and cooled by the moving air, is an important instrument for laboratory and atmospheric investigations.

### WOMEN'S PROGRAM

A special invitation is extended to the women to attend the District meeting with their husbands. Particular attention has been given the program of activities by the ladies committee and everything will be done to make their visit an enjoyable one.

**October 13**

Morning—Registration
Luncheon—Mayflower Hotel
Afternoon—Garden pilgrimage, courtesy of Akron Garden Forum, Mrs. T. A. Chittenden, president
Evening—Informal dinner dance

**October 14**

Morning—Portage Country Club. Golf, games, or bridge
Luncheon—Portage Country Club
Afternoon—Nela Park, Cleveland
Evening—Nela Park, Cleveland

## Future AIEE Meetings

**Middle Eastern District Meeting**
Akron, Ohio, Oct. 13–15, 1937

**Winter Convention**
New York, N. Y., January 24–28, 1938

**North Eastern District Meeting**
Pittsfield, Mass., Spring 1938

**Summer Convention**
Washington, D. C., June 20–24, 1938

**Pacific Coast Convention**
Portland, Ore., date to be determined

**Cuyahoge Valley, Metropolitan Park, and high-level bridge in Akron, Ohio, in which city the forthcoming AIEE Middle Eastern District meeting will be held. The Gorge hydro-electric plant of the Ohio Edison Company may be seen just beyond the bridge, to the right**

**October 15**

Morning—Blimp rides
Luncheon—Y.W.C.A.
Afternoon—Bridge-tea at the home of A. O. Austin, Barberton
Evening—Banquet

### Student Conference

After the student technical session on Friday morning a luncheon conference of the Branch chairmen and counselors will be held in the headquarters hotel.

### Rules on Presenting and Discussing Papers

At the technical sessions, papers may be presented in abstract, 10 minutes being allowed for each paper unless otherwise arranged or the presiding officer meets with the authors preceding the session to arrange the order of presentation and allotment of time for papers and discussion.

Any member is free to discuss any paper when the meeting is opened for general discussion. Usually 5 minutes is allowed to each discusser for the discussion of a single paper or of several papers on the same general subject. When a member signifies his desire to discuss several papers not dealing with the same general subject, he may be allowed a somewhat longer time.

It is preferable that a member who wishes to discuss a paper give his name in advance to the presiding officer of the session at which the paper is to be presented. Each discusser is to step to the front of the room and announce, so that all may hear, his name and professional affiliations. Three typewritten copies of discussion prepared in advance should be left with the presiding officer.

Other discussions to be considered for publication should be typewritten (double spaced) and submitted in triplicate to C. S. Rich, secretary of the technical program committee, AIEE headquarters, 33 West 39th St., New York, N. Y., on or before October 29, 1937. Discussion of unpublished addresses and papers need not be submitted.

### Hotel Rates

Members should make room reservations by writing directly to the hotel of their preference. For convenience the rates of the headquarters hotel, the Mayflower, as well as the rates of other hotels are listed in Table I.

### Advance Registration

Members of the District who will attend the meeting should register in advance by returning the addressed advance-registration card which they will receive by mail. This will be helpful to the registration committee and permit badges to be prepared in advance and reduce the work necessary on the opening day to a minimum.

A minimum registration fee of $2.00 will be charged all nonmembers except Enrolled Students and the immediate families of members.

### Committees

The committees handling the various phases of the work in connection with the meeting are as follows:

**District Meeting Committee:** W. H. Harrison, I. Melville Stein, H. A. Dambly, A. G. Ennis, Paul Frederick, Warren C. Kalb, E E. Kimberly, E. O. Lange, and O. C. Schlemmer.

**General Committee:** Harold L. Brouse, chairman; A. O. Austin, Ralph Higgins, R. A. Hudson, H. C. Paiste, Harold H. Schroeder, V. W. Shear, and J. T. Walther.

**Meetings and Papers Committee:** A. O. Austin, chairman; T. F. Brandt, S. C. Henton, and H. L. Rorden.

**Entertainment and Reception Committee:** R. A. Hudson, chairman; Thomas Dee, R. P. Dunmire, W. C. Fick, Fred Nimmer, R. C. Putnam, A. P. Regal, W. A. Smith, and William H. Tucker.

**Hotels and Registration Committee:** Verne W Shear, chairman; George G. Clark, H. D. Duncan, F. A. Green, and P. C. Smith.

**Transportation and Inspection Committee:** H. C. Paiste, chairman; E. B. Crane, T. J. Newman, and N. W. Wing.

**Student Sessions Committee:** J. T. Walther, chairman; Kenneth Burgan, Carl Delagrange, Robert Miller, and P. D. Remark.

**Attendance and Publicity Committee:** Harold H. Schroeder, chairman; P. S. Bechtol, R. W. Drushel, and Louis McConaghy.

**Finance Committee:** Ralph Higgins, chairman; John Grotzinger, R. R. Krammes, and A. L. Richmond.

**Women's Committee:** Mrs. Ralph Higgins, chairman; Mrs. A. O. Austin, Mrs. J. W. Funk, Mrs. R. A. Hudson, and Mrs. Verne W. Shear.

**Table I Hotel Rates**

| Hotel and Location | Single Without Bath | Single With Bath | Double Without Bath | Double With Bath | Twin |
|---|---|---|---|---|---|
| Mayflower (headquarters), 259 S. Main St. | $ .... | $3.00 to 4.50 | $ .... | $5.00 to 6.50 | $5.50 to 6.50 |
| Portage, 10 N. Main St. | 1.75 | 2.00 to 3.00 | 2.75 | 3.00 to 4.50 | 4.00 to 6.00 |
| Akron, 92 E. Market St. | 1.50 to 1.75 | 2.00 to 2.50 | 2.50 | 3.00 to 3.50 | 3.50 |
| Howe, 11 S. Main St. | .... | 1.75 to 2.75 | .... | 3.00 to 3.25 | 4.00 |
| Anthony Wayne, 314 S. Main St. | 1.50 to 1.75 | 2.50 to 2.75 | 2.50 to 3.00 | 4.00 to 4.50 | .... |

**ASME Fall Meeting.** Papers on power, railroads, fuels, and petroleum are planned for the 1937 fall meeting of The American Society of Mechanical Engineers, which will be held at Erie, Pa., October 4–6. Inspection trips to several industrial plants, including that of the General Electric Company at which railroad equipment and refrigerator bodies are made, have been planned.

## Additional Awards for 1936 Institute Papers

In addition to the national and District prize awards for papers presented before the Institute during 1936 announced in ELECTRICAL ENGINEERING for June 1937, page 756, the awards for Districts 5 and 8 have now been announced. These awards are:

DISTRICT 5

**Prize for Branch paper awarded to Orville A. Becklund for his paper "An Artificial Ear for Sound Measurements," presented at a joint meeting of Minnesota Section and University of Minnesota Branch, April 21, 1937.**

DISTRICT 8

**Prize for best paper awarded to Joseph S. Carroll (A'24, M'37) and John A. Koontz Jr., (A'11, M'20) for their paper "Cable Vibration—Methods of Measurement," presented at the summer convention, Pasadena, Calif., June 22–26, 1936.**

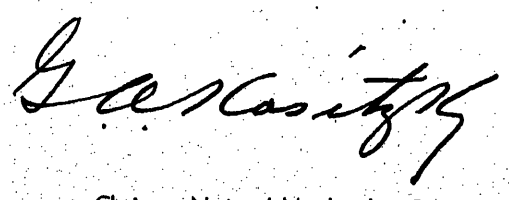
**Prize for initial paper awarded to Otto A. Knopp (A'09, M'34) for his paper "Some Applications of Instrument Transformers," presented at the summer convention, Pasadena, Calif., June 22–26, 1936.**

## ECPD Offers Guides to Engineers

A pamphlet containing suggestions to junior engineers and another presenting a list of university extension facilities throughout the United States have been prepared by Engineers' Council for Professional Development. These pamphlets, together with 5 bibliographical pamphlets described in ELECTRICAL ENGINEERING for August 1937, page 1060, are intended to guide engineers in postcollegiate study.

In "Suggestions to Junior Engineers," a questionnaire is given to aid making a personal appraisal and a reading list to serve as a basis on which the nontechnical culture of the engineer can be continued. The pamphlet giving university extension facilities presents the scope of 54 courses and indicates their availability through class or correspondence study at more than 30 American institutions. The separate pamphlets can be had for 10 cents each, or for 5 cents each in lots of 50 copies, assorted if desired. Requests should be sent to Engineers' Council for Professional Development, 29 West 39th Street, New York, N. Y.

**Chemical Industries to Hold Exposition.** Plans for The Sixteenth Exposition of Chemical Industries, to be held at Grand Central Palace, New York, N. Y., December 6–11, 1937, are progressing rapidly. A feature of the exposition will be the award of a prize of $250 in cash to the person submitting the "best descriptive expression encompassing the purposes and the benefits redounding to the common good from the activities of the chemical industries." Raw materials, finished products, plant equipment, and machinery and apparatus will constitute major sections of the exhibits. Metals and alloys and the newer synthetic plastics and molded products likewise will be featured. Admission will be without charge, by registration or invitation only, and no tickets will be sold.



## Membership—

Mr. Institute Member:

Progress commands respect and admiration. Our Institute has gone forward consistently and the progress made in membership growth is just one of the many reasons for the pride we feel in being identified with this organization. There has been a steady gain in members during the past few years, and each year has had a larger gain than the preceding one. This progress was possible only because of the active assistance and support of the members—not only the officers and committeemen, but you and you. We appreciate your help and want to thank you.

Another year began on August 1. There will be new officers, new committees, and, of course, new members.

We are hopeful that the growth in members in this coming year may be greater than last year's increase. With your help it *will* be greater. We are again counting on your support.

Chairman National Membership Committee

## Aluminum Company Plans Expansion

Expenditures which may finally reach $15,000,000 will be necessary to provide added facilities for production of virgin aluminum and for additional fabricating units, electrical installations, housing facilities, and other auxiliary equipment in an expansion program contemplated by the Aluminum Company of America at Alcoa, Tenn. This expansion will require many additional employees with the likelihood that the present force of approximately 5,000 will be doubled when the program is completed. A contract with the Tennessee Valley Authority has been signed whereby the company secures at an early date a large quantity of power to augment the present supply from its own hydroelectric system.

Aluminum Company of America was attracted to this section more than 25 years ago because of the hydroelectric possibilities for an industry which finds cheap power one of the prerequisites for manufacture of its product at a price at which it can compete with other materials. Despite the fact that all the raw materials except power have to be brought into the state, the company found it desirable constantly to expand operations at Alcoa where the annual output now represents about 30 per cent of the virgin aluminum produced in the United States. Fabricating operations at Alcoa have been an important part of the company's manufacturing plants for semifinished and finished aluminum, for many years the largest aluminum sheet and plate mill in the country being located at this point.

To provide power for existing operations, the company has developed 3 large hydroelectric projects on the Little Tennessee River and its tributaries at Calderwood, Cheoah, and Santeetlah. It has several other dam sites for future use, one of which, on the Nantahala River, is already partially developed. Application for the completion of several of these projects is about to be made to governmental authorities.

In addition to the large sums spent in Tennessee and western North Carolina for power projects to serve the Alcoa works, the company has its own hydroelectric plants on the Yadkin River to provide power for an aluminum works at Badin, N. C. Most recent announcement of expansion in that section was the statement within the past month that the company is building a dam at Tuckertown.

**Engineering Society of Detroit Receives Gift.** Total endowment of The Engineering Society of Detroit, successor to the Detroit Engineering Society, has reached $1,000,000 with a second gift of $500,000 from The Horace H. and Mary A. Rackham Fund. The purpose of this gift is to provide a suitable building to be used by the society as a permanent home; income from the first half-million-dollar gift is to be used for operating expenses. The Engineering Society of Detroit is an entirely new organization with 12 affiliated groups and a membership which numbers nearly 3,000.

## Student Training in Air Conditioning

An extensive educational program designed to attract young men into the air-conditioning industry has been begun by the General Electric Company. The plan is modeled after the test courses started by the company in 1888.

The new program, although sponsored by the company itself, will be worked out through its distributors in the field, in the belief that the distributor organization offers wider practical experience and greater possibilities for the employment of the students. It will be open primarily to graduates of colleges, technical schools, and high schools who desire to establish themselves in the industry, but in special instances it may be open to men who have been otherwise employed, provided they demonstrate potential capabilities for the business. Because many phases of air-conditioning work involve engineering problems, the opportunity is generally greatest for those who have had technical training.

Practical manuals, courses, and distributor training activities have been designed by the General Electric air-conditioning department. They will be augmented by various forms of instruction in the field by district managers and factory men. Applications for training should be made to distributors or to the headquarters of the air-conditioning division of the company in Bloomfield, N. J.

## Conference Board Elects Officers

At its 21st annual meeting, the National Industrial Conference Board elected officers for the ensuing year. Elon H. Hooker, president of the Hooker Electrochemical Company, was elected chairman, and John Henry Hammond was elected honorary chairman. Doctor Virgil Jordan continues as president and chief executive of the board.

The following vice-chairmen were elected: Irenée du Pont, director, E. I. du Pont de Nemours and Company; E. Kent Hubbard, president, Manufacturers Association of Connecticut; Hon. Walter J. Kohler, chairman, Kohler Company; and W. Gibson Carey, Jr., president, Yale and Towne Manufacturing Company. Fred I. Kent, director of the Bankers Trust Company, was re-elected treasurer. Members of the executive committee elected for the ensuing year are:

Neal Dow Becker, president, Intertype Corporation, Brooklyn, N. Y.
E. R. Behrend, president, Hammermill Paper Company, Erie, Pa.
Philip E. Bliss, president, The Warner & Swasey Company, Cleveland, Ohio
Walter S. Case, president, Case, Pomeroy & Company, New York, N. Y.
S. Bayard Colgate, president, Colgate-Palmolive-Peet Company, Jersey City, N. J.
Arthur M. Collens, president, Phoenix Mutual Life Insurance Company, Hartford, Conn.
John F. Deasy, vice-president, Pennsylvania Railroad Company, Philadelphia
William C. Dickerman, president, American Locomotive Company, New York, N. Y.
James F. Fogarty, president, The North American Company, New York, N. Y.
David M. Goodrich, chairman, The B. F. Goodrich Company, Akron, Ohio
De Forest Grant, chairman, Federal Seaboard Terra Cotta Company New York, N. Y.
R. J. Hamilton, president, American Radiator Company, New York, N. Y.
John Henry Hammond, Hines, Rearick, Dorr & Hammond, New York, N. Y.
Howard Heinz, president, H. J. Heinz Company, Pittsburgh, Pa.
J. Taber Loree, vice-president, The Delaware and Hudson Railroad Corporation, Albany, N. Y.
Thomas Luke, president, West Virginia Pulp and Paper Company, New York, N. Y.
Auguste G. Pratt, president, The Babcock and Wilcox Company, New York, N. Y.
A. W. Robertson (A'27), chairman, Westinghouse Electric & Manufacturing Company, Pittsburgh, Pa.
David Sarnoff (M'23), president, Radio Corporation of America, New York, N. Y.
Malcolm B. Stone, president, Ludlow Manufacturing Associates, Boston, Mass.
J. A. Sweetser, president, Bigelow-Sanford Carpet Company, New York, N. Y.

Conference board councilors include:

Eugene G. Grace, president of the Bethlehem Steel Company
Cornelius F. Kelley, president of the Anaconda Copper Mining Company
L. F. Loree, president of the Delaware and Hudson Railroad Corporation
Hon. Andrew W. Mellon, Pittsburgh, Pa.
George M. Verity, chairman of the American Rolling Mill Company
Owen D. Young, chairman of the General Electric Company

## Isle Maligne Plant Reaches Designed Capacity

With the completion of the current installation of the twelfth 33,500-kva 112.5-rpm hydroelectric unit, the Isle Maligne Hydroelectric power station at the head of the Saguenay river about 100 miles north of Quebec will have been brought to the ultimate of its designed capacity of some 402,000 kva.

Described as "the largest single installation in water power development ever undertaken" up to that time, by the late W. S. Lee in his paper "Hydroelectric Development of the Saguenay River," (AIEE TRANS., v. 44, 1925, pp. 722–36), the project was authorized in December 1922, and the plant went into operation in 1925 with 8 units installed and space provided for 4 more. Located at the outlet of Lake St. John, the station is authorized to use the storage capacity of that lake between "ordinary low water and ordinary high water." Surveys established the permissible depth variation at 17.5 feet. which corresponded to an area variation from 328 square miles at low water to some 408 square miles at high water, and made available effective storage, of an estimated 187.1 billion cubic feet, adequate to serve effectively for the estimated 30,000-square-mile run-off area. Median operating head is 110 feet.

The magnitude of the project, its far-northerly location and the consequent severe winter weather conditions, and its distance from centers of transportation and civilization, made the project one of especial interest at the time of its construction. As described and discussed in some detail by Mr. Lee, "the design and layout of the construction plant were given as much attention.... as the design of the power house."

## Ford of Canada to Expand Power Plant

A power plant expansion program to cost about $3,500,000 has been undertaken by the Ford Motor Company of Canada, Ltd., at its Windsor plant, according to a recent announcement. The program provides for increased output, lower production cost, and the use of some of the original equipment without enlarging the present plant building.

The original plant consisted of 3 boilers each having a capacity of 100,000 pounds of steam per hour, each at a pressure of 235 pounds per square inch and a temperature of 580 degrees Fahrenheit; space was provided for a fourth boiler. Two turbogenerators were used, with capacities of 10,000 and 5,000 kw, respectively. When the present program is completed, the generating capacity will have been increased to 35,000 kw and the steam generating capacity to 600,000 pounds per hour. The ultimate development contemplated to be undertaken in the future will have a maximum output of 45,000 kw and a steam generating capacity of 800,000 pounds per hour.

The program now under way will include the installation of 3 new boilers and 2 new turbines, one of which will be a superposed unit exhausting into the existing 10,000-kw turbine. After careful study, a turbine throttle pressure of 800 pounds per square inch and temperature of 800 degrees Fahrenheit were selected as being most economical for this installation.

The 800-pound-pressure turbogenerator will be a 5,000-kw unit and will exhaust at 175 to 200 pounds pressure and 500 to 600 degrees Fahrenheit into the existing low-pressure 10,000-kw condensing turbogenerator, and in addition will supply steam for high-pressure process use. The other turbogenerator to be installed will be a 20,000-kw condensing double-bleeding unit. Both bleed points will be automatically controlled so that the turbine will furnish high-pressure process or low-pressure heating steam.

## Electrical Companies to Exhibit at 1939 Fairs

Plans for electrical exhibits at the New York World's Fair and the Golden Gate International Exposition are progressing rapidly, and several large electrical companies already have signed leases for exhibition space in the fair buildings or have contracted for lots on which they will erect their own exhibition structures.

Although no definite plans for individual company exhibits have been made public, the Westinghouse Electric & Manufacturing Company, which has contracted for a floor space of 10,922 square feet in the projected Electrical Production Building (see accompanying illustration) of the New York World's Fair, has announced that its exhibit will include demonstrations of scientific research and electrical applications in air conditioning, transportation, and lighting equipment, radio, television, and X rays. The General Electric Com-

**Photograph of a scale model of the Electrical Production Building to be constructed for the 1939 World's Fair at New York**

pany, expecting to present an amplification of its "House of Magic," a series of dramatic demonstrations of the achievements of electrical research, has signed a contract for a lot 68,339 square feet in area upon which it will build its own exhibition structure.

The Radio Corporation of America likewise has contracted for a lot space of 81,699 square feet. David Sarnoff (M'23) president, in describing the World's Fair plans of RCA said that the exhibit would show " . . . how radio safeguards the passage of ships at sea, and the flight of ships in the air, . . . how photographs are transmitted across the ocean by radio, . . . the most modern equipment for recording sound in motion-picture studios and reproducing it in theaters." Other attractions will include a radio communications center at the fair, so that visitors may send radiograms to any part of the world, an actual demonstration of what goes on behind the scenes in radiobroadcasting, and a public demonstration of television, whatever its status may be at the time of the exposition.

Other companies that have contracted for building space at the New York fair include: Bell Telephone System, 139,400 square feet (see June 1937 issue, page 766); Consolidated Edison Company of New York, Inc., 75,183 square feet; Johns-Manville, 29,317 square feet; American Gas Association, 122,008 square feet; and United States Steel Corporation subsidiaries, 55,166 square feet.

The Electrical and Communications Exhibits Building at the Golden Gate International Exposition will occupy a ground area of 89,400 square feet near the main portal of the exposition grounds. Westinghouse Electric & Manufacturing Company, General Electric Company, and the Bell Telephone System have signed contracts for exhibition space, and have indicated broadly the nature of their exhibits. The Westinghouse display will occupy nearly 5,000 square feet, and is expected to be a comprehensive showing of products for industry and household, mostly operating demonstrations of a scientific and educational character. The General Electric exhibits will be similar to those at the New York fair. The Bell System exhibit, which will occupy a space of approximately 7,000 square feet in the electrical building, will provide demonstrations in which the visitors themselves will participate, and will present new features in communications devices. The demonstration equipment is being designed by Bell Telephone Laboratories, Inc., will be erected by the American Telephone and Telegraph Company, and will be operated by The Pacific Telephone and Telegraph Company.

Several foreign nations have completed negotiations for sending scientific and commercial exhibits to both fairs, and many others have signified their intentions of being represented.

**Swedish Engineers Plan 1,500-Kilometer Line.** Leading Swedish electrical engineers recently met in Stockholm to discuss problems of the electrical industry in that country, among which was a consideration of the possibility of transmitting to southern Sweden the energy produced in the rich waterpower sources of the far North. A line from Krångede, in northern Sweden, to Malmö, in the extreme South, a distance of 1,000 kilometers (621 miles) already is under construction, and a 1,500-kilometer (930-mile) line is being considered. Aluminum is being used in increasing amounts in the construction of these long Swedish lines, and the Stockholm convention of engineers paid a visit to a modern aluminum plant producing 2,000 tons of aluminum per year electrolytically, with a power consumption of 40,000,000 kilowatt-hours of electrical energy.

**Standard for Welding Electrodes.** The first draft of a specification for coated electrodes for structural steel has been issued by the French committee for welding standards. Eleven diameters (0.04 to 0.51 inch) and 4 lengths (6 to 18 inches) are standardized. Four standard colors are given to electrodes according to their mechanical properties. Mechanical properties are determined on all-weld-metal specimens machined from a deposit made in an angle iron 10 inches long. The speed of welding must be such that the corners of the angle iron do not become red. Copies of the draft have been ordered by the American Standards Association for use of its members.

## New Generating Unit to Use 2,400-Pound Steam

According to a recent announcement of the American Gas and Electric Company, a new steam-electric generating unit to operate at the record pressure of 2,400 pounds per square inch and temperature of 940 degrees Fahrenheit will be installed in the Twin Branch station of one of its subsidiaries, the Indiana and Michigan Electric Company, Mishawaka, Ind. The decision to use such high pressure and temperature is the outcome of studies in high temperatures and pressures for generating units made by engineers of the company with the object of reducing plant investment and increasing operating efficiency, with full consideration to the financial soundness of investment.

The new unit will have a rating of 62,500 kw and will consist of a 22,500-kw 2,400-pound-pressure turbogenerator, cross-compounded with a new 40,000-kw 400-pound-pressure turbogenerator. This unit, together with the 2,500-pound-pressure boiler and accessory equipment, will entail an expenditure of some $4,000,000.

## Westinghouse Creates "New Products" Division

Responsibility for developments either new in the art or not previously undertaken by the company has been centralized by the Westinghouse Electric & Manufacturing Company of East Pittsburgh, Pa. in a newly formed "new products" division, according to a recent announcement. Functioning the same as the other operating units of the company, this division will include separate engineering, manufacturing, and sales departments.

The division will concentrate its facilities in developing and broadening the field of applications of products that have not reached the status of commercial apparatus. Then, after the field for each new product has been determined and the product has passed through the initial plant stage, the product will be taken over by one of the regular divisions. It is stated also that the new division will be responsible for training a staff that will be "adequate for the further promotion of the product."

**Technological Trends Studied by Government.** New inventions necessitate constant revision of national policies, according to a report of the National Resources Committee on "Technological Trends and National Policy," recently released by Chairman Harold L. Ickes, Secretary of the Interior. The first report on the science resources of the United States deals with new inventions and their social implications and calls attention to the need for planning to meet the new situations caused by technological advance. Prepared by a large group of scientists and engineers, the report "presents a survey of most of the fields of technology and applied science. . . . " The National Resources Committee urges that a series of continu-

ous studies be undertaken by existing planning boards and by appropriate agencies developed by the Federal Government, with the definite function of investigating and reporting on the progress and trends of science and invention, and the possible social and economic effects that may follow them. The report recommends that to study the technical aspects of the question the science committee of the Natural Resources Committee make an investigation of the adequacy of reporting on inventions and discoveries and advise on the feasibility of more balanced coverage, of selecting those more socially significant, and of assembling such data in some central location. Copies of the report are available from the Superintendent of Documents, Washington, D. C.

**More Boulder Dam Generators.** Contracts for the supply of 2 additional turbogenerator units to increase the generating capacity of the Boulder Dam plant to half of its full projected value of 1,835,000 horsepower recently were awarded. The new turbines, vertical-shaft units rated at 115,000 horsepower each, are to be constructed by the Allis-Chalmers Manufacturing Company. Contracts for the generating equipment were awarded to the Westinghouse Electric & Manufacturing Company. Already serving the city of Los Angeles and other municipalities in southern California are 4 3-phase 60-cycle units, each rated at 82,500 kva, with an output voltage of 16.5 kv. Of these, 2 were manufactured by the General Electric Company and 2 by the Westinghouse Electric & Manufacturing Company; in addition, the General Electric Company now is constructing 2 similar units, which will be completed in 1938. The units just contracted for will be ready for operation in 1939 and 1940.

**New York Building Code Now Permits Welding.** A new building code for the city of New York, N. Y., to become effective January 1, 1938, permits the use of welding in place of riveting in steel construction work. Previously, welding was prohibited because the existing code was formulated before modern welding methods were evolved. This action is congruous with New York's recent noise-abatement campaign; moreover, welded steelwork is advantageous in several other ways, being lighter, stiffer, creating more compact joints, and effecting an appreciable saving in the amount of steel required.

**Power Exposition to Be Held.** The Chicago (Ill.) Exposition of Power and Mechanical Engineering, to be held at the New International Amphitheatre, October 4–9, 1937, is expected to be one of the largest events of its kind ever held in the Midwest area, according to plans of its sponsors. Advance reports of machines and materials to be exhibited are said to be comprehensive and of interest to both executives and operators in the power and mechanical-engineering fields.

**Standard Symbols for Welding.** Realizing that welding cannot take its place as an engineering tool unless suitable means for conveying explicit information from designer to workman are provided, the American Welding Society has derived and published a set of standard welding symbols covering both fusion and resistance welding. The symbols, which are ideographic, have been made as simple as possible, and are based upon a principle of having the most common form of any weld require a minimum of numerical data. In effect the system amounts to a shorthand system with which a large amount of information may be transmitted in a few simple lines and figures. Complete information may be obtained from the American Welding Society, 33 West 39th Street, New York, N. Y.

# Current Items From American Engineering Council

## Who's Who in Engineering

Engineers and engineering organizations have a new directory and biographical dictionary in the fourth edition of "Who's Who in Engineering," which has just been published by the Lewis Historical Publishing Company, Inc., 8th Avenue and 14th Street, New York, N. Y. It is well done and is a most excellent reference volume. In addition to the biographical dictionary this issue carries a comprehensive list of engineering organizations in the United States and brief descriptions of each of several functional instrumentalities of engineering societies.

## Coal Price Fixing Is Here

Twenty-three district boards of code members managed by the National Bituminous Coal Commission in the Investment Building at 15th and K Streets, N. W., Washington, D. C., came into existence on June 21, 1937. All are authorized by the Guffey or Bituminous Coal Act of 1937, entitled "An act to regulate interstate commerce in bituminous coal and for other purposes." The principle objectives are the establishment of marketing rules and regulations, fixing minimum and maximum prices, and the prevention of unfair competition in the bituminous-coal industry.

The Bituminous Coal Act of 1937 also created a Consumers' Counsel to provide protection for all consumers of bituminous coals in the United States. The counsel has established headquarters in the Tower Building at 14th and K streets, N. W., Washington, D. C. "It shall be the duty of the Consumers' Counsel to appear in the interest of consuming public in any proceedings before the Commission, to offer testimony, examine witnesses or parties to the proceedings," and to have the Commission certify to information or conduct investigations of conditions believed to be responsible for unfair consumer prices.

American Engineering Council has been asked to assist Consumers' Counsel and the Commission with the location of engineers and engineer executives experienced in the several phases of the bituminous-coal industry and it has been invited to co-operate in bringing the objectives of these regulatory bodies to the attention of all engineers connected with or interested in bituminous-coal production, distribution, and consumption. Both agencies are seeking engineering advice and assistance with efforts being made to improve the soft-coal situation in the public welfare.

Engineering societies are urged to acquaint individual engineers and committees with the fact that the coal agencies "are now attempting to help establish fair minimum and maximum prices and are sponsoring the promulgation of rules and regulations regarding the production, marketing, and use of bituminous coal which may have far reaching effects on all fuel users as well as all fuel producers, dealers, etc." Results of such efforts are likely to change power and other industrial costs for which certain engineers may be directly or indirectly responsible.

Copies of the "Bituminous Coal Act of 1937, the Bituminous Coal Code, Taxes on the Sale or Other Disposal of Bituminous Coal, and Rules of Practice and Procedure before the National Bituminous Coal Commission" may be obtained directly from the agencies named, from the National Coal Association in the Southern Building, or from the Government Printing Office in Washington, D. C. The Counsel and the Commission invite correspondence and co-operation calculated to improve the present bituminous coal situation.

Most of the activities of these soft-coal agencies involve problems of more concern to trade associations than professional societies, but questions of potential importance to engineers employed in industry as well as those in consulting and private practice are having serious consideration. It is, therefore, suggested that engineers who are concerned with any phase of the bituminous-coal industry or the use of soft coal in other industries be urged to keep themselves advised regarding what is being done by these government regulatory bodies with soft-coal prices and the control of production, distribution, and consumption.

Consumers' counsel is John C. Carson of Michigan, former secretary to the late Senator Couzens. His principal assistants

are Ellery P. Gordon and W. L. Chandler. The commission is: Chairman, Charles F. Hosford, Jr., of Pennsylvania; Pleas E. Greenlee of Indiana, Thomas S. Hammond of Kentucky, John C. Lewis of Iowa, Walter H. Maloney of Missouri, C. E. Smith of West Virginia, and Percy Tetton of Ohio. Although the National Bituminous Coal Commission and the Consumers' Counsel were created jointly by the Bituminous Coal Act of 1937, they function as independent agencies of the Department of Interior under the administrative control of Secretary Ickes.

# Letters to the Editor

CONTRIBUTIONS to these columns are invited from Institute members and subscribers. They should be concise and may deal with technical papers, articles published in previous issues, or other subjects of some general interest and professional importance. ELECTRICAL ENGINEERING will endeavor to publish as many letters as possible, but of necessity reserves the right to publish them in whole or in part, or reject them entirely.

ALL letters submitted for consideration should be the original typewritten copy, double spaced. Any illustrations submitted should be in duplicate, one copy, to be an inked drawing but without lettering, and other to be lettered. Captions should be furnished for all illustrations.

STATEMENTS in these letters are expressly understood to be made by the writers; publication here in no wise constitutes endorsement or recognition by the American Institute of Electrical Engineers.

## AIEE Publications

*To the Editor:*

The recent discussion at the summer convention in Milwaukee, Wis., regarding Institute publications prompts me to send the following comments.

At the outset I want to express my keen appreciation of the excellent work that has been done by the publication committee and of the able manner in which the editorial work of ELECTRICAL ENGINEERING has been conducted. As a regular contributor to Institute publications I have had full co-operation. The work has been efficiently conducted and speedily and accurately executed. Nor is my experience unique in this respect. I believe that a survey will show that other contributors have a similar reaction to Institute publications.

I am also mindful of the excellent services rendered to the Institute by the technical program committee. They have given us excellent technical programs at all Institute conventions. They have introduced technical conferences at which ideas are exchanged freely by authorities in the field. Through their efficient and capable secretary they have given contributors prompt and courteous service which is beyond criticism.

It is not in the administrative aspects of Institute publications that the fault lies, it is rather in the quality of the articles that are submitted for publication.

If one were to classify the Institute membership according to their interests he would find the following classes:

*a.* The highly-specialized analytically-inclined members. This group comprises a rather small minority of the Institute membership. It is technically strong and is responsible for the majority of the papers published in ELECTRICAL ENGINEERING and the TRANSACTIONS.

*b.* The practicing engineers whose work is of a technical nature and who like to keep up with the progress of the art but who are not sufficiently specialized or analytically inclined to read and understand the majority of the published work. This group constitutes, by far, the largest minority (if not a majority) of the Institute membership.

*c.* The student and cadet engineers who have no practical background but who will form the future backbone of the Institute. They constitute a sizeable minority of the membership.

A few would question the fact that Institute publications should be so designed as to meet the needs and requirements of all the membership. The problem is how to modify the publications so as to accomplish this result.

I wish to submit a plan which would seem to solve this problem and which follows closely the general plan presented by the publication committee and has for its object the endorsement of the policies submitted by that committee. The plan consists of making the TRANSACTIONS and ELECTRICAL ENGINEERING 2 entirely distinct publications.

The TRANSACTIONS would comprise exclusively highly technical and highly specialized papers which contain new contributions to the art. Such papers would be submitted to the various technical committees of the Institute and would be earmarked by these committees as worthy of presentation at Institute conventions and of publication in the TRANSACTIONS. The TRANSACTIONS would thus become a publication which satisfies the needs of group *a* of the membership.

The journal ELECTRICAL ENGINEERING, since it is received by all the members of the Institute, would comprise articles of interest to the membership at large (groups *a*, *b*, and *c*). Papers published in ELECTRICAL ENGINEERING would also be submitted to the various technical committees but would be earmarked by these committees for publication in the journal. Such articles need not contain new contributions. The following types of articles might properly be published in ELECTRICAL ENGINEERING:

*a.* Expository articles, written in text-book form and readily understood by practicing electrical engineers and engineering students, on important recent developments in electrical engineering. The paper by Travis on per-unit quantities and Prentice's paper on fundamental concepts of synchronous machine reactances, form excellent illustrations of this class.

*b.* Articles on economic and social problems of the engineer. Hellmund's paper in the April 1937 issue of ELECTRICAL ENGINEERING and Spooner's paper in the December 1934 issue are typical of this class. I might also here include the excellent addresses of Doctor Bush and Doctor Flanders which were delivered at the Milwaukee convention.

*c.* Articles on recent developments in the basic sciences such as physics and chemistry written from the point of view of possible application in the practice of electrical engineering. The services of the committee on basic sciences (formerly the electrophysics committee) may be pressed for obtaining such papers.

*d.* Educational articles. Several articles on education have appeared in Institute publications. These articles have always aroused interest not only among educators but also among practicing engineers.

*e.* Descriptive articles of recent engineering projects. Such articles are of interest to utility and power engineers.

*f.* Articles on the professional aspects of engineering including engineering ethics, licensing of engineers, etc.

*g.* News of the Institute, its activities and its members. This section in ELECTRICAL ENGINEERING is read by practically all members.

*h.* Short abstracts, prepared by the authors, of all technical papers presented at Institute conventions and published only in the TRANSACTIONS.

*i.* Student papers which are awarded prizes or/and honorable mention.

*j.* Letters to the editor.

Having at last arrived at the letter *j* my imagination ceases to function so I shall close with the hope that the readers of this letter will take enough interest in this vital matter to communicate to you their reaction to this proposal.

Very truly yours,

MICHEL G. MALTI (M'34)
Assistant Professor of Electrical Engineering, Cornell University, Ithaca, N. Y.

## Most Economical Voltages For Incandescent Lamps

*To the Editor:*

Until recently the writer has seen nothing written explaining how to determine the most economical voltages at which to operate incandescent lamps. When purchasing Mazda lamps the consumer has the 110-115-, and 120-volt lamps from which to select. If the socket voltage happens to be, say 115 volts, it most certainly does not follow that the most economical lamp to buy will be the 115-volt lamp. This fact, and a method to determine which voltage lamp the purchaser should buy, the writer will attempt to explain in this article.

It is well known that if the operating voltage of a lamp is raised, the life of the lamp will be materially shortened, and the lumens output will be increased accordingly. If the operating voltage is reduced, the opposite effect will take place, that is, the life will be lengthened and the lumens output diminished. If the socket voltage is very low, the cost of lamp renewals will be almost eliminated, but the cost of electric power per lumen will be high. On the contrary, if the socket voltage is high, the lumens output will be increased, but the total cost per lumen-hour will be prohibitive because of the cost of lamp renewals. At some voltage in between these extremes (for any given lamp with a specified cost for power) lies the point at which the user can get the most lumen-hours for his money.

In the Bureau of Standards Research Paper No. 502, characteristic equations are

given for tungsten-filament vacuum and gas-filled lamps. They are of the form

$$y_n = A_n x^2 B_n + C$$

The equations express the relation of voltage to lumens output, to current, to watts input, and to the efficiency. In these equations the variable $x$ is the logarithm of the ratio of any voltage to that voltage at which a lamp operates when it emits light at an assumed "normal" efficiency. The variable $y_n$ is the logarithm of the ratios of currents, lumen outputs, or watts at these voltages. $A$, $B$, and $C$ are constants.

These equations have proved to be quite accurate, but are cumbersome to use. Professor Parry Moon ("The Scientific Basis of Illuminating Engineering," McGraw-Hill Book Company, Inc.) has reduced these equations to a simpler form, for use where great accuracy is not required. However, by calculation, the errors do not exceed 5 per cent, even though the voltage varies from 80 per cent to 130 per cent normal. These equations, in part, are as follows:

$$F/F_0 = (V/V_0)^{B_2} \text{ luminous flux} \qquad (1)$$

$$P/P_0 = (V/V_0)^{B_3} \text{ power} \qquad (2)$$

$$L/L_0 = (V/V_0)^{-B_5} \text{ life} \qquad (3)$$

where $V_0$ is the rated voltage of the lamp and $F_0$, $P_0$, and $L_0$ are the values at rated voltage. The constants are obtained from table I.

With the ratio of socket voltage to lamp voltage as the independent variable, Professor Moon has set up another equation giving the cost per lumen-hour. Differentiating, a minimum voltage ratio is found, which is the most economical operating point. The proof will not be given here, but the general equation arrived at giving the voltage ratio for most economical operation is

$$\left(\frac{V}{V_0}\right)_m = \left[\frac{bP_0}{c}\frac{B_2 - B_3}{B_5 - B_2}\right]^{\frac{1}{B_5 - B_3}}$$

where
$c$ equals cost of one lamp plus installation charge (cents)
$b$ equals cost of power in cents per kilowatt-hour
$V$ equals actual operating voltage
$V_0$ equals rated voltage of lamp
$P_0$ equals rated power of lamp
Constants are taken from table I.

For each division of lamps in table I the writer has reduced equation 4 so that curves may be plotted, making it easier to determine the most economical voltage. These curves are shown in figure 1. As an example, consider a residence where $b$ equals 5 cents per kilowatt-hour, $P_0$ equals 60 watts, and $c$ equals 15 cents.

$$\frac{bP_0}{c} = \frac{5 \times 60}{15} = 20$$

From figure 1 the corresponding value of $V/V_0$ equals 1.126. If the circuit is operating at $V$ = 115 volts, the lamp rating for most economical operation should not be 115 volts, but

$$V_0 = \frac{V}{1.126} = 102 \text{ volts (approximately)}$$

As the cost of power becomes lower, $V_0$ and $V$ become more nearly equal. As a general rule, it is more economical to operate lamps above rather than below their rated voltage. It is of interest to note from the curves that when $bP_0/c$ = 4.5 or less, then $V/V_0$ becomes less than unity, and in that case, lamps should be operated below their rated voltage.

**Table I**

| Symbol | Gas-Filled Lamps | | |
|---|---|---|---|
| | 40-50 Watts | 60-150 Watts | 200 Watts and up |
| $B_2$ | 3.685 | 3.613 | 3.384 |
| $B_3$ | 1.523 | 1.523 | 1.543 |
| $B_5$ | 13.5 | 13.5 | 13.1 |

After determining from figure 1 what voltage lamp to buy, one can compute the savings to be made by using equations 1, 2, and 3. If it is desired to make a comparison on the basis of cost per 1,000 lumen-hour hours, the additional formula may be used,

$$\text{Cost per 1,000 lumen-hours} = \frac{Ct + c}{Lt/1{,}000} \qquad (5)$$

where
$C$ equals cost of power in cents per hour
$t$ equals life of lamp in hours
$L$ equals average lumens output of lamp

A very interesting example met with in actual practice, involving all of the foregoing formulas, is as follows: A certain firm was using 200-watt lamps for general illumination, which was considered sufficient. The cost of electricity was approximately 2½ cents per kilowatt-hour. The average operating voltage was close to 113 volts. Lamps rated 120 volts were bought at a 20 per cent discount, and the labor cost for installation was estimated at 8 cents per lamp.

$$\frac{bP_0}{c} = \frac{2.5 \times 200}{48 + 8} = 8.93$$

From figure 1, $V/V_0$ equals 1.053. Therefore, the lamp rating for most economical operation is

$$V_0 = \frac{113}{1.053} = 107 \text{ volts (approximately)}$$

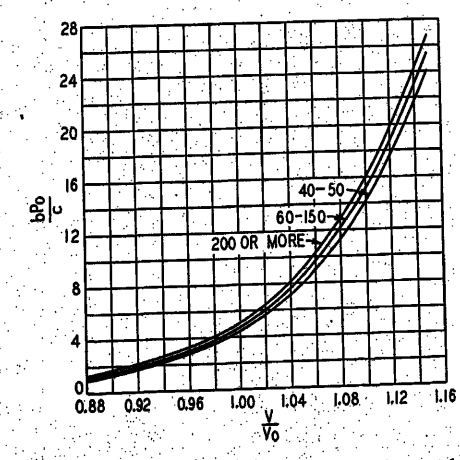


**Figure 1. Curves for determining most economical voltage**

Numbers on curves are ratings of lamps in watts

so 110-volt lamps should be used. But it has been stated that the illumination was considered sufficient, and using 200-watt lamps of this voltage rating would increase the illumination, the number of burn outs, and the power.

A comparison may now be made with 150-watt lamps. Using equations 1, 2, and 3 for the 200-watt 120-volt lamp, and obtaining the value of $F_0$ from the manufacturer's table,

Lumens output at 113 volts
Luminous flux = $F$ =

$$F_0\left(\frac{V}{V_0}\right)^{B_2} = 3{,}400\left(\frac{113}{120}\right)^{3.384} =$$

2,770 lumens.

Life of lamp = $L$ =

$$L_0\left(\frac{V}{V_0}\right)^{-B_5} = 1{,}000\left(\frac{113}{120}\right)^{-13.1} =$$

2,190 hours.

Power = $P$ =

$$P_0\left(\frac{V}{V_0}\right)^{1.543} = 200\left(\frac{113}{120}\right)^{1.543} =$$

182.5 watts.

Similarly, for the 150-watt 110-volt lamp on a 113-volt circuit, the following values are obtained:
$F$ equals 2,660 lumens
$L$ equals 698 hours
$P$ equals 156.2 watts
Using equation 5 for the 200-watt 120-volt lamp,

Cost per 1,000 lumen-hours =

$$\frac{2.5 \times \frac{182.5}{1{,}000} \times 2{,}190 + 56}{2{,}770 \times 2{,}190 \div 1{,}000} = 0.174 \text{ cents.}$$

For the 150-watt 110-volt lamp,
Cost per 1,000 lumen-hours =

$$\frac{2.5 \times \frac{156.2}{1{,}000} \times 698 + 40}{2{,}660 \times 698 \div 1{,}000} = 0.168 \text{ cents}$$

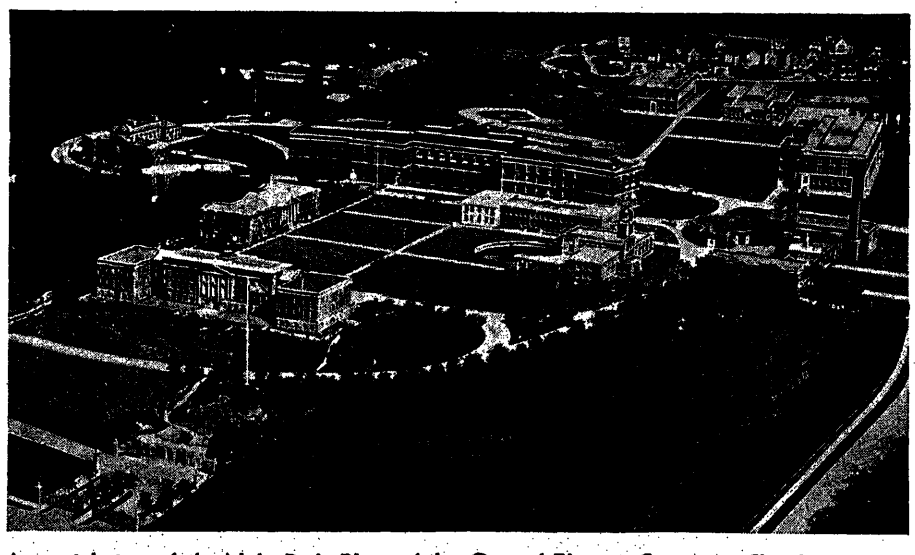
Now since the 150-watt lamp in this case has a lumen output almost equal to that of the 200-watt lamp, and the cost per lumen-hour is less for the 150-watt lamp, then the latter is the one to use.

However, the most interesting part is that there was another electric rate which the firm wanted to get on. The cost for power on this more favorable rate would amount to about 2 cents per kilowatt-hour, while the firm was paying around 2½ cents per kilowatt-hour on the rate which it was on. In the availability clause of this better rate was this requirement, "the lighting load shall not exceed 10 per cent of the total connected load." This requirement made the firm ineligible for the better rate, although their percentage of lighting load did not exceed 10 per cent by a great margin. However, it so happened that changing over to the 150-watt 110-volt lamps made it possible to get more lumens per kilowatt-hour, practically the same amount of illumination, and at the same time, to reduce the lighting load so as to get on this more favorable rate and net a savings of almost $2,000 a year.

Very truly yours,
CAMPBELL McCORD
Engineer, The Knoxville News-Sentinal, Knoxville, Tenn.

# Personal Items

S. P. MacFadden (A'19, M'30) vice-president of the Puget Sound Power & Light Company, Seattle, Wash., has assumed new duties as executive vice-president of the company. Mr. MacFadden was born June 17, 1894, at Laredo, Texas and received the degree of bachelor of science in electrical engineering at the Texas Agricultural and Mechanical College in 1916. Following his graduation, he entered the student engineering course of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., and upon completion of the course in 1917 became affiliated with the Eastern Texas Electric Company, Beaumont. In the same year, however, he received a commission as lieutenant in the Coast Artillery Corps of the United States Army, and served with the American Expeditionary Force in France until 1919. At the end of the World War, Mr. MacFadden returned to the employ of the Eastern Texas Electric Company, but remained there only briefly before being designated assistant to the district manager of the southwestern district of Stone and Webster, Inc., with offices at Houston, in 1920. From 1924 until 1930 he was associated with several companies, including the Eastern Texas Electric Company, Port Arthur; Western Public Service Company, Scottsbluff, Nebr.; and Stone and Webster Service Corporation, Boston, Mass. Mr. MacFadden has been vice-president of the Pugent Sound Power & Light Company since 1930.



F. B. Corey (A'93, F'12, member for life) plant engineer, Pittsburgh Valve and Fittings Division, The Pitcairn Company, Barberton, Ohio, has retired from active service. Mr. Corey was born September 28, 1869, at Homer, N. Y., and was graduated from Cornell University with the degree of mechanical engineer in 1892, following which he entered the employ of the Elektron Manufacturing Company as a sales engineer in the Boston, Mass., offices. After several other brief affiliations he became a designing engineer in the railway engineer department of the General Electric Company in 1900. Mr. Corey remained with that company until 1911 before becoming engineer of inspection and tests for the Union Switch and Signaling Company Swissvale, Pa. In 1914 he established his own consulting-engineering offices in Pittsburgh, Pa., but in 1916 was appointed efficiency engineer for the Pittsburgh Valve and Fittings Company, Barberton. He was employed by that company in various capacities for more than 20 years before his retirement.

B. T. Anderson (A'35) who has been director of the bureau of railway signaling economics of the Union Switch & Signal Company, New York, N. Y., has been appointed general sales manager of the company. Mr. Anderson, a native (1884) of Alexis, Ill., received the degree of bachelor of science in electrical engineering at the University of Illinois in 1907, and upon graduation entered an apprenticeship course in railway signaling in the Union Switch and Signaling Company, Swissvale, Pa. In 1910 he became a draftsman for the Atchison, Topeka, and Santa Fe Railway Company, Topeka, Kans., but later was made construction foreman and assistant signal engineer and remained with that company until 1914. In that year he was appointed assistant signal engineer with the Delaware, Lackawanna, and Western Railway Company, Hoboken, N. J., where he remained until 1923. For 4 years (1923–27) Mr. Anderson was superintendent of signals for the Chesapeake and Ohio Railway Company, with offices at Richmond, Va., and during that period became active in the work of the American Railway Association. Since 1927 he has been affiliated with the Union Switch and Signaling Company as assistant to the vice-president, assistant to the president, publicity representative, and director of the bureau of railway signaling economics.

M. M. Kenneally (M'29) for the last 7 years manager of the power utilities department of the Ohio Brass Co., Mansfield, has been appointed sales manager of the Porcelain Insulator Corporation, Lima, N. Y. Mr. Kenneally was born March 16, 1894, at Oelwein, Iowa, and received the degrees of bachelor of science in electrical engineering (1915) and electrical engineer (1920) at Iowa State College. Following brief associations with several public utility companies, he was appointed electrical engineer on operation and construction for the Iowa Public Service Company, at Humboldt, in 1924. In 1926 Mr. Kenneally became assistant to the electrical engineer of the United Gas Improvement Company, Philadelphia, Pa., in which capacity he assisted in designing and supervising the construction of transmission equipment for that system. In the following year he became affiliated with the Ohio Brass Co. in its high-voltage laboratory, and after a few months' training there, was transferred to the New York, N. Y., offices of the company. In 1928 he was named district sales manager in the New York area, and in 1930 was returned to the Mansfield offices as manager of the power utilities department, in charge of sales, advertising, and engineering.

H. F. Boe (M'30) eastern district manager, Westinghouse Electric & Manufacturing Company, New York, N. Y., has assumed additional duties as commercial manager of the company. Mr. Boe, a native (1884) of Mansfield, Ohio, attended Carnegie Institute of Technology, and has been associated with the Westinghouse company since 1900, continuously except for one year (1916–17) as chief engineer and manager of the Vaile Kimes Company, Dayton, Ohio. Until 1916 Mr. Boe's work was in general engineering and sales in the East Pittsburgh offices of the Westinghouse company; in 1918 he was transferred to the Rochester, N. Y., offices as a sales engineer, and in 1922 he went to Buffalo, N. Y., as district industrial division manager. Later he was made manager of that office, and in 1935 was transferred to New York, N. Y., where in 1936 he became eastern district manager.

H. W. Tenney (M'36) section engineer in the materials and process engineering department of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., has been appointed engineering manager of the recently created new products division of the company. Mr. Tenney, a native (1899) of Leominster, Mass., received the degrees of bachelor of science in electrical engineering (1920) and electrical engineer (1922) at Worcester Polytechnic Institute, and has been associated with the

**An aerial view of the Nela Park Plant of the General Electric Company, Cleveland, Ohio which may be visited by those attending the Middle Eastern District meeting, Akron, Ohio, October 13-15**

Westinghouse company continuously since his graduation in 1920. He entered the employ of the company as a laboratory assistant, but later became successively oscillograph specialist, foreman in charge of the engineering laboratory, assistant section engineer in the materials and process engineering section, and section engineer.

S. L. NICHOLSON (A'00, F'13, member for life) assistant to vice-president, Westinghouse Electric & Manufacturing Company, New York, N. Y., has relinquished his duties in that organization, and is retiring from active business. Mr. Nicholson was born November 10, 1870, at Germantown, Pa., and received his formal education in private schools in Philadelphia. After having held several engineering positions in Philadelphia and New York, he was engaged by the Westinghouse company as a sales engineer in 1898. In 1909 Mr. Nicholson was made sales manager, and in 1917 became assistant to the vice-president. He has been active in the affairs of the National Electrical Manufacturers Association and the American Standards Association.

VANNEVAR BUSH (A'15, F'24 Lamme Medalist '35, director) vice-president and dean of engineering, Massachusetts Institute of Technology, Cambridge, has been appointed a member of a special committee of the National Research Council to make a comprehensive survey of the applications of radio, sound recording and reproduction, motion pictures, photography, and other scientific achievements in the field of education.

C. L. COLLENS (A'07) president of the Reliance Electric and Engineering Company of Cleveland, Ohio, has been elected to membership on the board of directors of the American Standards Association, on nomination of the National Electrical Manufacturers Association. Mr. Collens is a past member of the ASA board (1929–32) and a past-president of NEMA in various activities of which he long has been active.

F. B. JEWETT (A'03, F'12, Edison Medalist '28, past-president) vice-president American Telephone and Telegraph Company, New York, N. Y., has been appointed a member of a special committee of the National Research Council to make a comprehensive survey of how radio, sound recording and reproduction, motion pictures, photography, and other scientific achievements may be applied to learning.

W. R. VAN BOKKELEN (A'12, M'26) has been appointed chief of the division of electricity for the 1939 Golden Gate International Exposition at San Francisco, Calif. Mr. Van Bokkelen was electrical engineer and chief engineer of the Coast Counties Gas and Electric Company, San Francisco, for 18 years; has been in consulting practice for the past few years.

G. V. HARRAP (A'34) assistant engineer in the power station of the Hull (England) Corporation Electricity Department, has been awarded a premium by the Institution of Electrical Engineers (Great Britain) for his paper "Taxation of Electricity Undertakings," recently presented before a session of the Institution.

O. A. BECKLUND (Enrolled Student) has received the AIEE Great Lakes District prize for branch paper for his paper "An Artificial Ear for Sound Measurements." Mr. Becklund is a native (1915) of St. Paul, Minn., and received the degree of bachelor of engineering in June 1937, at the University of Minnesota.

R. E. LYLE (A'32) who has been an electrical engineer in the engineering experiment station of Washington State College, Pullman, recently joined the engineering division of the Westinghouse Electric & Manufacturing Company, Seattle.

FRANK WALSH (A'26, M'30) district manager, Puget Sound Power and Light Company, Bellingham, Wash., has been elected a vice-president of the Northwest Electric Light and Power Association for the state of Washington.

P. J. AMBROSE (A'36) who has been a radio-engineering instructor at Indiana Technical College, Fort Wayne, now is employed in the power distribution department of the Consumers Power Company, Jackson, Mich.

E. A. RICKER (A'36) formerly a demonstrator on the faculty of applied science of the University of Toronto (Ont., Canada), now is a draftsman for the Canadian Westinghouse Company, Hamilton, Ont.

W. H. MCGRATH (A'02, M'20) has retired from active duty as executive vice-president of the Puget Sound Power & Light Company, Seattle, Wash. He will continue as a director of the company.

F. L. WEST (A'37) assistant engineer, Niagara, Lockport, and Ontario Power Company, Buffalo, N. Y., has been transferred to the Avon, N. Y., offices of that company in the capacity of superintendent.

H. E. PEARSON (A'26, M'32) formerly district power maintainer for the Board of Transportation of the City of New York, N. Y., now is employed by the Roller-Smith Company, Bethlehem, Pa.

## Obituary

JOHN WHITE HOWELL (A'87, M'88, F'12, Edison Medalist '24, member for life, past manager) retired chief engineer of the lamp works of the General Electric Company, died July 28, 1937. Mr. Howell was born at New Brunswick, N. J., December 22, 1857. In 1881, he finished a special course in electrical engineering at Stevens Institute of Technology, and received the honorary degree of electrical engineer in 1899. He became identified with the Edison Lamp Company as an electrician in 1881, and became technical adviser to the manager of works in 1890; in 1912, when the company became a part of the General Electric Company, he was engineer and assistant manager of the lamp works. He retired in 1931 as chief engineer. He was recognized as one of the most distinguished of electrical pioneers in the production of incandescent lamps. Among his important achievements were the development of a successful portable voltmeter, a Wheatstone bridge type of potential indicator, and the comparative indicator. He determined for the first time the relation between the life and candle power of an incandescent lamp (1886); introduced a carbonaceous clamp that decreased clamping and filament costs and increased the quality of the lamp (1887); and later made changes to effect an increase in the speed of exhausting the envelope. He improved the Thomson-Houston method of treating carbon filaments, and devised a machine that made great advances in the treating process. He assisted in the design of the first stem-making machine and in the derivation of metalized filaments. Mr. Howell was a manager of the Institute, 1888–90, and a member of The American Society of Mechanical Engineers, Franklin Institute, and other technical societies. He was a member of the Edison Medal Committee from 1926 to 1931.

CHARLES BROSSMAN (M'28) consulting engineer, Indianapolis, Ind., died June 30, 1937. Mr. Brossmann was born January 17, 1877, at Philadelphia, Pa., and received his formal technical education at the Philadelphia Manual Training High School. In 1896 he became a draftsman and designer for the Baldwin Locomotive Works at Philadelphia, were he remained until 1898, when he served in the Spanish-American War. In 1900, he was engaged by the Indianapolis Water Company for some special design work, and in 1904 he established the consulting-engineering company of Brossman and King, with offices at Indianapolis. Mr. Brossman maintained his consulting practice continuously for more than 32 years, and was active in the affairs of the Indiana Engineering Society. He was a member of The American Society of Mechanical Engineers, American Society of Civil Engineers, and American Water Works Association.

FRANK BENJAMIN RAE (A'84, M'20, member for life) retired consulting engineer, Berkeley, Calif., and a charter member of the Institute, died July 28, 1937. Mr. Rae was born July 25, 1854, at Elmira, N. Y., and was self-educated. From 1870 until 1881 he was engaged in the telegraph business, first as messenger and operator, and later as manager of the Atlantic and Pacific Telegraph Company and the Western Union Telegraph Company. In 1881, he resigned the position of electrician at San Francisco for the Western Union company and became engineer for the Brush Electric Light Company, San Francisco,

and manager of the San Jose (Calif.) Brush Electric Company. In 1883 he became engineer for the Commercial Telegram Company, an organization devoted to dispatching stock quotations, at New York, N. Y. From 1885 to 1887 he was a consulting engineer in New York, as a member of the firm of Mailloux and Rae. In 1887 Mr. Rae was consulting engineer for the Barker Syndicate in China, and from 1887 until 1892 was engineer for the Detroit (Mich.) Electrical Works, engaged on the Rae Electric Railway System. Since 1892 he had been a consulting electrical engineer in various cities throughout the United States. In 1923 he became electrical engineer for the city of Berkeley, Calif., but resigned and retired from active service in 1930. Mr. Rae was the holder of about 100 patents on various electrical devices and systems.

WILLIAM GODFREY HEPTINSTALL (A'26) manager of Waikato Carbonisation, Ltd., Rotowaro, New Zealand, died October 1, 1936, according to word just received at Institute headquarters. Mr. Heptinstall was born July 2, 1883, at Yorkshire, England, and attended London (England) University. Following a period of service with the Royal (British) Naval Volunteer Reserve he went to Canada, where he took charge of the operation of a small municipal gas and electric plant for the town of Minnedosa, Man. In 1920 he became plant superintendent of the Lignite Utilization Board, Bienfait, Sask., and remained there for almost 10 years before going to New Zealand to become manager of Waikato Carbonisation, Ltd.

ROBERT KING (A'35) electrical engineer in the port department, City of Oakland, Calif., died recently. Mr. King was born March 4, 1885, in Alaska, and received his technical education by serving an apprenticeship in an electrical shop. In 1901 he established an electrical-contracting business, which he maintained until 1925, when he started a wholesale electrical-supply business. From 1927 until 1929 he served as a consulting engineer during the construction of several public schools in or near Oakland. He was appointed electrical engineer in the port department of that city in 1929.

# Membership

## Addresses Wanted

A list of members whose mail has been returned by the postal authorities is given below, with the addresses as they now appear on the Institute record. Any member knowing of corrections to these addresses will kindly communicate them at once to the office of the secretary at 33 West 39th St., New York, N. Y.

Charlton, H. C., 4827 Wilson Avenue, Montreal, Que., Canada.
Evans, Maldwyn F., Canadian Comstock Company, Ltd., Toronto, Ont., Canada.
Gregory, G. A., 1217 Jefferson Street, Olympia, Wash.
Hardy, John E., 1741 Pennsylvania Avenue, Denver, Colo.
Jones, K. B., Trumbull Electric Manufacturing Company, Inc., Ludlow, Ky.
Roberts, Fred A., 2010 West Michigan Street, Indianapolis, Ind.
Schaefer, Philip E., 5154 St. Paul Avenue, Chicago, Ill.
Sikofsky, George L., 1206 East New York Avenue, Brooklyn, N. Y.

## Applications for Election

Applications have been received at headquarters from the following candidates for election to membership in the Institute. If the applicant has applied for direct admission to a grade higher than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the national secretary before September 30, 1937 or November 30, 1937, if the applicant resides outside of the United States or Canada.

# Engineering Literature

## New Books in the Societies Library

Among the new books received at the Engineering Societies Library, New York, recently are the following which have been selected because of their possible interest to the electrical engineer. Unless otherwise specified, books listed have been presented gratis by the publishers. The Institute assumes no responsibility for statements made in the following outlines, information for which is taken from the preface of the book in question.

ALIGNING PHILCO RECEIVERS. By J. F. Rider. New York, John F. Ryder, 1440 Broadway, 1937. 136 pages, diagrams, 8x5 inches, cloth, $1.00. A practical manual for the repairman, containing diagrams and tables for every model of Philco receiver from the earliest to those for 1937.

FUNDAMENTALS of ENGINEERING ELECTRONICS. By W. G. Dow. New York, John Wiley, 1937. 604 pages, illustrated, 10x6 inches, cloth, $5.00. Emphasizes chiefly internal operating principles. A large part of the text is devoted to a study of the use of various geometrics and materials in electronic devices, and a relatively small part to circuit studies. The point of view is that of the engineer.

SOUND. By A. T. Jones. New York, D. Van Nostrand Company, 1937. 450 pages, illustrated, 9x6 inches, cloth, $3.75. An elementary book on sound. Sound production and transmission, free and forced vibrations, musical scales and instruments, speech and hearing are considered with their modern technical applications.

**Engineering Societies Library**
29 West 39th Street, New York, N. Y.

MAINTAINED as a public reference library of engineering and the allied sciences, this library is a co-operative activity of the national societies of civil, electrical, mechanical, and mining engineers.

Resources of the library are available also to those unable to visit it in person. Lists of references, copies or translation of articles, and similar assistance may be obtained upon written application, subject only to charges sufficient to cover the cost of the work required.

A collection of modern technical books is available to any member residing in North America at a rental rate of five cents per day per volume, plus transportation charges.

Many other services are obtainable and an inquiry to the director of the library will bring information concerning them.

# Officers and Committees for 1937-38

## Officers

**President**

W. H. HARRISON — New York, N. Y.
*(Term expires July 31, 1938)*

**Junior Past-Presidents**

J. B. WHITEHEAD — Baltimore, Md.
*(Term expires July 31, 1938)*

A. M. MacCUTCHEON — Cleveland, Ohio
*(Term expires July 31, 1939)*

**Vice-Presidents**

| Dist. No. | | |
|---|---|---|
| 1 | A. C. STEVENS | Schenectady, N. Y. |
| 3 | O. B. BLACKWELL | New York, N. Y. |
| 5 | C. F. HARDING | Lafayette, Ind. |
| 7 | L. T. BLAISDELL | Dallas, Tex. |
| 9 | C. E. ROGERS | Seattle, Wash. |

*(Terms expire July 31, 1938)*

| | | |
|---|---|---|
| 2 | I. MELVILLE STEIN | Philadelphia, Pa. |
| 4 | E. D. WOOD | Louisville, Ky. |
| 6 | L. N. McCLELLAN | Denver, Colo. |
| 8 | J. P. JOLLYMAN | San Francisco, Calif. |
| 10 | M. J. McHENRY | Toronto, Ont. |

*(Terms expire July 31, 1939)*

**Directors**

F. M. FARMER — New York, N. Y.
N. E. FUNK — Philadelphia, Pa.
H. B. GEAR — Chicago, Ill.
*(Terms expire July 31, 1938)*

F. ELLIS JOHNSON — Columbia, Mo.
C. R. JONES — New York, N. Y.
W. B. KOUWENHOVEN — Baltimore, Md.
*(Terms expire July 31, 1939)*

K. B. McEACHRON — Pittsfield, Mass.
C. A. POWEL — East Pittsburgh, Pa.
R. W. SORENSEN — Pasadena, Calif.
*(Terms expire July 31, 1940)*

C. R. BEARDSLEY — Brooklyn, N. Y.
VANNEVAR BUSH — Cambridge, Mass.
F. H. LANE — Chicago, Ill.
*(Terms expire July 31, 1941)*

**National Treasurer**

W. I. SLICHTER — New York, N. Y.
*(Term expires July 31, 1938)*

**National Secretary**

H. H. HENLINE — New York, N. Y.
*(Term expires July 31, 1938)*

**General Counsel**

Parker & Aaron
20 Exchange Place, New York, N. Y.

**Local Honorary Secretaries**

AUSTRALIA—V. J. F. Brain, Dept. of Works & Local Govt., Bridge St., Sydney, N. S. W.

BRAZIL—F. M. Servos, Rio de Janeiro Tramways Light & Power Co., Rio de Janeiro, Brazil, S. A.

ENGLAND—A. P. M. Fleming, Metropolitan Vickers Elec. Co., Trafford Park, Manchester.

FRANCE—A. S. Garfield, 173 Boulevard Haussmann, Paris, 8E.

INDIA—H. P. Thomas, Oriental Building, The Mall, Lahore, Punjab.

ITALY—Renzo Norsa, Piazza Irnerio 8, Milano.

NEW ZEALAND—P. H. Powell, Canterbury College, Christchurch.

SWEDEN—A. F. Enstrom, Ingeniorsvetenskrapsakademien, Stockholm.

TRANSVAAL—W. Elsdon-Dew, P. O. Box 4563, Johannesburg, Transvaal, Africa.

## General Committees

**Executive**

W. H. Harrison, Chm., 195 Broadway, New York, N. Y.

| | |
|---|---|
| O. B. Blackwell | A. M. MacCutcheon |
| F. M. Farmer | W. I. Slichter |
| C. R. Jones | A. C. Stevens |

**Board of Examiners**

F. V. Magalhaes, Chm., Consolidated Edison Co. of New York, Inc., 4 Irving Place, New York, N. Y.
H. E. Farrer, Secy., AIEE., 33 W. 39th St., New York, N. Y.

| | | |
|---|---|---|
| F. E. D'Humy | | A. E. Knowlton |
| F. M. Farmer | | R. H. Marriott |
| Harold Goodwin, Jr. | | A. G. Oehler |
| C. D. Gray | | A. L. Powell |
| H. A. Kidder | S. D. Sprong | H. E. Shreeve |

**Code of Principles of Professional Conduct**

H. V. Carpenter, Chm., State College of Washington, Pullman, Wash.

| | |
|---|---|
| L. W. Chubb | H. T. Plumb |
| D. C. Jackson | C. E. Stephens |
| F. B. Jewett | J. B. Whitehead |

**Columbia University Scholarships**

W. I. Slichter, Chm., Columbia University, New York, N. Y.

| | |
|---|---|
| Francis Blossom | H. C. Carpenter |

**Constitution and By-Laws**

L. W. W. Morrow, Chm., Corning Glass Works, Corning, N. Y.

| | | |
|---|---|---|
| C. O. Bickelhaupt | | H. A. Kidder |
| R. N. Conwell | W. I. Slichter | Everett S. Lee |

**Co-ordination of Institute Activities**

Vannevar Bush, Chm., Massachusetts Institute of Technology, Cambridge, Mass.

| | |
|---|---|
| H. H. Henline | H. S. Osborne |
| C. R. Jones | I. Melville Stein |
| L. W. W. Morrow | W. H. Timbie |

**Economic Status of the Engineer**

R. W. Sorensen, Chm., California Institute of Technology, Pasadena, Calif.

| | |
|---|---|
| T. F. Barton | F. M. Feiker |
| C. O. Bickelhaupt | A. H. Lovell |

**Edison Medal**

*Appointed by the President for term of 5 years*

V. Bush — H. P. Charlesworth, Chm. K. S. Wyatt *(Terms expire July 31, 1938)*

H. B. Gear — L. W. W. Morrow — J. B. Whitehead *(Terms expire July 31, 1939)*

F. J. Meyer — R. A. Millikan — Marion Penn *(Terms expire July 31, 1940)*

G. L. Knight — H. W. Osgood — W. S. Rodman *(Terms expire July 31, 1941)*

C. R. Jones — Everett S. Lee — H. S. Osborne *(Terms expire July 31, 1942)*

*Appointed by the Board of Directors from its own membership for term of 2 years*

F. M. Farmer — C. E. Rogers — A. C. Stevens *(Terms expire July 31, 1938)*

C. R. Beardsley — K. B. McEachron — A. M. MacCutcheon *(Terms expire July 31, 1939)*

*Ex-Officio*

W. H. Harrison, President
W. I. Slichter, National Treasurer
H. H. Henline, National Secretary
*(Terms expire July 31, 1938)*

**Finance**

C. R. Jones, Chm., Westinghouse Elec., & Mfg. Co., 150 Broadway, New York, N. Y.

| | |
|---|---|
| O. B. Blackwell | N. E. Funk |

**Headquarters**

F. M. Farmer, Chm., Electrical Testing Laboratories, 80th St. & East End Ave., New York, N. Y.

| | |
|---|---|
| H. H. Henline | C. R. Jones |

**Institute Policy**

A. M. MacCutcheon, Chm., 1088 Ivanhoe Rd., Cleveland, Ohio

| | |
|---|---|
| H. P. Charlesworth | C. F. Harding |
| Mark Eldredge | R. H. Tapscott |
| F. M. Farmer | J. B. Whitehead |

**Iwadare Foundation**

F. B. Jewett, Chm., 195 Broadway, New York, N. Y.

| | |
|---|---|
| J. W. Barker | H. H. Barnes, Jr. |

**Lamme Medal**

L. W. Chubb — N. E. Funk, Chm. — W. H. Harrison *(Terms expire July 31, 1938)*

V. Bush — C. R. Jones — D. C. Prince *(Terms expire July 31, 1939)*

F. J. Chesterman — A. H. Kehoe — C. F. Hirshfeld *(Terms expire July 31, 1940)*

**Legislation Affecting the Engineering Profession**

J. B. Thomas, Chm., Texas Electric Service Co., Electric Building, Fort Worth, Tex.

| | |
|---|---|
| J. P. Alexander | F. M. Gunby |
| T. F. Barton | D. C. Jackson |
| C. R. Beardsley | L. S. Ready |
| B. M. Brigman | C. E. Rogers |
| D. T. Canfield | M. R. Scharff |
| O. J. Ferguson | R. L. Thomas |
| N. E. Funk | W. K. Vanderpoel |

**Membership**

G. A. Kositzky, Chm., The Ohio Bell Telephone Co., 750 Huron Rd., Cleveland, Ohio.
R. L. Webb, Asst. Chm., Consolidated Edison Co. of New York, Inc., 4 Irving Pl., New York, N. Y.

| | | |
|---|---|---|
| T. F. Ball | | P. G. Edwards |
| W. E. Crawford | | F. Ellis Johnson |
| E. A. Crellin | | Everett S. Lee |
| C. L. Dawes | J. R. MacGregor | C. A. Loveless |

*District Vice Chairman*

| | |
|---|---|
| C. M. Foust (1) | Nelson R. Love (6) |
| M. W. Smith (2) | E. T. Gunther (7) |
| J. E. McCormack (3) | F. B. Doolittle (8) |
| A. S. Anderson (4) | John Bankus (9) |
| C. A. Cora (5) | A. B. Cooper (10) |

*Ex-officio*

Chairman of membership committees of all Sections

**Prizes, Award of Institute**

H. S. Osborne, Chm., American Tel. & Tel. Co., 195 Broadway, New York, N. Y.

| | |
|---|---|
| J. W. Barker | I. Melville Stein |
| | W. B. Kouwenhoven |

**Publication**

I. Melville Stein, Chm., Leeds & Northrup Co., 4901 Stenton Ave., Philadelphia, Pa.
F. A. Lewis, Secy., AIEE, 33 W. 39th St., New York, N. Y.

| | |
|---|---|
| J. W. Barker | H. S. Osborne |
| O. W. Eshbach | H. S. Phelps |
| H. H. Henline | D. M. Simmons |
| L. W. W. Morrow | M. W. Smith |
| A. G. Oehler | W. H. Timbie |

GENERAL COMMITTEES—Continued

### Safety

Wills Maclachlan, Chm., 50 Oakwood Ave., Toronto, Ont.

L. F. Adams — M. G. Lloyd
A. W. Berresford — H. N. Pye
G. S. Diehl — A. R. Small
J. E. Goodale — Frank Thornton, Jr.
F. D. Knight — W. C. Wagner
W. B. Kouwenhoven — H. S. Warren
H. H. Weber

### Sections

W. H. Timbie, Chm., Massachusetts Institute of Technology, Cambridge, Mass.

M. S. Coover — E. T. Mahood
W. M. Dann — H. H. Race
O. W. Holden — C. S. Thorn — I. Melville Stein

*Ex-officio*

Chairmen of all Institute Sections

### Standards

V. M. Montsinger, Chm., General Electric Co., Pittsfield, Mass.

H. E. Farrer, Secy., AIEE, 33 W. 39th St., New York, N. Y.

O. B. Blackwell — A. H. Kehoe
L. E. Fogg — J. Franklin Meyer
C. R. Harte — E. L. Moreland
R. E. Hellmund — S. L. Mortensen
R. T. Henry — H. W. Price — E. B. Paxton

*Ex-officio*

Chairmen of Working Committees
Chairmen of AIEE delegations on other standardizing bodies or sole representative thereon.
President of U.S. National Committee of International Electrotechnical Commission.

### Student Branches

F. Ellis Johnson, Chm., University of Missouri, Columbia, Mo.

Edward Bennett — T. W. Fitzgerald
E. E. Dreese — E. A. Loew
O. E. Edison — Charles F. Scott
O. W. Eshbach — R. W. Sorensen

*Ex-officio*

Student Branch counselors

### Technical Program

H. S. Osborne, Chm., American Tel. & Tel. Co., 195 Broadway, New York, N. Y.

C. S. Rich, Secy., AIEE, 33 W. 39th St., New York, N. Y.

C. R. Beardsley — L. W. W. Morrow
H. S. Bennion — M. W. Smith
R. N. Conwell — I. Melville Stein
V. M. Montsinger — W. E. Wickenden
T. A. Worcester

*Ex-officio*

Vannevar Bush, Chairman, Committee on Co-ordination of Institute Activities
Wills Maclachlan, Chairman, Committee on Safety
Chairmen of all Technical Committees

### Transfers

Everett S. Lee, Chm., General Electric Co., Schenectady, N. Y.

F. M. Craft — Harold Goodwin, Jr.
H. C. Don Carlos — C. F. Harding
F. O. McMillan

## Technical Committees

### Automatic Stations

O. J. Rotty, Chm., Union Electric Light & Power Company, 315 N. 12th Boulevard, St. Louis, Mo.

F. F. Ambuhl — L. N. McClellan
A. E. Anderson — G. E.Northup
R. B. Arthur — N. C. Pearcy
H. W. Codding — A. Perry Peterson
A. M. de Bellis — C. F. Publow
F. S. Douglass — M. E. Reagan
W. W. Edson — Garland Stamper
Joseph Hellenthal — L. J. Turley
F. H. Lane — Chester Wallace
J. T. Logan — W. C. Whitman

### Basic Sciences

E. E. Dreese, Chm., Ohio State University, Columbus, Ohio

S. S. Attwood — M. G. Malti
A. Boyajian — K. B. McEachron
W. F. Davidson — K. W. Miller
L. O. Grondahl — G. W. Penney
V. Karapetoff — H. H. Race
M. J. Kelly — J. Slepian
H. P. Lawther, Jr. — J. D. Tebo
F. C. Lindvall — Ernst Weber — A. Von Hippel

### Communication

W. L. Everitt, Chm., Ohio State University, Columbus, Ohio

E. J. O'Connell, Secy., American Tel. & Tel. Co., 195 Broadway, New York, N. Y.

C. B. Aiken — H. J. Pierce
A. L. Albert — H. Pratt
W. C. Ballard, Jr. — C. E. Rogers
H. H. Beverage — M. A. Sawyer
E. L. Bowles — E. R. Shute
L. W. Chubb — Arthur Bessey Smith
A. B. Clark — Burke Smith
John L. Clarke — D. F. Smith
J. B. Coleman — H. W. Sundius
H. J. Dible — A. H. Taylor
Melville Eastham — C. H. Taylor
E. E. George — F. E. Terman
G. H. Gray — J. R. Tolmie
W. F. Grimes — H. M. Turner
C. B. Jolliffe — M. P. Weinbach
H. E. Kent — W. C. White
J. R. MacGregor — F. A. Wolff
F. R. McBerty — F. C. Young
V. K. Zworykin

### Education

J. W. Barker, Chm., Columbia University, New York, N. Y.

Robin Beach — F. Ellis Johnson
H. W. Bibber — A. S. Langsdorf
F. C. Bolton — A. D. Moore
H. V. Carpenter — E. L. Moreland
M. S. Coover — R. C. Putnam
J. A. Correll — E. M. Strong
E. E. Dreese — F. E. Terman
A. M. Dudley — Norman L. Towle
O. W. Eshbach — H. N. Walker
C. Francis Harding — R. I. Wilkinson

### Electric Welding

W. E. Crawford, Chm., A. O. Smith Corp., Milwaukee, Wis.

C. A. Adams — G. G. Landis
J. H. Blankenbuehler — Hermann Lemp
A. M. Candy — J. C. Lincoln
J. W. Dawson — C. L. Pfeiffer
Saul Dushman — C. A. Powel
D. D. Ewing — C. Stansbury
K. L. Hansen — H. E. Stoddard
H. M. Hobart — Malcolm Thomson
C. J. Holslag — H. A. Winne

### Electrical Machinery

J. L. Hamilton, Chm., Century Electric Co., St. Louis, Mo.

P. L. Alger, Vice-Chm., General Electric Co., Schenectady, N. Y.

C. M. Gilt, Secy., Consolidated Edison Co. of N. Y., Inc., 4 Irving Pl., New York, N. Y.

P. H. Adams — O. K. Marti
E. S. Bundy — V. M. Montsinger
J. E. Clem — T. H. Morgan
W. M. Dann — S. H. Mortensen
M. S. Hancock — F. L. Moser
F. E. Harrell — J. R. North
C. A. Harrington — E. B. Paxton
E. W. Henderson — F. D. Phillips
F. B. Hynes — P. H. Rutherford
C. E. Johnson — W. I. Slichter
F. Ellis Johnson — J. B. Severing
Charles Kingsley, Jr. — B. R. Teare
C. M. Laffoon — C. G. Veinott
F. C. Lindvall — G. A. Waters
W. L. Winter

### Electrochemistry and Electrometallurgy

F. O. Schnure, Chm., Bethlehem Steel Co., Sparrows Point, Md.

F. V. Andreae — C. C. Levy
E. L. Bailey — Allan Monkhouse
G. H. Clamer — J. D. Noyes
C. Dantsizen — E. M. Richards
C. L. Dudley — W. R. Schofield
F. W. Godsey, Jr. — M. F. Skinker
W. C. Kalb — N. R. Stansel
W. B. Kouwenhoven — C. P. Yoder

### Instruments and Measurements

H. C. Koenig, Chm., Electrical Testing Laboratories 80th St. & East End Ave., New York, N. Y.

C. E. Bathe — W. B. Kouwenhoven
T. M. Blakeslee — Everett S. Lee
P. A. Borden — Paul MacGahan
H. B. Brooks — H. W. Price
A. L. Brownlee — H. C. Rankin
E. D. Doyle — E. J. Rutan
W. N. Goodwin, Jr. — A. C. Seletzky
C. H. G. Gray — W. J. Shackelton
T. S. Gray — G. M. L. Sommerman
S. S. Green — H. L. Thomson
H. C. Hamilton — H. M. Turner
N. S. Hibshman — H. N. Walker
F. C. Holtz — Joseph Weil
I. F. Kinnard — R. J. Wiseman
A. E. Knowlton — D. A. Young

### Iron and Steel Production, Applications to

Wray Dudley, Chm., National Tube Co., McKeesport, Pa.

F. B. Crosby — D. M. Petty
A. C. Cummins — F. O. Schnure
James Dixon — A. C. Stevens
R. S. Fleshiem — L. A. Umansky
E. Gordon Fox — H. A. Winne
R. W. Graham — Wm. J. Wooldridge
F. E. Harrell — R. H. Wright

### Light, Production and Application of

Robin Beach, Chm., The Polytechnic Institute of Brooklyn, 99 Livingston Street, Brooklyn, N. Y.

D. W. Atwater — W. C. Kalb
J. W. Barker — R. D. Mailey
W. T. Blackwell — P. S. Millar
L. T. Blaisdell — F. H. Murphy
H. B. Dates — A. L. Powell
E. E. Dorting — F. A. Rogers
C. L. Dows — E. M. Strong
L. A. Hawkins — I. A. Yost
H. H. Higbie

### Marine Work, Applications to

A. Kennedy, Jr., Chm., General Electric Co., Schenectady, N. Y.

E. C. Alger — H. M. Southgate
R. A. Beekman — W. E. Thau
H. C. Coleman — A. E. Waller
H. F. Harvey, Jr. — O. A. Wilde
C. J. Henschel — J. L. Wilson
I. H. Osborne — R. J. Wiseman
C. A. Powel — R. L. Witham
Wm. H. Reed — W. N. Zippler

### Mining Work, Applications to

R. L. Kingsland, Chm., Consolidation Coal Co., Inc., Fairmont, W. Va.

W. A. Buchanan — H. P. Musser
J. H. Edwards — F. C. Nicholson
C. A. Faust — D. E. Renshaw
A. A. Hall — G. W. Swenson
L. C. Ilsley — W. A. Thomas
G. M. Kennedy — J. F. Wiggert
L. N. McClellan — C. D. Woodward

### Protective Devices

J. P. McKearin, Chm., Western Massachusetts Companies 73 State St., Springfield, Mass.

K. B. McEachron, Vice-Chm., General Electric Co., Pittsfield, Mass.

F. R. Longley, Secy., 73 State St., Springfield, Mass.

E. H. Bancker — H. J. Lingal
H. D. Braley — J. T. Logan
W. R. Brownlee — J. B. MacNeill
J. O'R. Coleman — J. R. McFarlin
H. W. Collins — J. W. Milnor
M. T. Crawford — C. A. Muller
L. N. Crichton — J. H. Neher
J. M. Flanigen — J. R. North
F. R. Ford — H. W. Osgood
G. W. Gerell — D. C. Prince
I. W. Gross — A. H. Schirmer
Herman Halperin — H. K. Sels
C. F. Harding — H. P. Sleeper
R. T. Henry — L. G. Smith
B. M. Jones — R. M. Smith
A. V. Joslin — H. R. Summerhayes
R. A. Larner — H. R. Stewart
T. G. LeClair — A. H. Sweetnam
W. A. Lewis — O. C. Traver
J. D. Wood

TECHNICAL COMMITTEES—Continued

**Power Applications, General**

H. W. Rogers, Chm., General Electric Company, Schenectady, N. Y.

E. A. Armstrong — H. A. McCrea
R. F. Chamberlain — M. J. McHenry
L. K. Del Homme — F. J. Meyer
C. W. Drake — J. J. Orr
J. F. Gaskill — J. B. Thomas
W. M. Harbaugh — A. E. Waller
C. N. Johnson — R. L. Walsh
A. E. Knowlton — C. J. White
F. T. Leilich — M. R. Woodward

**Power Generation**

G. M. Armbrust, Chm., Commonwealth Edison Co., 72 W. Adams St., Chicago, Ill.

H. C. Albrecht — W. E. Lloyd, Jr.
F. A. Annett — G. A. Mills
W. L. Cisler — E. F. Pearson
H. M. Cushing — G. G. Post
M. D. Engle — C. A. Powel
J. H. Foote — C. R. Reid
E. D. Freeman — H. R. Sills
R. L. Frisby — A. E. Silver
N. B. Hinson — Philip Sporn
F. H. Hollister — E. C. M. Stahl
S. J. Lisberger — E. D. Wood — Robert Treat

**Power Transmission and Distribution**

R. D. Evans, Chm., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.
Raymond Bailey, Vice-Chm., Philadelphia Elec. Co., 900 Sansom St., Philadelphia, Pa.
L. G. Smith, Secy., Cons. Gas Elec. Lt. & Pr. Co., Lexington Bldg., Baltimore, Md.

A. E. Bauhan — W. W. Lewis
D. K. Blake — E. A. Loew
M. O. Bolser — J. T. Lusignan, Jr.
A. B. Campbell — G. R. Milne
J. S. Carroll — E. W. Oesterreich
C. V. Christie — J. S. Parsons
Harold Cole — H. J. Scholz
M. T. Crawford — G. B. Shanklin
A. E. Davison — A. E. Silver
G. E. Dean — D. M. Simmons
F. W. Deck — C. T. Sinclair
Mark Eldredge — Philip Sporn
D. D. Ewing — P. B. Stewart
F. M. Farmer — Stanley Stokes
E. D. Freeman — J. J. Torok
T. H. Haines — W. K. Vanderpoel
Herman Halperin — C. F. Wagner
Edwin Hansson — H. S. Warren
K. A. Hawley — L. F. Woodruff
L. F. Hickernell — T. A. Worcester
J. P. Jollyman — H. E. Wulfing

**Research**

W. B. Kouwenhoven, Chm., Johns Hopkins University, Baltimore, Md.

F. W. Atkinson — V. Karapetoff
R. W. Atkinson — A. E. Kennelly
Leo J. Berberich — K. W. Miller
O. E. Buckley — T. D. Owens
L. W. Chubb — K. K. Paluev
M. S. Coover — H. H. Race
E. C. Crittenden — W. J. Seeley
O. G. C. Dahl — J. M. Smith
W. F. Davidson — V. G. Smith
F. M. Farmer — G. M. L. Sommerman
Herman Halperin — T. Spooner
F. Hamburger, Jr. — Ernst Weber
L. A. Hawkins — A. J. Williams
H. M. Hobard — C. H. Willis
D. C. Jackson, Jr. — R. J. Wiseman
K. S. Wyatt

**Transportation**

G. I. Wright, Chm., Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

R. Beeuwkes — A. J. Klatte
C. M. Davis — H. N. Latey
E. G. Davis — J. J. Linebaugh
J. V. B. Duer — P. A. McGee
D. D. Ewing — John Murphy
E. B. Fitzgerald — A. J. Nichol
J. E. Gardner — J. A. Noertker
Selby Haar — F. B. Powers
W. S. H. Hamilton — Dwight L. Smith
C. R. Jones — L. J. Turley
L. C. Josephs — W. M. Vandersluis
Sidney Withington

## Institute Representatives

(Where names are missing, appointments have not yet been made for 1937–38)

**Alfred Noble Prize Committee, ASCE**

H. S. Osborne

**Am. Assoc. for the Adv. of Science, Council**

C. C. Knipmeyer — R. E. Nyswander

**American Committee on Marking of Obstructions to Air Navigation**

G. E. Dean — H. L. Huber

**American Engineering Council, Assembly**

C. O. Bickelhaupt — William McClellan
F. J. Chesterman — C. E. Stephens
W. H. Harrison — H. H. Henline, *Alternate*

**American Marine Standards Committee**

**American Standards Assoc., Standards Council**

A. M. MacCutcheon — V. M. Montsinger
E. L. Moreland

*Alternates*

R. E. Hellmund — H. S. Osborne — E. B. Paxton

**American Stds. Assoc., Bd. of Directors**

H. P. Charlesworth

**American Year Book, Advisory Board**

H. H. Henline

**Charles A. Coffin Fellowship and Research Fund Committee**

W. H. Harrison

**Committee of Apparatus Makers and Users, NRC**

**Committee on Heat Transmission, NRC**

**Committee on Low Voltage Hazards, ASSE-Engg. Section, National Safety Council**

**Electrical Standards Committee, ASA**

A. M. MacCutcheon — E. L. Moreland
H. S. Osborne

*Alternates*

H. E. Farrer — R. E. Hellmund — E. B. Paxton

**Engineering Foundation Board**

F. M. Farmer — W. I. Slichter

**Engineering Societies Monographs Committee**

F. M. Farmer — W. I. Slichter

**Engineers' Council for Professional Development**

Charles F. Scott — L. W. W. Morrow

**Hoover Medal Board of Award**

H. H. Barnes, Jr. — Gano Dunn — Wm. McClellan

## Geographical District Executive Committees

| District | Chairman (Vice-President, AIEE) | Secretary (District Secretary) | Chairman, District Committee on Student Activities |
|---|---|---|---|
| No. 1—North Eastern | A. C. Stevens, General Electric Co., Schenectady, N. Y. | R. G. Lorraine, General Electric Co., Schenectady, N. Y. | F. N. Tompkins, Brown University, Providence, R. I. |
| No. 2—Middle Eastern | I. Melville Stein, Leeds & Northrup Co., 4901 Stenton Ave., Philadelphia, Pa. | H. A. Dambly, Philadelphia Electric Co., 900 Sansom St., Philadelphia, Pa. | A. G. Ennis, George Washington University, Washington, D. C. |
| No. 3—New York City | O. B. Blackwell, 463 West St., New York, N. Y. | J. F. Fairman, Consolidated Edison Co. of New York, Inc., 4 Irving Pl., New York, N. Y. | H. N. Walker, N w York University, University Heights, New York, N. Y. |
| No. 4—Southern | Edwin D. Wood, Louisville Gas & Electric Co., 311 W. Chestnut St., Louisville, Ky. | Stanley Warth, Southern Bell Tel. & Tel. Co., 521 W. Chestnut St., Louisville, Ky. | S. W. Anderson, Virginia Military Institute, Lexington, Va. |
| No. 5—Great Lakes | C. F. Harding, Purdue University, Lafayette, Ind. | A. G. Dewars, Northern States Power Co., 15 S. 5th St., Minneapolis, Minn. | S. S. Attwood, University of Michigan, Ann Arbor, Mich. |
| No. 6—North Central | L. N. McClellan, U.S. Bureau of Reclamation, 440 Customhouse, Denver, Colo. | W. F. McPhail, U. S. Bureau of Reclamation, Customhouse, Denver, Colo. | L. A. Bingham, University of Nebraska, Lincoln, Neb. |
| No. 7—South West | L. T. Blaisdell, General Electric Co., 1801 N. Lamar St., Dallas, Tex. | L. C. Starbird, 820 Telephone Building, Dallas, Tex. | Chester Russell, University of New Mexico, Albuquerque, N. M. |
| No. 8—Pacific | J. P. Jollyman, Pacific Gas & Electric Co., 245 Market St., San Francisco, Calif. | A. M. Bohnert, Ohio Brass Co., 1006 Matson Bldg., San Francisco, Calif. | E. F. Peterson, University of Santa Clara, Santa Clara, Calif. |
| No. 9—North West | C. E. Rogers, Pacific Tel. & Tel. Co., 1203 Telephone Bldg., Seattle, Wash. | Sidney E. Caldwell, Pacific Power & Light Co., Public Service Bldg., Portland Ore. | J. A. Thaler, Montana State College, Bozeman, Mont. |
| No. 10—Canada | M. J. McHenry, Canadian General Electric Co. Ltd., 212 King St. W., Toronto, Ont. | J. M. Thomson, Ferranti Electric Ltd., Mount Dennis, Toronto, Ont. | |

Note: Each District executive committee includes also the chairmen and secretaries of all Sections within the District, and the District vice-chairmen of the national Membership Committee.

INSTITUTE REPRESENTATIVES—Continued

**John Fritz Medal Board of Award**

A. W. Berresford — A. M. MacCutcheon — J. B. Whitehead

**Library Board, United Engineering Trustees, Inc.**

W. S. Barstow — H. H. Henline
W. A. Del Mar — W. I. Slichter

**National Bureau of Engineering Registration, Advisory Board**

W. I. Slichter

**Nat'l Fire Protection Assoc., Electrical Committee**

F. V. Magalhaes, *Alternate*

**National Fire Waste Council**

**Nat'l Research Council, Division of Engineering & Industrial Research**

V. Bush — Everett S. Lee — J. B. Whitehead
H. H. Henline, *ex-officio*

**Radio Advisory Committee, Bureau of Standards**

**Research Procedure Com., Engg. Foundation**

L. W. Chubb

**Thomas Alva Edison Foundation**

H. H. Barnes, Jr. — Charles F. Scott
L. W. W. Morrow — Clayton H. Sharp

**United Engineering Trustees, Inc.**

H. P. Charlesworth — G. L. Knight
H. R. Woodrow

**U.S. National Committee of the International Commission on Illumination**

Robin Beach — A. E. Kennelly — Clayton H. Sharp

**U.S. Nationa Committee of the International Electrotechnical Commission**

A. M. MacCutcheon — E. L. Moreland
H. S. Osborne

*Alternates*

H. E. Farrer — R. E. Hellmund — E. B. Paxton

**Commission of Washington Award**

H. B. Gear — G. G. Post

## Student Branches of the Institute

| Name and Location | District | Counselor (Member of Faculty) |
|---|---|---|
| Akron, Univ. of, Akron, Ohio | 2 | J. T. Walther |
| Alabama Polytechnic Inst., Auburn, Ala | 4 | W. W. Hill |

# Industrial Notes

**Pittsburgh Flood Prevention Project.**—The first major flood prevention project to reach the construction stage in the Pittsburgh district will protect the Turtle Creek Valley in which lies the huge works of the Westinghouse Elec. & Mfg. Co. and other major industries. In the future when high water from the Monongahela river threatens the valley, two huge gates will be lowered, forming a barrier against rising waters and the normal flow of Turtle Creek will be continued by means of powerful pumps. The project announced by Westinghouse vice-president Ralph Kelly, will cost $500,000. Installation of the gates will be made just below the main Westinghouse works. One of the steel gates, 80 feet long by 30 feet high will form a dam in Turtle Creek; the other, 40 feet long and 20 feet high will close the street. When not in use the gates will be held approximately 20 feet above the street level to accommodate traffic. The three pumps, of the vertical type, were designed by the Westinghouse condenser engineering department at South Philadelphia, and will have a combined capacity of 5000 to 7500 cubic feet per second. Each will be 11 feet 11 inches in diameter and will be driven at 112 rpm by 5000 hp electric motors. Each of the motors will be 23 feet in diameter.

**Progress in Building Construction.**—With the July record, once again construction has established a new high level for the recovery. According to figures of F. W. Dodge Corp., the July total for all classes of construction amounted to $321,602,700 in the 37 eastern states, topping the previous high figure of the recovery reported in June of this year in the amount of $317,842,100 and representing an increase of 8 per cent over the total of $294,734,500 reported in July 1936. Of the July 1937 volume, $81,046,000 was for residential building, $138,063,500 for non-residential building, and $102,493,200 for civil engineering projects, i.e., public works and public utilities.

**New Coil Winding Company.**—Electrical Windings, Inc., 16 No. May St., Chicago, has been organized to specialize in the design and manufacture of all types of transformers, solenoids, chokes, magnets, etc. The new company is set up to design coils and mountings for any specific purpose, or to work from manufacturers' specifications. Orland Murphy, president, was formerly associated with Utah Radio Products and Standard Transformer Corp. and was recently chief engineer for Robertson-Davis.

**Empire Sheet Appointment.**—Joseph B. Montgomery, Jr. became associated with Empire Sheet & Tin Plate Company's organization August 1st and assumed charge of sales. At a meeting of the Board of Directors held on Monday, August 9, he was elected vice-president in charge of sales, according to an announcement made by J. M. Hill, president. Mr. Montgomery was previously employed in the sales organization of the Bethlehem Steel Corp., in the sheet and strip sales department.

**American Rolling Mill Appointment.**—Marvin Marsh, special Armco sales representative in the Kansas City territory, has been named manager of the company's newly created district office at 7100 Roberts St., Kansas City, Mo., according to W. W. Sebald, vice-president in charge of commercial activities of The American Rolling Mill, Middletown, O.

**Absorbs E-M Capacitor Division.**—The Cornell-Dubilier Electric Corp., South Plainfield, N. J., has taken over the condenser manufacturing equipment and sales staff of the Electric Machinery Mfg. Co., Co., Inc., Minneapolis. According to Octave Blake, president of Cornell-Dubilier, the additional equipment supplements the modern machinery already housed in the company's 11 buildings covering more than 33 acres.

# Trade Literature

**Transformers.**—Bulletin 2259, 4 pp. Describes industrial substation service transformers. Allis-Chalmers Mfg. Co., Milwaukee, Wis.

**Motors.**—Bulletin GEA 1195B, 4 pp. Describes large synchronous motors for driving metal-rolling mills. General Electric Co., Schenectady, N. Y.

**Switchgear.**—Bulletin 1187, 8 pp. Describes indoor type cubicle switchgear, listing outstanding advantages, applications, and details of construction as well as complete dimensions. Allis-Chalmers Mfg. Co., Milwaukee, Wis.

**Aircraft Wires and Cables.**—Bulletin A-832, 28 pp. Describes mechanical control cords and aircraft strand, galvanized wire and fittings; also electrical cables for use in airplane construction. John A. Roebling's Sons Co., Trenton, N. J.

**Switchboards.**—Bulletin GEA 2617, 8 pp. Describes safety enclosed, air circuit breaker switchboards, with trip-free air circuit breakers rated at 250 volts d-c, 600 volts a-c; up to 10,000 amperes, manually or electrically operated. General Electric Co., Schenectady, N. Y.

**Lift Magnet Controller.**—Bulletin, 4 pp. Describes a new automatic-discharge type controller enabling high speed lifting magnet operation, as well as quick release of the load. The Electric Controller & Mfg. Co., Cleveland, O.

**Silent Gears.**—Bulletin, 8 pp. Describes Celeron (laminated plastic) silent gears. Recommended practises for machinery, gear tooth data and tables on horsepower rating per inch of face are included. Continental-Diamond Fibre Co., Newark, Del.

**Arc Welder.**—Bulletin GEA 2447C, 10 pp. Describes new Mutator arc welder (electronic rectifier) specially designed to provide direct current at the low values required for welding of light-gauge metal. General Electric Co., Schenectady, N. Y.

**Booster Regulators.**—Catalog, Sec. 47–230, 8 pp. Describes application, operation, construction and ratings of the four step feeder-voltage booster-regulator, designed for use on rural lines or distribution circuits where the load changes over a wide range. Westinghouse Elec. & Mfg. Co., E. Pittsburgh, Pa.

**Cable Testing Equipment.**—Catalog E-54 (3), 8 pp. Describes apparatus for power factor measurements by the phase defect compensation method for high voltage production tests of power cables. Leeds & Northrup Co., 4962 Stenton Ave., Philadelphia, Pa.

**Porcelain in Wiring.**—Bulletin, "The Fact Manual of Standard Electrical Porcelain," second edition, rearranged and revised to illustrate the 1937 National Electric Code Revisions. Includes wall chart depicting proper use of porcelain knobs, tubes and cleats, as well as the newly developed all porcelain outlet, switch and receptacle boxes. Standard Electrical Porcelain Manufacturers, 201 No. Wells St., Chicago, Ill.

**Diesel Generating Sets.**—Bulletin 3600-A2, 16 pp. Describes the construction and application of model 36-A Diesel generating sets in industrial plants, either as independent units carrying the entire load or for parallel or auxiliary operation in conjunction with other electrical service. Alternating-current sets are offered in ratings from 5.3 to 100 kva and direct current sets from 5 to 80 kw. Fairbanks, Morse & Co., 900 So. Wabash Ave., Chicago, Ill.

**Condensers.**—Catalog, 32 pp. Lists a large and diversified line of condensers, together with essential resistors, in a manner which permits of finding any required condenser in minimum time. Condensers are grouped first under their general type classification, and then under working voltage, and finally by capacity. Eight pages of exact duplicate replacement condensers are included, covering practically all standard set requirements. Aerovox Corp., 70 Washington St., Brooklyn, N. Y.

**Distribution System.**—Catalog, 40 pp. Describes Universal type "Trol-E-Duct," a mobile electrical distribution system designed for general lighting and light duty power applications. This innovation consists essentially of section lengths of formed steel duct enclosing copper bus bars partially wrapped in insulating material. Movable current-carrying trolleys and stationary twistout plugs to which lights, tools and appliances can be wired are inserted in a narrow continuous slot extending along one side of the duct. The new system supplements Industrial "Trol-E-Duct," for heavy duty power applications. Bull Dog Electric Products Co., 7610 Jos. Campau Ave., Detroit, Mich.

Accepted for mailing at special postage rates provided for in Section 1103, Act of October 3, 1917, authorized on August 3, 1918. ¶ Publication Office: 20th & Northampton Streets, Easton, Pa. Editorial and Advertising Offices at the headquarters of the Institute, 33 West 39th Street, New York

## The Cover

**A 14-foot discharge at the high-voltage laboratory of the Ohio Brass Company, Barberton, which may be visited by those attending the forthcoming AIEE District meeting at Akron**

# High Lights

**Spinning Atoms and Electrons.** In the construction of the physical world, mass and charge fulfill the rôle of raw materials, and laws of angular momentum furnish the principles of the architecture thereof, according to a noted authority who recently discussed the subject at a meeting of the Institute's New York Section (*pages 1228–35*).

**Out-of-Step Protection.** Relay requirements for the protection of machines operating out of step may be determined by geometric treatment, which reveals that the common method of assuming a system to be pure reactance leads to errors in low-frequency systems that have low reactance (*pages 1261–7*).

**Radio Interference.** Radiobroadcast listeners today demand reception free from interfering noises, while the variety of devices that may produce noise increases continually; co-operation between manufacturers and service men, radiobroadcast interests, and public utilities may bring interference under control (*pages 1248–52*).

**Alternator Currents.** By the application of symmetrical components, armature and field currents of an alternator under unsymmetrical short-circuit conditions may be obtained that agree well with oscillograms; the method aids in the determination of the effect of resistance in armature and field circuits (*pages 1268–76*).

**Lightning.** Laboratory tests with the lightning-stroke generator and field observations have given information on the lightning-stroke channel; the results suggest a pressure in the "core" some 40 to 60 times atmospheric pressure and a corresponding gas temperature in the range of 11,000 to 17,000 degrees Kelvin (*pages 1253–60*).

**Protective Multiple Earthing.** Investigation in England shows that the present methods of earthing (or grounding) rural electric circuits are not wholly adequate for all circuits; recommendations for improving the situation have been made (*pages 1245–7*).

**Letters to the Editor.** Subjects discussed in the "Letters" columns of this issue include: AIEE Student Branch activities; Institute programs and publications; characteristics of human nature; electric-range units, and solution of impedances in multiple (*pages 1326–9*).

**Specialization in Education.** "Get the humanities and foundations of science, but don't get technology," say industrial leaders when asked what type of education they want in the engineers they hire (*pages 1238–40*).

**Engineering Profession.** The method of engineers rather than their occupation is the characteristic of the engineering profession that distinguishes it from other learned professions, according to a well-known past-president of the Institute (*pages 1235–8*).

**Adding With the Slide Rule.** By combining the ability of the slide rule to perform addition with its more usual functions as a multiplying device and a set of tables, the usefulness of this familiar device may be greatly extended (*pages 1243–4*).

**Engineers and Economics.** A noted engineer and educator, past-president of the Institute, has suggested some ways in which engineers may secure greater influence in guiding economic affairs that have an impact on engineering (*pages 1225–7*).

**Induction Motor Performance.** A method of predicting the performance of single-phase induction motors from design data has been developed which is said to be shorter and more direct than some other methods in common use (*pages 1277–84*).

**Pacific Coast Convention.** Activities at the Institute's 1937 Pacific Coast Convention held recently at Spokane, Wash., are reported in the news section of this issue; a total of 266 members and guests registered (*pages 1320–2*).

**New Photometric Unit.** A new unit of candlepower has been adopted by the International Committee on Weights and Measures which it is hoped will be put into use in 1940 (*pages 1323–4*).

**New Committee Chairmen.** Beginning with this issue, newly appointed chairmen of AIEE committees are being introduced to the membership through the "Personals" columns (*pages 1330–1*).

**D-C Machine Tests.** Recently developed methods of measuring the stray load loss of d-c machines with consistent results permit more accurate determination of the losses and efficiency (*pages 1285–9*).

**Physics in Engineering Education.** According to one authority, effective instruction in physics determines the quality and tempo of engineering teaching (*pages 1241–3*).

**Government Reorganization.** Comments on this subject were included in the current "News Letter" of American Engineering Council (*pages 1325–6*).

# DISCUSSIONS

Appearing in this issue are discussions of the following papers:

## Insulation

Oxidation in Insulating Oil—Whitehead and Mauritz 1304

Properties of Saturants for Paper-Insulated Cables—Sommerman 1302

Tests on Oil-Impregnated Paper—II—Race . . 1298

The Dielectric Strength of Noninflammable Synthetic Insulating Oils—Clark 1299

## Electrical Machinery

Approximating Potier Reactance—Beckwith . . 1318

Characteristic Constants of Single-Phase Induction Motors—Morrill 1312

End-Winding Inductance of a Synchronous Machine—Caldwell 1312

Reactance of End Connections—Douglas . . . 1315

## General Power Applications

A-C Motor Protection—Kuhn . . . . . 1306

Coincidental Electric Drives—Miller . . . . 1307

Impulse Operation of Magnetic Contactors—Stansbury 1307

## Insulation Co-ordination

Application of Spill Gaps and Selection of Insulation Levels—Melvin and Pierce 1290

Application of Arresters and the Selection of Insulation Levels—Foote and North 1293

Basic Impulse Insulation Levels—EEI NEMA Joint Committee 1298

Insulation Co-ordination—Sporn and Gross . . 1296

Insulation Strength of Transformers—AIEE Subcommittee 1297

## Power Transmission

New Oil-Filled Cable Lines in Chicago—Halperin and Shanklin 1307

System Recovery Voltage Determination by Analytical and A-C Calculating Board Methods—Evans and Monteith 1308

## Vibration and Balance

Dynamic Balancing of Small Gyroscope Rotors—Esval and Frische 1305–6

Vibration Isolation of Machinery—Hansel. . . 1306

Vibration-Measuring Instruments—Greentree 1305–6

# Engineers and Economics—II

By DUGALD C. JACKSON
PAST-PRESIDENT AIEE

**What is the appropriate attitude for engineers to take toward economic problems, as individuals and through the AIEE? In response to a request from the Institute's publication committee, a noted engineer and educator here gives his answer to that question.**

AT THE 1937 AIEE summer convention held in Milwaukee, Wis., an informal session was held to discuss, among other subjects, what the Institute might do to aid the thinking of members regarding the engineer and his relation to economics, over which session I was asked to preside. The circumstances lead me to take that session as an example and as text for this article. The session was attended by perhaps 35 of the younger members of the Institute, including those who were in and out. The discussion was lively. It mostly related to what the Institute and its individual members can do to aid in economic controls. Extreme diversity was exhibited in the views individually expressed with full sincerity, which is common in such forums when economic and social problems are discussed. Also several aspects of any problem were likely to be entangled together in confusion by any speaker, which also is usual in such forums. When I speak of "such forums," I mean groups of able and sincere men who have lived through widely different social and economic experiences and who therefore have diverse (and often contradictory) intellectual outlooks which have arisen from their diverse experiences.

In their primary vocations, engineers have a distinguished habit of studying all the facts of a problem in hand, analyzing the problem into its component elements, filling in incomplete premises by judgment founded on experience with previous problems, then solving the problem by logical reasoning from the premises, but always remembering that the synthesis is only an approximation to exact truth because some of the analyzed premises were incomplete as to facts and were filled in through the application of judgment.

Here we have the age-old, sound process of guiding our thinking by our learning. The Chinese philosopher Confucius, nearly 2,500 years ago, admonished his disciples that thinking without learning is dangerous. We engineers habitually avoid the danger in connection with our technical problems by learning all we can relating to analysis and synthesis of each problem and guiding our thinking thereby. Under these conditions, different engineers of broadly competent experiences readily agree upon the relative merits of different solutions for an engineering problem. Sentiment and prejudice have little place for expression in such situations, and wishful thinking without a factual foundation no place whatever. Examples in which associations of engineers have become of recognized influence as voluntary advisers in engineering matters relating to municipal affairs, such as the situation in Milwaukee which was referred to in the session at the AIEE Milwaukee Convention, are instances where the facts have been sedulously studied for each problem and recommendations made after careful analysis to assure that the facts are understood, followed by synthesis of the results into a clear solution. Recommendations based on such a foundation are always persuasive and are likely to be convincing to any unprejudiced mind.

It is difficult, however, to secure facts for such a solution in social affairs which play so large a part in political economy. I use the phrase political economy as a synonym for economics, in the sense of that branch of learning which comprises the physical and financial, i.e., the material, aspects of social organization, as distinguished from the moral and sentimental aspects of human relations which are peculiarly comprised within the fields of religion and philosophy. We thus have for political economy (of which phrase, the word economics is a synonym) a field which is modified by the state of science and invention and by the modes of living which change from generation to generation as a consequence of experience guided by changes of science and invention. It is a big field which includes concretely the various problems discussed at the informal session in Milwaukee, besides many other important problems.

Economists are likely to leave us considerably in the dark regarding the economic aspects of our problems. Moreover much of economic writing is not directly applicable to engineering affairs. Engineering is a branch of learning and practice which bridges the gulf between the physical sciences and political economy. Therefore, it is natural that only a part of the structure of political economy should at present directly affect our engineering affairs, just as only a part of the structure of science directly affects engineering at present. We, therefore, must help ourselves toward understanding the impact of political economy on our engineering affairs, while enlisting

---

This is the second in a series of articles on this subject prepared especially for ELECTRICAL ENGINEERING; the first, by Morris E. Leeds (A'01, F'26) was published in the February 1937 issue, pages 206–07.

DUGALD C. JACKSON is professor emeritus of electrical engineering, Massachusetts Institute of Technology, Cambridge. He received the degree of civil engineer from Pennsylvania State College in 1885 and the honorary degree of doctor of science from Columbia University in 1932. From 1887 to 1891 Doctor Jackson was engaged in the design and construction of electric light and power plants and distribution systems, and in electric railway work. In 1891 he became professor of electrical engineering at the University of Wisconsin, and in 1907 professor and head of the department of electrical engineering at Massachusetts Institute of Technology, which position he held until his retirement in 1935. He was engaged in consulting engineering from 1891 to 1930, and was particularly active in the fields of railway electrification and public utility affairs. In addition to his term as president of the AIEE (1910–11), Doctor Jackson has served on many AIEE committees over a period of more than 20 years, including chairmanship of the following: standards, 1920–21; traction and transportation, 1914–16; education, 1909–10; Edison Medal 1930–32–33; institute policy, 1928–30. He is a member of many other technical societies in this and other countries, and among other honors he has received the Lamme Medal of the Society for the Promotion of Engineering Education, of which society he was president 1905–06. He is the author of 5 books and numerous articles and papers.

the aid of economists in our effort to gain that understanding. This may be carried out in a way that is analogous to the manner in which we have come to understand the impact of science on engineering. As engineers, we continue our intimacy of thought regarding science, and we mutually discuss our problems in the light of science. Our situation calls for a like mental attitude toward political economy.

Those economists who call themselves sociologists are sincerely endeavoring to assemble a factual basis which ultimately may be helpful to our understanding of the relations of engineering to the betterment of life, but the basis is yet so meager that the forward visions of the sociologists are mostly hope, guided by sentiment. As highly as we all regard those 2 qualities (hope and sentiment), we must dismiss the combination from consideration as an adequate foundation for engineering works. Hope guided by science or experience, accompanied by great industry, has led to many great inventions in our field; but this combination of hope guided by science or experience commands infinitely greater reliance than hope guided by sentiment.

The sociologists have produced writings from which we can glean an understanding of the reason why certain types of organizations in the field of engineering are objects of so much popular suspicion and even resentment. For example, the recently published book entitled "American City, a Rank and File History," by Charles R. Walker, with its sordid but unhappily true tale of illegalities and tricky practices exercised or condoned by those least to be justified by standing and education, discloses some of the grounds. However, we must make our interpretations for ourselves rather than accept, second-hand, the interpretations of disciples.

Of this last point, I may be permitted to elaborate an illustration. Karl Marx, of widespread note, author of "Das Kapital" and other widely quoted writings, was a genius in investigating and expounding the philosophy of history, but when dealing with man's daily interests his writings are sometimes contradictory and, it seems to me, are frequently inaccurate. His numerous disciples have interpreted his writings into a structure of the utmost unsoundness, so that such truth as exists in Marx's own philosophy can be grasped only by reading his own productions and considering the groundwork from which his philosophy springs.

There is thus at large much loose talking and much wishful thinking about affairs in the realm of economics which affect us as engineers. Considerable American legislation and some business activities follow the dictates of wishful thinking. We engineers are not altogether without blame. In this realm of economics, which is not a specific part of our own field, we (ourselves) are likely to do thinking and talking without first securing a competent degree of learning regarding the realm and its various features. We go contrary to our usual practice in our engineering specialties. We sometimes take our opinions second-hand, without such critical examination as will assure us that the opinions are founded upon a broad base of facts, and we reach mental decisions without adequate facts for a basis. Leisure is not available for engineers actively employed in their absorbing vocational specialties to follow this collateral path with will and concentration. The results are not in keeping with our repute in the realm of scientific matters. We become imbued with ideas which are only partially supportable. We may come to believe that these ideas are sound "principle," which leads to such reluctance toward modifications that our colleagues with other views may cry "prejudice."

Here again, I may be permitted to illustrate. For some 25 years I lectured on the organization and administration of public service companies as part of my duties as head of the department of electrical engineering at Massachusetts Institute of Technology. This imposed the necessity of discussing corporation forms of organization for such companies. Year by year the students in the group were 15 to 20 graduates of MIT and other engineering schools, and were fairly mature. All had preceded their engineering school undergraduate career by one of the usual forms of preparation for college admission. They were drawn from all parts of the country and many walks of life. They came from the homes of mechanics, industrial managers, bankers, merchants, merchants' clerks, farmers, and so on.

The corporate form of organization (i.e., a corporation) for doing business, established in conformity with specific laws of our several states, is so widely used as an instrumentality of legitimate businesses (large and small) in so wide a range of business activities that obviously it has been accepted by experienced and honest business men as a fair and useful instrument in our social setting. Indeed some who have studied and reflected on the matter believe the corporate form in business to be one of the most serviceable evolutions which have occurred for advancing general welfare. It makes practicable the carrying on of large enterprises which otherwise could not be carried on with equal advantage to the public. It is serviceable in large and small businesses. It operates under legal limitations which can prevent abuses. I confess to being one of those who believe in the desirability of corporations; but I am ready to recognize abuses which arise from the application of defective laws. These abuses can be eradicated on public demand arising for modification of the applicable laws.

In opening the discussion of corporate forms to this group of graduate students I usually asked a few questions to bring out the knowledge which they already possessed respecting corporations and the opinions of the individuals in regard to the corporation as an instrumentality for carrying on business. Year after year without exception a considerable proportion expressed opinions adverse to corporations and often inferred that they were instrumentalities for legalized extortion from customers or other unfair practices. "One sided," do you readers mentally exclaim? But read farther! Now and then there would be in this category of corporation detractors the son of a merchant or of a merchant's employee, proud of the business in which his father was engaged and proud of his father's pride in it, but unknowing that this business, worthy of honest pride, was carried on as a corporation. One sided? I agree; but more—it is an illustration (perhaps somewhat extreme, though true)

of our frequent manner when dealing with economic matters of thinking (and talking) without associating the thoughts with proper learning, contrary to Confucius' ancient but excellent admonition and equally contrary to our own habit when dealing with technical affairs.

To show that observation of such an attitude is not an isolated experience of my own, I will quote from a test by the distinguished psychologist E. L. Thorndike. Professor Thorndike in 1934 made a test of the extent of information and quality of reasoning on business and economic issues exhibited by a group of 76 unemployed persons (44 men and 32 women). He says that the group was "much above the average for the United States" in general intelligence and education. Over half this group alleged that no trade can possibly benefit both parties to the trade. Except that such unsound thinking is injurious to our national society, we might view it with the same humorous tolerance as we view the schoolboy's reputed definition of the word "husbandry" to mean "male dominance." Unfortunately the tragedy lying in the wake of economic errors strips them of all humor.

Some of the responses to certain of his test questions appeared to Thorndike "to be symptomatic of a tendency to regard owners of business concerns and traders as being paid too highly for the services which they and their property render." He worked out such things into what he calls a "prejudice score" for the individuals of his group, a high score meaning high prejudice. He sums up by saying that the abler minds in the group have slightly lower prejudice scores, but the differences can be accounted for by the fact that they make fewer errors of all sorts; that the younger individuals show higher prejudices than the older ones and the women show less than the men; also that ability in an academic examination in economics involves but slight decrease in the prejudice. This prejudice (regarding business affairs) is of a peculiar character "being immune to intelligence of the individual and almost immune to academic knowledge of economics." Of course, Thorndike's group was not composed of engineers; but, are we engineers immune from the same typical prejudices? The informal session at Milwaukee showed that in economic affairs we manifestly arrive at diverse conclusions (which we individually stick to as though they represent abstract, right "principle"), all drawn from alleged similar premises. Is not this definite evidence that in economic affairs people (even engineers) are likely to do their thinking without first accumulating adequate learning? Also, may it not demonstrate that emphatic reliance on our individual inferences leads us to forget that the inferences of no single purely human being ever approximated to "abstract principle," and therefore such inferences should be open to criticism and argument without acrimony?

The circumstances being as thus outlined, what can we do to rescue ourselves from so false a situation and thereby secure more influence in guiding economic affairs which have an impact on engineering? Obviously we must improve our thinking, which we may accomplish in several ways, including among others the following procedure:

First: Members of our Sections can promote informal discussion sessions directed toward economic affairs, in which all points of view regarding the particular affairs are sought out and the adequacy of the foundation for each view is frankly discussed, while rancor is suppressed. By such discussions, the causes of divergence of views may often be exposed and correct views mutually reached. Some who enter such discussions may profit by reading the little book by John Morley (the distinguished British Liberal) entitled "On Compromise," which was published many years ago. The Engineers' Council for Professional Development (which is a mutual instrument of 7 great national societies in the engineering field) has as one of its objectives the aim to give aid to the younger engineers in arranging their continuing self-education. Through its headquarters at 33 West 39th Street in New York City advice may be secured regarding the co-operation of sections of other engineering societies in discussion sessions and collateral educational activities. It is important for the welfare of such discussion sessions that the general topic for consideration shall be clearly announced in advance and that the chairman shall hold each speaker to limits within range of the topic. Aside from this, and the rule that each speaker shall assume the sincerity of all other speakers, no discussion rules are needed.

Second: Sections may invite influential men of the community who are men of experience in business affairs to make addresses in exposition of their own views on questions about which differences have arisen in the informal sessions, if such sessions have been held. To gain any effectiveness from this, any guest invited to give the address on a controversial subject should understand that on some other date an equally distinguished man known to have opposing views will be (or has been) heard. Such bilateral exposition in controversial fields by experienced and honest men of diverse views is the only means of gaining real learning in controversial matters where lectures are relied on. For real learning, however, the discussion sessions are preferable. Professional lecturers dealing with this realm should be viewed with caution because they often are either over-dogmatic or superficial in their expressions.

Third: An informal session at each national convention, of character similar to the Milwaukee discussion session and programmed in advance, would bring together views from all parts of the country if there is as much interest in economic questions among the members under 50 years of age as was alleged in Milwaukee. Catch-as-catch-can rules for debate are appropriate for such sessions provided each speaker will respect the sincerity of every other one, and the presiding officer possesses a fund of common sense in restraining the speakers from straying too far from the objective topic which was programmed. After several such occasions we might find (at least in some of our problems) such unity of views founded on adequate grounds that our mutual influence in the nation would become large in relation to economic affairs affecting our particular branch of engineering. At present we have no such joint influence because we do not agree with each other. We have not as yet mutually accumulated the learning sufficient to support and guide that soundness and unity of thinking in economic affairs which is essential for securing an influence in them that is comparable with our influence in specific technical affairs.

# Spinning Atoms and Spinning Electrons

## An address* describing how it is known that atoms, electrons and other fundamental particles are continually spinning

By K. K. DARROW
ASSOCIATE AIEE

NO DOUBT you are all accustomed to thinking of atoms as objects—very small objects, of course—which are endowed with *weight*. I can say that with perfect safety to an audience of engineers and physicists; but indeed it can be said with safety to any audience—I mean, of course, any audience literate enough to attach any meaning at all to such a word as "atom." It may be that philosophers of the past have imagined weightless atoms—I am not historian enough to deny that, nor to affirm it; but if such have ever been invented, they have remained quite outside the currents of modern thought. For us, weight is a property which we attribute to the atom. Since this is, after all, a professional audience, I will now change over to that other word which many people have such difficulty in distinguishing from "weight": I will say that *mass is a property which we attribute to the atom.* In a way, that is a negative statement. It means that we do not hope to explain mass in terms of something more fundamental; it means that we accept mass as being itself so fundamental that even the elementary particles have it. When I say "elementary particles," I am still referring in part to the atoms, though it is a somewhat careless usage to do so; but I am referring also to electrons both positive and negative, to protons, to alpha-particles, to nuclei—to all the particles, in effect, of which the atoms are built up. Also I ought to include the corpuscles of light, but this lecture will be quite long enough if I leave them almost unmentioned. All of these particles, then, are endowed with mass; each of them has a characteristic mass of its own, which we do not attempt to explain, but which we do try to measure as closely as we can.

There is another property, familiar to you though not to everyone, which we accept as equally fundamental and equally unexplainable with mass: it is *electric charge.* We attribute it also to the elementary particles, though not, it is true, to all of them. We assign it to the electrons, of course, and to protons and alpha-particles and all of the hundreds of nuclei which distinguish the elements and the isotopes thereof from each other. When I say that we "assign" it, I do not for a moment mean that we are doing something arbitrary or untestable. We *know* that these elementary particles are charged, and indeed we have measured their charges. Atoms do normally appear to us uncharged, but we know that that is because the elementary particles of which they in their turn are made up are some of them positive, some of them negative, and the balance normally happening to be perfect. Some particles, the neutrons and the corpuscles of light, seem permanently chargeless; but perhaps some day we shall find it expedient to regard them as groups of smaller particles having charges which balance one another. Apart from these 2 cases, we may say with assurance that whenever we penetrate as far into the fine structure of substance as we are able to go, we find the elementary particles invested with mass and with charge.

And now I arrive at the subject of this talk, the *third* property of the elementary particles: the property which is called "angular momentum," or "spin" for short. Now of course I am speaking as to an audience of physicists, for if this were an audience of laymen it would certainly be frightened by such a term as "angular momentum." This is a misfortune, and perhaps a defect of general education; for angular momentum is about as important as mass or charge, not only on the scale of the elementary particles but also on the scale of the visible world. Think what it would mean if there were no such thing as the conservation of angular momentum! The earth might cease from turning, it might cease from providing us with the regular alternation of day and night, and with our standard of the flow of time; it might even cease from traversing its regular orbit, and fly off into space or fall into the sun. Well, I do not wish to scare you with any such dire imaginings—I only want to remark on the fact that the human race has been acquainted for a very long time indeed with angular momentum as something which is unvarying, imperturbable, incessant; for of all the unvarying and imperturbable and incessant things in the world, the rotation of the earth is the most obvious and the most striking. So striking it is, that you might reasonably expect that all the philosophers and all the physicists of the past would have conferred the property of spin on all the atoms which they have invented. Well, they did not; the notions of the spinning atom, the spinning electron, the spinning nucleus are among the newest in physics. I think that some of the reasons for the delay will be evident later on in this talk, but it remains partly mysterious, at least to me. Looking back on the situation with the well-known advantages of hindsight, I do feel a good deal of surprise that the spinning atom did not make an earlier

*An address delivered before the AIEE New York Section, May 6, 1937.

K. K. DARROW is research physicist of the Bell Telephone Laboratories, Inc., New York, N. Y. He received the degree of bachelor of science from the University of Chicago in 1911 and doctor of philosophy from that institution in 1917. During 1911 and 1912, he studied at the Universities of Paris and Berlin. Since 1917 Doctor Darrow has been in the employ of the Western Electric Company and Bell Telephone Laboratories. He has been engaged largely in writing on various fields of physics and the allied sciences.

entry upon the scientific stage. Perhaps some of you will remember hearing the words "vortex atom" and "vortex theory" which used to be so prominent in physics, and will take the spinning atom of today for a lineal descendant of those vortices of old. If this were correct, we could trace back the ancestry of the spinning atom for about 300 years; but I think that it is not correct. The vortices of which Descartes and Malebranche were dreaming 3 centuries ago were more like whirlpools of streaming particles, and the vortices which were imagined by Helmholtz and Lord Kelvin some 50 years ago were also whirlpools, but they were whirls in an idealized continuous frictionless fluid. Let us pause for a moment to notice how the attitude of physicists has altered in these 50 years! Kelvin and Helmholtz began with the idea of an ethereal fluid pervading the whole of space, and valiantly tried to represent the atoms as whirlpools in that fluid; but we have long since discarded that ether, and our spinning atoms and other elementary particles are small delimited rotating bodies voyaging in a void.

It is not therefore the vortex which I will introduce to you as the ancestor of the spinning atom, but rather the "Amperian whirl" as it still is sometimes called. You remember, of course, how Ampère in 1820 made a very great achievement which for the purposes of this talk I will divide into three. First, he discovered the fact that an electric current flowing in a circuit is equivalent to a magnet. Next, he worked out the mathematical laws whereby, given a current and the circuit in which that current is flowing, we may calculate the strength or the moment of the equivalent magnet. I will write down the formula for the case of a current $i$, flowing in a plane loop of area $A$: the magnetic moment of the equivalent magnet, $\mu$, is given thus:

$$\mu = iA/c$$

Here $c$ is a factor of transformation which we are now obliged to employ because we habitually use, in atomic physics especially, a unit-system different from Ampère's. The third part of the great achievement was this: Ampère founded what remains to this day the theory of magnetism, by presuming that *the individual atoms of any magnetizable substance are themselves little magnets*, and that *the atoms are magnets because they have little whirls of current in them.*

This notion—the notion that atoms are magnets, and that they are magnets because they have internal circulating currents—is the true forerunner of our present conception of the spinning atom. It is, however, only a very primitive form of the modern conception, and there is much to be added to it. First of all and above all, there is the question of angular momentum. Is angular momentum an attribute of these whirling intra-atomic currents, or is it not? You may think that the answer to this question is self-evidently "yes!" But remember that for many generations of our forefathers electricity was an *imponderable* fluid. Weber, however, did consider the affirmative answer, and Maxwell even attempted to ask the question of Nature by experiment—vainly, as it turned out. Not till the electron was discovered did the mass of electricity become a prominent part of experience. A moment ago I divided Ampère's achievement into three parts; similarly I wish now to divide the discovery of the electron into three. Those who isolated and identified and measured the electron were proving three things: first, that negative electricity consists of corpuscles of a definite charge, $e$; second, that these corpuscles have a mass, $m$; and following from these two, the principle which I have called the third part of the discovery, namely, that an electron revolving in an orbit has an angular momentum.

I will designate angular momentum in general by the letter $p$, and now I will show you a formula for the ratio of $\mu$ to $p$ in an atom in which an electron is running around in an orbit and constituting an Amperian whirl. The formula, like this other one, for $\mu$, is valid for an orbit of any shape, but to get it quickly I will simplify by postulating a circular orbit. The radius of the circle being $r$, the area $A$ is $\pi r^2$; the current around it is equal to the electron-charge $e$, multiplied by the number of times per second that the electron runs around the orbit; if I denote the velocity of the electron by $v$, this number is $v/2\pi r$; hence the product $iA/c$ is equal to $evr/2c$. Now the angular momentum $p$ of the electron, as you all know, is $mvr$; and hence for the ratio I derive:

$$\mu/p = e/2mc$$

which is one of the most important formulas in the whole of atomic physics. You notice that it does not involve in any way the size or shape of the orbit or the frequency with which the electron travels around it. It is the same for any or all of the revolving electrons of any atom of any kind.

Now let us see how this formula may be tested. Imagine a rod of some highly magnetizable metal, iron for instance, and imagine it to be unmagnetized at the start. This means, that at the start the little atomic magnets are pointing at random in all directions; that is to say, the vectors which represent their magnetic moments are pointing every way, and so are the vectors which represent their angular momenta, the latter being parallel to the former. Since these atomic vectors of angular momentum are pointing every way at random, they add up to zero, and the rod as a whole possesses no resultant angular momentum; it is just standing still. Now let the rod be surrounded with a solenoid, and by means of a current in the solenoid let it be magnetized to saturation. Now all the arrows representing magnetic moments are pointing parallel to the axis of the rod. But so are all the arrows representing atomic angular momenta! Their resultant is no longer zero—suddenly there has arisen a *resultant angular momentum*, belonging to the totality of all the atomic magnets, and quite large enough to be detected, instead of being tiny like the angular momentum of an individual atom. Unless our theory is fundamentally wrong somewhere, we should be able to observe this resultant angular momentum.

The experiment is done by hanging the rod vertically from a fine suspension, and sending the magnetizing current through the solenoid. At the instant of the magnetization, the rod turns sharply on its axis, twisting the suspending fiber. Thus it manifests the angular momentum

of which I have just been speaking—though I ought to say that what we observe is of the nature of a recoil, or back-kick: when the totality of the little atomic magnets suddenly acquires its resultant angular momentum, the substance of the rod as a whole acquires an equal and opposite amount (so as to keep constant the total amount of angular momentum in the universe) and it is the latter which we detect. The experiment is quite a delicate one, but its technique has been developed to a remarkable degree since it was first attempted twenty years ago by Einstein and de Haas. What we measure is the ratio of the magnetization of the rod-as-a-whole to the angular momentum of the rod-as-a-whole; and this is just the same as the ratio of $\mu$ to $p$ for the elementary atomic magnets. There are not many properties of matter of which we can say that the value measured on a large piece of matter is the same as the value for the individual atom; but there are a few, and this is one of them.

Now in giving you the result, let me first emphasize the general principle that here we have evidence of the spinning of elementary particles, and of the interrelation between spinning and magnetism. Next, I give you the numerical result itself. For iron and nearly all of the other ferromagnetic materials, we find:

$$\mu/p = e/mc$$

or *twice* the theoretical value which I quoted a moment ago.

This cannot be explained by assuming any peculiarity of size or shape or frequency of the electron-orbits in the atoms, for as I just said the theoretical formula is independent of all these things. We are obliged to make some more drastic assumption. If I had unlimited time before me, I might sketch the history of our assumption; but as I don't, I will come straight to the present situation. We assume first, that in the iron atoms in the rod the electron-orbits are so oriented with respect to each other that their magnetic moments kill one another off completely. We then assume that every electron has a magnetic moment and an angular momentum of its own, intrinsic to it and inherent in it, and altogether independent of whether or not the electron is revolving in an orbit. Just as the earth has a rotation of its own in addition to its elliptical course around the sun, so we imagine that the electron has a rotation of its own; this rotation has an angular momentum, and with it there is connected a magnetic moment. (You will remember doubtless that the earth also has a magnetic moment, but this is one of the analogies which it is better not to force too far.) When we magnetize the iron rod, it is the *electrons* which we are turning; the vectors which we cause to point all in the same direction are the magnetic moments and the angular momenta which are inherent in the electrons, and the value of their ratio is the value which is characteristic of the "spinning electron," as we call it. Therefore, amplifying the notation a little, I write:

$$\mu/p = g(e/2mc) \begin{cases} g = 1 \text{ for electron-orbits} \\ g = 2 \text{ for spinning electron} \end{cases}$$

and now I leave the spinning electron for a few minutes, in order to turn again to the theory of electrons revolving in their orbits.

You all realized, of course, that when I converted the Amperian whirl of current into an electron running around an orbit, I was adopting the atom-model known by the names of Rutherford and Bohr; for these were the original thinkers who impelled all the rest of us, following in their footsteps, to think of the atom as a positively charged nucleus around which electrons are revolving like planets around the sun. This is an atom-model in which magnetism is inherent—*a Rutherford-Bohr atom is intrinsically a magnet.* Anyone who did not know the history of the model might well assume that it was designed expressly to account for magnetism, and any such person might also quite reasonably assume that all the physicists of the early nineteenth century thought of it simultaneously as soon as the electron was discovered. Well, it was *not* designed expressly to account for magnetism, and most of the physicists of the early nineteenth did *not* think of it—or if they did, they thought of it only to reject it. At that time, the atom-model with the orbital electrons seemed to be disqualified by a very potent reason; for according to the classical electromagnetic theory, an electron revolving in an orbit ought to radiate all of its energy in a very short time and fall into the nucleus. Bohr was the man who overrode this objection. He overrode it, not in order to construct a theory of magnetism in defiance of it, but in order to construct a theory of spectra in defiance of it. This theory has been extraordinarily successful. Our theory of magnetism is hardly more than a by-product of that theory of spectra; and this, in an odd sort of way, enhances its credit. A theory devised expressly for a certain purpose is always less impressive than one which follows incidentally from a successful theory devised for quite another purpose; and the contemporary theory of magnetism is a wonderful example of this latter and more impressive type.

The main element of Bohr's theory of spectra—if one can speak of one element as the main one, which is really not quite proper—is an assumption about the angular momentum of the electron in its orbit or, let me say, the angular momentum $p$ of the electron-orbit. It was assumed that the electron may revolve, without radiating its energy, in any orbit of which the angular momentum is an integer multiple of $h/2\pi$, —$h$ now standing, of course, for the famous quantum-constant of Planck which is the emblem of modern physics. I write this down as follows:

$$p = (1,2,3,4,\ldots)(h/2\pi)$$

Bohr was thinking at first about the hydrogen atom; but hydrogen is an inconvenient example to use in talking about magnetism, and iron is a very complicated case indeed, so I will talk entirely about the sodium atom.

The sodium atom has a nucleus with a charge of $+11e$, and 11 electrons circulating in orbits around it. This certainly sounds formidably complex, but it happens—and I shall later remind you of this fact—that the orbits and also the spins of 10 of the electrons are so oriented with respect to one another that their angular momenta and their magnetic moments completely neutralize each other.

I shall therefore ask you to imagine these 10 inner electrons as a sort of cloud. The eleventh electron of the sodium atom—known technically as the "valence" electron—cruises around this system; sometimes it is traveling in an orbit completely outside the cloud, sometimes in an orbit which cuts across the cloud, but never in an orbit which is entirely or even mainly inside the cloud. The 10 inner electrons which constitute the cloud neutralize a part of the force with which the nucleus acts upon the valence-electron; but they make—I repeat—not the slightest contribution to the angular momentum or to the magnetic moment of the atom.

I have given above, the permitted values of the angular momentum of this orbit of the valence-electron. Now I point out that to each of these permitted values of $p$ corresponds a permitted value of the magnetic moment $\mu$, which I obtain by multiplying the former with $e/2mc$:

$$\mu = (1,2,3,4, \ldots)(eh/4\pi mc)$$

However, only one (at most) of these values can be appropriate to the normal state of the sodium atom; all the rest must correspond to abnormal, unusual, or "excited" states. We are going to be interested primarily in the normal state, so we must identify the right one. In the early days of the Bohr theory, the right one was supposed to be the first which I have written down. However, the theory has been greatly remodeled and bettered since those days, with the aid of what is known as "quantum mechanics"; and it now seems quite certain that these lists of the permitted values of $p$ and $\mu$ for electron-orbits are both incomplete. I must add to each of them the value *zero*, so that the 2 lists become

$$p = (0, 1, 2, 3, 4, \ldots)h/2\pi$$
$$\mu = (0, 1, 2, 3, 4, \ldots)eh/4\pi mc$$

Moreover, it is precisely this new value *zero* which belongs to the normal state of the sodium atom. So the theory, in this stage, quite definitely prescribes that the sodium atom in its normal state should have no magnetic moment and no angular momentum. But now let us look at the data.

It would do no good in this connection to make measurements on solid or liquid sodium, for in those "condensed phases" the atoms are crowded so closely together as to be badly distorted. We can, however, experiment on free atoms of sodium, in their normal state, in the way illustrated by figure 1. In the upper portion, $A$ represents an "oven" consisting of a small box heated electrically and containing some liquid sodium which is steadily being vaporized. There is a hole in the wall of the box through which free sodium atoms are steadily shooting in all directions, with the distribution-in-speed which we know from the theory of thermal agitation; and beyond, there is a sequence of diaphragms with slits in them which delimit a straight and narrow beam of these fast-moving atoms. Disregarding what the theory has just said, let us suppose that each of these atoms is a magnet—a bar magnet, with a north pole and a south pole. As they emerge from the oven, these atoms must surely be oriented at random in all directions.

Continuing to look at the upper part of figure 1, we have 2 large magnet-poles, and the beam travels between them, having no trouble with molecules of air as it shoots along, for the whole of this apparatus is enclosed in a highly evacuated tube. It may seem natural to visualize these magnet-poles as the 2 broad flat extremeties of a horseshoe magnet, with a uniform magnetic field pervading all the space between them. Such an arrangement, however, would make the experiment futile. Nothing would happen to any of the atoms, for in the uniform field the north pole of each atomic magnet would be pressed downward just as hard as and no harder than the south pole is drawn upward, and the net force would be zero. The beam would go on unbroadened and undeflected, and make a small spot on the screen $S$, the spot being just opposite the slits in the diaphragms. Something else must be tried; and what we do—or rather, what Gerlach and Stern did in Hamburg some 14 years ago—is, to shape one of the magnet-poles in the form of a wedge and hollow out the other, so that the field between the two shall no longer be uniform. The lower part of figure 1 represents the cross section of such a pair of pole-pieces. The field-strength is now much greater near the wedge than near the opposite pole-piece, and there is a vertical gradient of field-strength which may be made fairly constant over most of the inter-

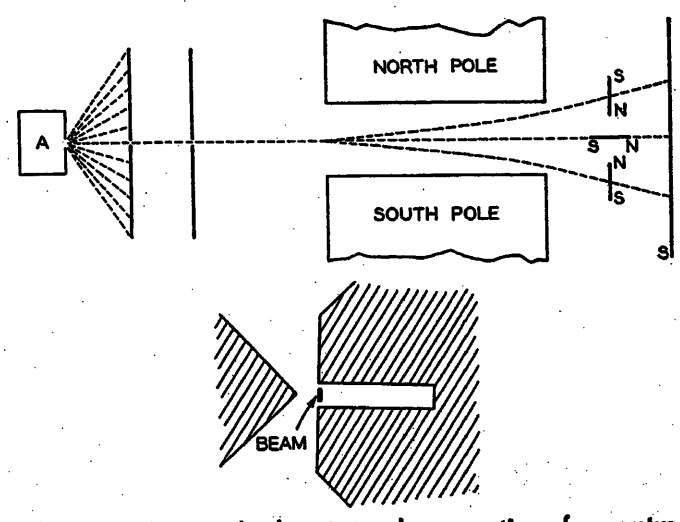

**Figure 1. Longitudinal section and cross section of apparatus for the Gerlach-Stern experiment**

space. Rabi at Columbia achieves the same result more efficiently by peculiar arrangements of current-carrying wires instead of iron magnets.

Now consider (thinking classically!) a few of the atomic magnets as they shoot across this nonuniform field. Think of one which originally is oriented vertically, with north pole down and south pole up—the south pole will be in a stronger part of the field than its mate; it will be drawn upward harder than the north pole is pushed downward; the atom will sweep in a parabolic arc upward. Think of another which originally is oriented vertically with north pole up and south pole down—it will be swept in a parabolic arc downward. Think of another which originally has its axis pointing horizontally—it will shoot in a straight line across the field, as though the pole-pieces were not

there.[1] Now think of all those which are oblique to the vertical; they will describe parabolic arcs of intermediate curvatures, upward or downward as the case may be. One infers that the beam must be spread out into a continuous fan, making a continuous vertical band upon the photographic plate.

Moreover, from the upper edge or from the lower edge of this continuous band, it should be possible to determine the magnetic moment $\mu$ of the atoms. For let us consider one of the vertically oriented atoms, and call its pole-strength $M$ and the length of its magnet $r$. The upward force on the north pole is $MH$, $-H$ standing for the field strength at the point where the north pole is. The downward force on the south pole is $M(H + dH/dz \cdot r)$. The net force is $Mr \cdot dH/dz$, which is $\mu(dH/dz)$, because $Mr$ is the magnetic moment $\mu$ of the magnet by definition. The acceleration of the little atom is equal to this force divided by $m_a$, the mass of the sodium atom. The deflection is equal to half the acceleration by the square of the time during which the atom is exposed to the force. This time is equal to the distance $D$ which the atoms traverse across the field, divided by $v$ the speed which they have when they come out of the furnace. So finally, we have:

$$\text{Deflection} = \frac{1}{2}\,\frac{\mu(dH/dz)}{m_a}\,(D/v)^2$$

We ascertain the deflection by looking at the end of the band on the photographic plate, and we can ascertain all the other things in the equation excepting $\mu$, $-v$ is the hardest to estimate accurately—and so we can solve the equation for $\mu$.

When the experiment is done there appears, however, a very remarkable thing. Instead of there being a long band upon the plate, there are just 2 spots. Instead of the beam having been broadened out into a continuous fan, it has evidently been split into 2 separate pencils. It looks as though the field had acted first of all upon the magnets, by setting them all vertical—half of them with north pole up, and half with north pole down. Not this phenomenon alone, but many others in nature show us that this is just what happens. You may perhaps feel for the moment that it is intelligible, after all; the compass-needle turns to the north—why should not the little atomic magnets, as soon as they enter the field, turn their south poles toward the north pole of the magnet which attracts them? Well this would not account for the magnets which constitute the beam which bends away from the wedge-shaped north pole, instead of toward it; and indeed it does not even account for the beam which bends toward the wedge-shaped pole. Classically the field should have no orienting effect whatsoever upon the atoms, and yet it evidently does.[1] This is one of the phenomena of the atomic world which we cannot properly visualize in terms of the behavior of objects large enough to be tangible and visible. All that I can do is to assert it, and to say that it justifies us in using this formula to calculate $\mu$. When we use it, the value which we find for the magnetic moment of the sodium atom in its normal state is

$$eh/4\pi mc$$

which happens to be one of the values in the sequence which I just wrote down.

I repeat that according to the theory in its present stage the electron-orbits in the normal sodium atom have a net magnetic moment of zero. This value $eh/4\pi mc$ is, therefore, the magnetic moment due to the spin of the valence-electron—it is the magnetic moment of the spinning electron. I write it in the appropriate place, and then with the aid of the $g$-value derived from the gyromagnetic effect I write down the value of angular momentum which we assign to the spinning electron:

$$p = {}^1/_2(h/2\pi)$$

To this roster of 3 statements about the spinning electron I now make a final addition. The Gerlach-Stern experiment on sodium shows that a beam of sodium atoms—which for this purpose is the equivalent of a beam of spinning electrons—is divided into two by a magnetic field. I write down "2" to indicate this number of separated beams; but I will call it by preference the "number of orientations in the field," because that is the fundamental point. The spinning electron always sets itself in one or the other of 2 orientations, with respect to whatever field it happens to be traversing. We call them the "parallel" and the "antiparallel" orientations, though according to quantum mechanics these terms are a little too strong. Here then is the list of the properties of the electron-spin: $g$ equal to 2—angular momentum equal to ${}^1/_2(h/2\pi)$magnetic moment equal to $eh/4\pi mc$—2 permitted orientations in any field.

It has doubtless struck you as rather odd that I began by talking about the angular momenta and the magnetic moments of electron-orbits, and then carefully picked out a couple of special cases in which these neutralized each other altogether and there was nothing left over except what I ascribed to the electron-spin. Is there no point at all, then, in talking about the electron-orbits? Oh, very much so! Indeed there are cases in which the electron-spins neutralize each other altogether, and we have nothing left over except what is attributed to the orbits. To do this I may choose an atom like magnesium, which has a nuclear charge of $+12e$, a cloud of 10 inner electrons which neutralize one another completely as to angular momentum and magnetic moment (just as in sodium), and 2 valence electrons instead of one. In some of the states of the magnesium atom—not in all of its states, but in *some* of them—the spins of the 2 valence electrons are oriented opposite to each other in the atom, and cancel each other out. When the atom is in a state of this kind, then nothing is left over except the angular momenta and the magnetic moments of the orbits of the 2 valence-electrons; and then, all the statements of the orbital theory (page 1230) are applicable—$g$ is equal to unity, the angular momentum takes one of the values $nh/2\pi$ and the magnetic moment takes one of the values $n(eh/4\pi mc)$. Moreover, there is another theorem derived from quan-

1. When thinking classically, we must not expect the atomic magnets to turn their axes toward the field-direction as they shoot across the field; the gyroscopic quality of these magnets, due to their angular momentum, inhibits this.

tum mechanics which turns out to be valid: The number of orientations of such an atom in a field, the number of separated beams which appear in the Gerlach-Stern experiments, is chosen from among the members of this sequence: 1, 3, 5, 7. . . . (It is a most interesting historical fact, that Gerlach and Stern were moved to undertake their difficult experiment by the wish to test this remarkable assertion of quantal theory.) You notice that the number 2 does not appear in the sequence; were it not for the electron-spin, we never could obtain it; it is distinctive of the spinning electron.

I must, however, admit that all these cases of which I have been speaking are special, and comparatively rare. Both the cases in which the spins neutralize each other perfectly, and the cases in which the orbital moments neutralize each other perfectly—both types are unusual. Still more unusual, and yet occurring here and there, is the most special of all cases—that in which *all* of the moments and *all* the momenta, both those of the spins and those of the orbits, balance one another perfectly so that the sums are zero. An atom in such a state is completely devoid both of magnetism and of spin; such atoms are those of helium, of neon, of argon and the other noble gases, when in their normal states. Usually, however, we find ourselves confronted with some example of the general case, in which neither the spins nor the orbits are completely neutralized. The atom has an angular momentum which is a sort of composite or resultant of the angular momenta of the spins and the orbits, and it has a magnetic moment which also is a sort of composite or resultant.

If I were to embark on the description of the general case this lecture might go on interminably, and at its end you would probably not remember anything except what you had already known at its beginning. The laws of the composition of spins and orbits are so foreign to our customary ways of thinking, and the formulas which express them are so curiously built, that to work once only through them is not sufficient: One has to memorize the derivations and the results alike, and go over them incessantly until they are imprinted on the brain. I think you will agree to this readily enough, when I remind you that this theory is none other than the general theory of spectra; for even quite outside the ranks of physicists, the theory of spectra is beginning to be notorious for its complexity. I shall not venture even to give the formulas, much less their derivations; it must suffice to fill out the 2 lists of $p$-values and $\mu$-values on which I have already begun, and the list of $n$-values or numbers-of-permitted-orientations.

The spinning atom is a congeries of electrons, all of them always possessing spin, most of them usually possessing orbital motions; and these motions are compounded with each other in such ways, that:

First, the angular momentum of the spinning atom has one of the values,

$$p = (0, {}^1/_2, 1, {}^3/_2, 2, {}^5/_2, 3 \ldots)h/2\pi$$

Second, the number of beams in the Gerlach-Stern experiment, or the number of permitted orientations of the atom in the field, has one of the values,

$$n = 1, 2, 3, 4, \ldots$$

Third—and now comes a surprise, for you will probably expect me to say of the magnetic moment that it is $eh/4\pi mc$ multiplied either by an interger or a half-integer; but this is not so. The actual state of affairs is described by a formula which is called the $g$-formula, because it gives $g$ in terms of the moments, both spin and orbit, of the individual electrons. It was discovered by Landé and interpreted in terms of the spinning electron by Goudsmit. The $g$-formula gives unity, as of course it must, in the special cases where the electron-spins cancel each other and only the orbital moments are left over, and it gives 2 in the special cases where the orbital moments are neutralized with only the spins left over. In the other cases it may give any one of a large variety of values: mostly one gets simple-looking fractions such as ${}^9/_8$ and ${}^4/_3$ and ${}^5/_6$. The magnetic moments are then computed by multiplying the appropriate $g$-values times $e/2mc$, into the existing values of angular momentum.[2]

I now turn to that component of the atom of which the spin remains to be discussed—to the *nucleus*.

As I have already intimated, the values of $p$ and $n$ and $\mu$ for the electron-family of any atom are mostly ascertained by analyzing their spectra and utilizing the great general theory of spectra. Such magnetic experiments as I used for my examples are relatively few, and feasible for relatively few substances. The reason for making this remark at this late moment is, that by analyzing spectra we may also learn something about the spins of nuclei; for nuclei also are invested with these properties of angular momentum and of magnetic moment. I take in particular the case of the *proton*—that lightest of all nuclei, the nucleus of the lightest known kind of atom which is ordinary hydrogen, so called to distinguish it from "heavy" hydrogen. Analysis of the spectrum of hydrogen shows us that the proton is capable of taking 2 permitted orientations in a field; thus, our first piece of information about the proton-spin is conveyed by writing $n = 2$.

Now that we have this piece of information, we deduce that as the spinning electron has an $n$-value of 2 and an angular momentum of ${}^1/_2(h/2\pi)$, so the proton with its $n$-value of 2 must have an angular momentum of ${}^1/_2(h/2\pi)$. Continuing along this line of thought, we are further tempted to infer that the proton should have a $g$-value of 2 and a magnetic moment of $(eh/4\pi mc)$. But what shall we suppose about $m$? Formerly it represented the mass of the electron; now we are dealing with a different sort of particle, having a mass which (as many other kinds of experiments show us) is about 1,835 times as great as the electron-mass. I denote this mass by $M$. It seems natural, then, to expect for the magnetic moment of the proton the value $eh/4\pi Mc$, or about ${}^1/_{1,835}$ of that of the spinning electron.

This is a formidably small magnetic moment to hope to measure, nay even to detect! Yet Stern and his pupils undertook to measure it, and they succeeded. Of course,

2. Should any reader intend to proceed from this article to a thorough study of atomic theory, he should be warned in advance that according to the latest form of quantal theory, the $p$-values and the $\mu$-values here given are the values of the projections of these vectors upon the field-direction, the magnitudes of the vectors themselves being somewhat greater: I have given details as to this in "Contemporary Advances in Physics, XXIX, ..." *Bell System Technical Journal*, volume 14, 1935, page 293.

modifications had to be made in the technique which worked so well for sodium. Hydrogen being a gas at room-temperature, no heated oven was required; nevertheless they used an "oven," but it was refrigerated instead of being heated—a sort of super-ice-box; this was in order to obtain slow-moving atoms, for the slower the atoms traverse the field, the more accurately the experiment can be made. I just said "atoms"; but as most people know, the particles of gaseous hydrogen are not atoms, but diatomic molecules—systems composed of 2 protons and 2 electrons apiece. This is a circumstance which in many desirable tests of modern theoretical physics is a great inconvenience, for usually our simplest theoretical affirmations refer to hydrogen atoms and we should like to be able to experiment on them directly. Here, however, it turns out to be a great convenience, indeed perhaps the only thing that makes the experiment possible. For if we had an isolated hydrogen atom, the magnetic moment of its electron would so far exceed that of its proton that the latter would be indetectable. (Perhaps it is not superfluous to mention that bare protons could not be used in the experiment either, as the magnetic field would exert so large a force upon their moving charges that the forces upon their magnetic poles would be insignificant by comparison.)

But if in a single hydrogen atom the magnetic moment of the electron swamps that of the proton, how shall this fate be avoided for a system composed of 2 electrons and 2 protons? Here enters in, and in a very important and significant way, that law of the permitted orientations. Just as a spinning particle of angular momentum $^1/_2(h/2\pi)$ can take only 2 permitted orientations in a field, so it can take only 2 with respect to another particle of its kind—the parallel and the antiparallel. It chances—or rather it does not chance, it follows from the underlying laws of nature—that in the hydrogen molecule the 2 electrons are oriented antiparallel to each other. Their magnetic moments cancel each other, and do not trouble the experimenter.

May not, however, the same thing happen in respect to the 2 protons, so rendering the experiment hopeless? It turns out that for these the spins are antiparallel in some molecules but parallel in others. Molecules of the former type, which is called para-hydrogen, are indeed useless for the experiment; but molecules of the latter type, which is called ortho-hydrogen, are available, and in them the magnetic moments of the 2 protons collaborate so that the magnetic moment of the molecule-as-a-whole is twice as great as that of the single proton, a welcome assistance! In ordinary gaseous hydrogen at room temperature, about $^3/_4$ of the molecules are ortho-hydrogen.

When the experiment was at last achieved by the school of Stern, it was found that the foregoing inference as to the $\mu$-value of the proton is roughly but not exactly correct! The latest information is, that the magnetic moment of the proton is close to $2^1/_2$ times $eh/4\pi Mc$. Measurements with another method by Rabi and his school have confirmed these results; and we are definitively debarred from believing that for the proton and the electron, the magnetic moments stand in the inverse ratio of the masses. Perhaps this signifies that the proton is itself a composite particle, a notion for which there is some support from other sources.

I mention briefly the characteristics of a few other nuclei. After the proton, the next simplest is the deuteron or nucleus of the heavy-hydrogen atom. It is composed of a proton and a neutron, the latter being a neutral particle of about the same mass as the proton. We can observe free neutrons wandering about in space, but we cannot determine their spins nor their magnetic moments. The deuteron, however, has 3 permitted orientations (this we discern from the spectrum of heavy hydrogen) and consequently an angular momentum of $(h/2\pi)$. It is inferred that the neutron has $^1/_2(h/2\pi)$ for its angular momentum, and that in the deuteron these 2 constituent particles—proton and neutron—are oriented with their equal spins parallel to one another. The magnetic moment of the deuteron is less than that of the proton, and accordingly the neutron must have its magnetic moment oppositely directed to that of its companion in the system, even though their angular momenta be similarly directed—a strange complication!

After the deuteron, the next simplest among the nuclei (except 2 which are much too rare for investigation) is the alpha-particle or helium nucleus. It is composed of 2 neutrons and 2 protons. We find that its angular momentum and its magnetic moment are zero, a clear indication that the 4 spins of its components are cancelling each other 2 by 2, and the 4 magnetic moments likewise. Next comes a nucleus composed of 3 protons and 3 neutrons, belonging to the element lithium. It is found that in angular momentum as in magnetic moment it is practically a duplicate of the deuteron, its 6 components having disposed themselves into a nearly normal deuteron attached to a nearly normal alpha-particle. I might proceed some distance farther along the list of the known nuclei after this fashion, were there space; but it is best to close this section with a general rule: *nuclei with an even number of constituent particles* (protons and neutrons) *have even spins, nuclei with an odd number of particles have odd spins.* "Even" and "odd" in this formulation mean that the angular momentum is an even or an odd integer multiple of $^1/_2(h/2\pi)$, respectively. One sees that if any 2 spins of magnitude $^1/_2(h/2\pi)$ are allowed to choose only between parallel and antiparallel orientations, the rule follows inevitably; reversely, from the rule (which is based on experience with some 50 or 60 kinds of atom), we derive extra strength for that theorem about orientations.

Now to come to the conclusion and the climax. Although this property of angular momentum, of being allowed to take only a limited number of permitted orientations—although this strange and wonderful property of angular momentum was introduced in this lecture as though it pertained only to atoms subjected to applied external fields, yet it manifests itself far more broadly. Indeed, it manifests itself universally, and the stability and the character of the world are due to it. I have already mentioned in half-a-dozen places how it manifests itself within the molecule and within the atom: how in the atom, it is responsible for those laws of composition

which determine the angular momentum and the magnetic moment of the electron-family—how in the hydrogen molecule, it establishes a difference between ortho-hydrogen and para-hydrogen—how in the nucleus it fixes the angular momenta and the magnetic moments of composite nuclei as sharply as those of their constituents the proton and the neutron. Perhaps these seem to be remote and unimportant qualities; but what has just been said of them may be said with equal truth and equal force of *all* the chemical and physical properties of all the elements, mass alone excepted (and even mass not fully excepted). If this feature of angular momentum did not prevail, there could not be the fixity of properties which characterizes each element by itself and the variety of properties which characterizes the totality of the elements. Gold would not be gold, lead would not be lead, oxygen would not be oxygen, helium would not be helium; for though it is commonly said that each element is distinguished by its nuclear charge and the number of electrons in its electron-family, this is not adequate. It is the law governing angular momentum which imprints upon these electron-families the characters which we recognize as the properties distinctive of the elements. It seems strange indeed that character should depend upon motion, and fixity upon the laws of whirling things; but however strange it may seem, there is no doubt about it. In the construction of houses the builder requires raw material in the form of brick and stone and wood and steel; but he requires also principles of architecture, whereby the raw materials may be parceled off and integrated into the general design. In the construction of the physical world, mass and charge fulfill the rôle of raw materials, and the laws of angular momentum furnish the principles of the architecture thereof.

# The Engineering Profession

## Not what the engineer does, but how he does it differentiates engineering from the other learned professions

By GANO DUNN
PAST-PRESIDENT AIEE

THE ADVENT of the scientific method and the rapid spread of its use in connection with practical things, which began not much more than 150 years ago, called forth the ministrations of many specialists in the application of science to social purposes. There always had been military engineers who made roads, bridges, catapults, and petards; but in the sense we are now considering it, they did not constitute a profession.

To distinguish the new men from these time honored military engineers, they were called civil engineers. In those days civil engineers busied themselves in the whole field of then known science instead of in the narrower field which civil engineering now embraces. James Watt, for instance, was a civil engineer. These civil engineers, as distinguished from military engineers, began to constitute a new class in the community; this class has grown in geometrical ratios as to its numbers and as to the varieties of its occupation, until it has spread its activities into every material department of life. The very foundations of society would be shattered if the class should today cease to exist.

Specialization in this great and growing class has created over 50 branches of engineering sufficiently distinct to be recognized in library catalogs. Because of this growth in scope and subdivision into widely different specialties. occupations in the various engineering branches have become so differentiated that the extremes bear almost no resemblance to each other. Even the grand divisions of the engineering profession represented by the national societies of civil, mining, mechanical, electrical, and chemical engineers, give little more than a hint as to occupation. An electrical engineer may spend his days on the macrocosmic problems of corona in the long-distance transmission of vast amounts of power, or he may wrestle with the microcosmic subtleties of the multiplex modulation of carrier waves. As an indication not only of this diversity of occupation but of the rapidity with which change of subject matter has taken place, I will give a few examples.

It is within my time that power transmission did not

---

Essential substance of the commencement address delivered at the 70th graduation exercises of the Massachusetts Institute of Technology, Boston, June 8, 1937.

GANO DUNN has been president of the J. G. White Engineering Corporation, New York, N. Y., since 1913, and is also president of Cooper Union for Advancement of Science and Art, New York, N. Y. He has received the following degrees: bachelor of science (1889) and master of science (1897) from the College of the City of New York; electrical engineer (1891) and master of science (honorary, 1914) from Columbia University. Mr. Dunn is a life member of the AIEE, and in addition to having served as president of the Institute in 1911–12, he has served on many Institute committees over a period of more than 20 years. He was president of the New York Electrical Society, 1900–02, and of the United Engineering Society (now United Engineering Trustees) 1913–16; he also served as chairman of The Engineering Foundation, 1915–16, and of National Research Council, 1923–28. He is a member of many other engineering and allied organizations, and has served as a director of the American Society of Mechanical Engineers and of the American Society of Civil Engineers, and as honorary secretary for the United States of the British Institution of Electrical Engineers. He is the author of various papers on electrical and engineering subjects.

exist. The electrical engineer of that day, in one group was concerned with the intricacies of direct-current commutation or with the then still unsuccessful endeavor to produce an electric motor that would run on alternating current, which was at that time a novelty limited to the field of electric illumination. In another group he was estimating the economic barrier represented by the cost of 2-wire metallic circuits for telephones, and cogitating whether the priority which telephones shared with the telegraph in the exclusive use of circuits of a single wire with increasingly noisy ground returns was worth the expensive legal fight its preservation was forcing upon him. In another field the coherer was unconscious of the vacuum tube that was to follow.

Mechanical engineers in their sphere burned midnight oil developing a reciprocating steam engine that would run at a speed high enough for the direct driving of electric generators, in order to make possible the elimination of the grave disadvantages of the ubiquitous leather belt. The successful internal combustion engine and a useful steam turbine had not been born.

I could go on, but trust that I have indicated that the progress of the engineering art in the past already has demonstrated the folly of attempting to forecast in the electrical field alone what will occupy the electrical engineer of 150 years hence.

It is possible that I already have gone far enough to have suggested what it actually is that constitutes the practice of the engineering profession and sets it apart from the other learned professions. The answer is: it is not what the engineer does, but how he does it! Not what the engineer's occupation is, but the intellectual processes by which he attacks that occupation.

In other words the method of engineers rather than their occupation is the characteristic of the engineering profession. Method is the common denominator of all engineers. While the *subject matter* of engineering unquestionably will continue to change in the future, not so with the *method* of engineering. It is certain that the engineer of the future will be using the present method 150 years hence, even if no prescience is capable of forecasting to what occupations that method will be applied.

What is this remarkable method that has changed the nature of the world? As is well known, it is the method of science—that process of reasoning based upon observed data and working hypothesis which, by inductive and deductive procedure and experiment, arrives at new knowledge.

It must be pointed out that, except where their qualities are combined, the engineer and the scientist are not the same person, however much they use the same method. Their objectives are different. Many attempts have been made to define engineering, and engineers do not agree on any one definition; but a definition I worked out some years ago seems to stand the test of criticism and of perspective. It is as follows: Engineering is the art of the economic application of science to social purposes.

Being an art, engineering thrives on repetition. It develops skill and it develops style. The second and third power plants that an engineer builds are likely to be better than the first, although there may not have been introduced a single new principle. The scientist, however, shuts his mind as far as possible to all human prejudice and influence of feeling, save only for the divine fire of that imagination which creates the working hypothesis; and he learns how to discern truth and new knowledge in a study of the order of nature.

The engineer, by the same intellectual processes as the scientist, applies that new knowledge to social service. The essential difference between the scientist and the engineer lies in the economic involvement of the engineer's work. In this hot crucible of the economic test all that an engineer does must be tried. To repeat an old saying, an engineer is a man who can do with one dollar what any fool can do with two; and it is in his economic involvement that the engineer can rise to some of his greatest powers.

Economics is a social, not a physical, science. It embraces problems of the human spirit and the behavior of man as man; and because the engineer's art deals with dollars and economic relations, he is bound into the great business structure of society in a way that the scientist is not. Being bound into this structure, he must be a man among men. He must be able to make his views prevail. He must be able to persuade and to contend. He must be able to give blows and to take them. These activities do not devolve upon the scientist in his laboratory. To the engineer, they are everyday life.

If an engineer's training neglects the great human mirrors of history and languages, particularly his own language; if his mind and heart are not sensible to the great social forces of his day and of his community; if he but feebly develops the subtle qualities of character that make for personality, his career as an engineer is limited, no matter how much science he may know.

If the key to the scientist is thought, the key to the engineer is action. Value and utility are the engineer's criteria, rather than truth, which is the criterion of science.

For these reasons, as the engineering profession has developed, the center of education for engineers has been shifting more toward the humanities. This is one reason for the greater part engineers constantly are playing today in the great rôles of life. But while the humanities are of profound and increasingly recognized importance in the arch of an engineer's education, its keystone always will be science.

Not all men with an engineering education take up the practice of engineering. It is significant how many are drawn off into the field of organization and other fields, where the engineering method of approach to problems and the engineering point of view introduce fermenting leaven into many of the processes of traditional business procedure. Partly for this and for other reasons, engineering has become the cornerstone of industry. In the precipitations of relationships brought about by big business and mass production, the function of management has fallen very largely to the engineer.

In the field of management, involving the play of the human spirit at its best and at its worst, where, particularly in labor relations, generosity, loyalty, and independ-

ence are manifest as well as passion, ignorance, and vanity, the engineer's capacity for organization, leadership, and sympathy has rare opportunities. Even in these days which we often think to be so far advanced, the sway of prejudice and of certain kinds of superstition is still profound. It awaits the light of reason and human understanding.

Executions for witchcraft were once a common part of everyday life. At the time when Salem shocked the colonies by a series of 19 such executions, literally thousands of witchcraft executions every year were carried out in Europe. Over a period of 40 years there were 8,000 such executions in intelligent Scotland alone. The least unusual circumstance or unexplained phenomenon was liable to be charged to occult and demoniac causes, and constantly brought the penalty of death by flames upon upright and innocent persons or upon individuals who were unpopular or politically inconvenient, or who were merely intellectually independent. This madness, which had spread over most of the civilized world, was dissipated by the same great light that founded the engineering profession. About that time the dawn of the scientific method began to shed its beams of intelligence into the darkness of human prejudice. The results it accomplished in the social sphere through the dissipation of superstition, although overshadowed by the results in the sphere of the material world, have been of immeasurable importance.

The social sphere today is still a field that needs the light, a field in which the engineer with his training and point of view has open to him doors of rare opportunity. While not as sinister as the witchcraft problems, there are problems of prejudice in our social field that are, like witchcraft, based upon distrust and ignorance—problems that act as a brake on industry and separate man from man.

While I have dwelt upon the essentially economic character of the engineer's field and the social service rendered by him in the cultivation of that field, such social service is an indirect one, effected by his function rather than by a disinterested will to serve. For performing his function he receives compensation, and therefore it often is urged that he is not entitled to personal credit for social service, since he is paid for it. In the case of certain engineers, there is much weight in this criticism. It also is urged that much of an engineer's work comes under the head of business for which the professional status cannot be claimed, and that the only really professional engineer is the consulting engineer; who, it must be admitted, is usually an ornament to the profession and perhaps more conscious of a professional responsibility than many of his fellow engineers.

Similar questions have beset the older professions; and they have been worked out in a tolerably satisfactory way. No lawyer considers it a reflection, especially an ambitious young lawyer in a country district, to be referred to as conducting a law business; nor does a lawyer consider that he is not a member of the legal profession if he accepts an annual salary from a corporation for continuous service. Equally unaffected as to his professional status is the physician who works for a salary as distinguished from fees for general practice.

The essence of the professional status lies in the moral obligation involved in the act of professing. This act is always personal; and it is in the engineer's personal relations to his fellows and to society and the obligations therein involved, wholly over and beyond obligations for which he is compensated, that his professional status resides.

These moral obligations are the reasons why such particular weight is put upon character and integrity by the boards of examiners of the great national engineering societies before admitting to membership, and why violations of professional ethics rather than failures in professional competence have been practically the only grounds on which expulsions from these societies have been based.

Turning to the older professions for our models, we find that questions of personal obligation to fellows and to society constitute the very foundation of the professional conception. In these older professions the engineering profession has noble examples of the practice of obligations that are self-assumed and disinterested. The medical profession has its Hippocratic oath peculiarly pledging its novitiates to the service of mankind, irrespective of compensation. The legal profession, in its defense of penniless defendants and the vast amount of uncompensated service it renders to the courts and to the public as an arm of the law, illustrates its conception of professional service outside the field of compensation. As to the clergy, its objective is exclusively social, and its devotion is unmeasured by compensation.

Engineers themselves have been the first to recognize obligations that inhere in a growing consciousness of the professional status. Their great societies have been created not merely for self-education and intellectual development, but to give expression, in their relations with each other, with other professions, and with the public, to a desire for a standard of personal relations and for the recognition of obligations, beyond those which are pecuniary. Just as the peculiar equipment of the clergyman, the lawyer, and the physician gives him a peculiar power and authority when disinterestedly devoted to social betterment, so does the equipment of the engineer.

The engineer today finds himself in a pivotal position in industry, intermediate between capital and labor, with the problems of both of which he deals intimately and is in a position to understand, interpret, and judge. In consequence, there is offered to him entirely in addition to the service he performs through his engineering function, an opportunity for social service through his professional and personal status which, if he rightly conceives and seizes it, gives him a strategic advantage to render social service, which at this moment, the representatives of the older professions do not possess.

Is it too much to hope that with an enlightened method of approach and the habit of factual investigation which are the intellectual birthrights of the engineer, his increasing participation in management may bring to the solution of some of the social problems of industry a prejudice-dissolving light? Such a light is capable of showing the

path to a new happiness in work, in which there is a recompense greater than all wages—joy in the act of creation. If there could come about a spirit of reciprocal confidence on the part of all elements, we could not fail to see increased production and increased leisure go hand in hand, securing those satisfactions deep in the consciousness of all Americans, which the immortal Declaration of Independence describes as the inalienable rights of life, liberty, and the pursuit of happiness.

To seize these opportunities for social service necessarily involves a demand upon the souls of engineers as well as upon their minds, which will be a test of their love of their fellow man. It is a case of *noblesse oblige*. Every engineer certaintly will have some occasion for meeting this test. When and as often as the test shall come, may none ever ask, in the words of Cain, "Am I my brother's keeper?" unless he already has resolved in his heart the intention to answer "I am."

# Our Sons Specialize

## But most scholars and industrial leaders consider a foundation in science and the humanities more valuable to the engineer than specialized technical training

By GILBERT E. DOAN

THE engineer's influence in modern society may be pictured by considering him as an energetic surgeon operating in a large and effective way upon the social organism. He is skilled in the use of instruments, but generally quite ignorant and unconcerned about the nerves and endurance of his suffering patient. His one-sided interest in tools and techniques begins in the engineering college where his teachers are content if he learns technology. Later, when he comes to apply the knife of modern science to the vitals of society, does he inflict needless pain? Does he suffer too? But can it truly be said that the average engineering graduate is uneducated? The academic-minded scholars may say he is, but that proves nothing. These scholars have forced a liberal education upon our physicians and lawyers. After all, the captains of industry employ the engineers. They might tell what training leads to long-range success. What do they say about our modern engineering education?

These leaders are keenly aware of the many strong features of engineering, but they condemn the narrowness of the present system in no uncertain terms. As men of vision as well as men of practical affairs they preach the same doctrine as the scholars: "Get the humanities and the foundations of science, but don't get technology. Industry will teach the man its technologic methods quickly enough. But industry cannot undertake to give him a liberal education or a sound scientific background if he comes without these."

What is this narrow training that the engineering schools give their students? A survey of representative engineering schools, conducted several years ago by the Society for the Promotion of Engineering Education, shows that the student in these schools received 30 per cent of his credits in basic science, 60 per cent in technology, and 10 to 15 per cent in subjects that can be called broadening or cultural—a little English, a taste of a foreign language, a bit of economics. A report published by the SPEE this year shows that the situation remains essentially unchanged. Evidently the student gets a good foundation in science and technology, but very little else. This evidence does not contradict the industralist's charge.*

But the 10 to 15 per cent of liberalism may be misleading. Perhaps the *spirit* of the engineering school is broad and liberal as it was in Germany before Hitler. It could be, but 20 years of experience in and out of such institutions both here and abroad seems to indicate that the American curriculum is not misleading. It truly represents the student's preparation for life. In spirit as in subject matter the typical engineering education offered in this country, possibly with a few exceptions, is essentially the same narrowly specialized schooling, involving for many fine boys the same spirit-stifling ordeal, the same growth-stunting régime today that it did when these industrialists were students. In fact, with the rapid advance of technology into new fields less room is left in the curriculum for the humanities than there was 35 years ago. The social upheaval of the thirties resulted in a measure of soul-searching on the part of engineering faculties, but so

Essential substance of an article "Our Sons Specialize" published in the summer 1937 issue of *The American Scholar*, official publication of the United Chapters of Phi Beta Kappa, pages 294–303.

GILBERT E. DOAN is associate professor of metallurgy at Lehigh University, Bethlehem, Pa.; a member of the Society for the Promotion of Engineering Education and of the American Institute of Mining and Metallurgical Engineers.

*In September 1936, Massachusetts Institute of Technology took an important step toward liberalization by raising the percentage of humanistic subjects to approximately 17 per cent, running a band of 3 hours in humanistic fields through the entire 4 years. These courses have been integrated to avoid haphazard selection. Most important, perhaps, is the liberal point of view encouraged in the faculty by this step.

far it has led to little effective action.

Fresh out of high school the boy comes to college eager as boys are for a deeper understanding of the big things of life. He trusts his college to know what industry wants him to learn and to steer him wisely—a sacred trust if ever there was one. Enrolled as a freshman engineer he faces a stiff schedule of chemistry, physics, mathematics, and drawing. From 3 to 5 afternoons a week in the laboratory accompany them. He sees that he must shut out everything but science from his serious attention or fail his courses. In his sophomore year the intensity of specialization increases. The humanism encouraged in him at high school is effectively submerged. His budding intellect passes through a desiccating desert of abstract science—science which furthermore, so far as he can see at the time, has little significance for his chosen special field of engineering. For his vacations he gets practical experience by working in an industrial plant, and in his junior or senior year a little economics. That is all. His course contains 60 per cent of technology, including much semivocational training. Rapidly his broader interests atrophy under this pressure. Human problems become extraneous to his chief concerns, pale into unreality and vanish from his ken. If you want to see the result try reading a college magazine published by engineering students or talking to them about social security. The student is so busy learning new techniques that he has no leisure left for contemplating the significance of anything in college or out of it. He has no contact with history, biology, or philosophy.

As a result of this diet the most stimulating intellectual adventure that many a boy can remember at college is the fraternity "bull-session" prolonged into the wee hours of the morning. Here such vital topics as success, religion, morals, and marriage are discussed. If one boy in such a group were soundly informed on these subjects the discussion might be enlightening, but the engineering student must rely on casual heresay for the answers to humanistic problems, and the interests which such sessions stir in him are next day stifled.

Is this sacrifice of breadth in the boys' education justified? Fifteen years after these students have left their alma mater we expect to find them practicing engineering. Actually, less than 50 per cent of them are. Even the more successful of the engineering group are in positions where the managerial and administrative problems completely overshadow the technical. The farther these engineers advance, the less is the relative value of their technical training and the greater would be the benefit of a liberal education. Is the sacrifice justified for the boys of either group?

We have always believed that the "mental discipline" acquired in engineering studies will make men keener analysts in all the other problems they will meet. Many engineering educators still preach that doctrine. They don't realize that psychologists long since have shown that "mental discipline" is at best only partially transferable from one field of knowledge to another. Does your training in calculus, for example, enable you to grasp the roots of a labor situation one whit more surely than you could without it? No. We are compelled to accept what the scholars have long maintained: The engineer's schooling is of minor value in the advanced stages of his career and of even less value in his private life. Engineers we certainly must have, but must there be a lack of cultural balance in their preparation? If they are uneducated, has the college kept faith with the boys?

Even in the truly professional group a chemical engineer will find himself employed in the production of electric power, while a civil engineer manages a group of metallurgical furnaces. The conclusion will not down: The investment of undergraduate time in specialization is unwise.

Thus it is not the study of science that prevents our engineering students from getting a balanced preparation for life. It is the crowding out of an education by semivocational training. This overemphasis goes on in spite of the fact that industries can and do give vocational training to the graduates they select and do it better than the colleges.

Why, then, is the student given courses of this kind at college? In the first place the student gets them because his parents want him equipped to earn a better living, and they believe specialization is the best preparation. Having, in the majority of cases, no college experience of their own, they seek out the shortcuts offered by schools giving the earliest and most intensive specialization. In the second place the director of a student's curriculum is usually an engineering graduate and his own training was largely of this specialized kind. Specialties seem to the director essential to an engineering curriculum. They give it distinction, differentiate it from the indefinite "arts" curriculum. If it were too much like other curricula it might indicate lack of faith in the value of the special field. Certainly it would attract fewer students. Finally, the student gets the specialized course because he wants it. He can see what it did for the professor. It promises to prepare him for a definite career, which is more than "philosophy" promises. He hears there are good jobs open in that field. He likes the label, too. It has a ring of modernity that history and biology lack. Look at the expensive laboratory equipment used in the couse! That is what his high tuition buys. He should get all of it he can while the opportunity lasts. The enrollment for the course will be large, the students pleased with their opportunity and eager. What attitude could more surely warm the heart of a professor?

But don't the boy and his parents know that industrial leaders as well as scholars disapprove of specialized courses for undergraduates, that they consider a foundation in science and the humanities far more valuable than technical training? The answer is "no." They think that at least industrial leaders would strongly approve. Don't they know that at graduation the boy will take the best job offered, whether it is in his specially chosen field or not, and that the chances are several to one that it will not be?

When the subject of engineering school curricula is studied broadly, as was done in 1926–29 by the Society for the Promotion of Engineering Education, the need for liberalization is unanimously acknowledged. The society recommends that the proportion of liberal subjects be increased from 13 to 17 per cent. What have the engi-

neering educators done about this recommendation, inadequate as it is? The report was read, no doubt, by the president of each institution and passed on to the curriculum directors with recommendation that it be perused thoughtfully. Each director will agree half-heartedly that liberalization probably is desirable, but always in another department, not in his own. The director of civil engineering will feel strongly that the electrical-engineering curriculum should be liberalized by dropping specialized courses, but that with civil engineering it is different. Perhaps as a concession to appearance a course in "railroads and terminals" would be moved from the "required" list and made "optional" with one in economics. He dosen't think "arts" courses are worth much anyway. He never felt the lack of them. The report gets as much action as the 1923 Carnegie report on professionalism in college football, although for a different reason. Our question "Why does the student not get the kind of education the industrial leaders and the scholars say he should have?" has now been answered; parents seek speculative shortcuts. The engineering educators are steeped in their own tradition, and that tradition is not liberal. Perennially the scholars have said engineering education was wrong from the idealistic standpoint. The industrial leaders now find it wrong from a practical standpoint.

The teachers of engineering are a group of sincere and capable men. Many have made noteworthy contributions to the technical aspects of engineering. But the price they paid was a life of narrow devotion. Only the exceptional man escapes the restricted outlook thus entailed. Their chief fault, if it be one, is this intense devotion to their own field and their undeveloped vision, often amounting to partial blindness in other fields. Usually they are not concerned with the broader problems of industry. In many cases it is their sincere belief that industry prefers men with a maximum of technical training, whether they are soundly educated or not. Thus even the changes that the farsighted leaders of engineering education agree upon in this direction do not receive very wide adoption.

Do the alumni who invested in these technical specialties at college later criticize their alma mater or feel resentment at the faculties which trained them so narrowly? Generally not. The alumnus enjoyed the prospect of an engineering career and the sincere enthusiasm of his teachers for their subjects. He saw the practical usefulness of the studies he pursued—even if they never were useful to him. When he left engineering he did so of his own free will. He had bettered himself by so doing. Anyway, college had been fun. "If I had it to do again I would take the same course" says the engineering graduate who has become a nontechnical executive. But you must note that the liberal-arts graduate who holds a similar job says exactly the same thing. One cannot expect him very ardently to long for what he doesn't understand. Few men regret what they did in a period of life which on the whole they enjoyed; few will bewail a deficiency they have later partly overcome. Most of the highly successful graduates are too busy and too tolerant to try to influence the educational policies of their alma maters.

This unsound state of affairs in the education of 50,000 bright boys a year should not continue. The preparation of engineering students should attain the standard agreed upon by both scholars and leaders of industry. And I believe it will. An adequate grounding can be achieved in 4 years. Most of the engineering specialties will have to be eliminated. To those who want them, specialties will be available in a fifth year.

Equally important, the attitude of engineering educators toward liberal education must change, for they hold the boy's complete confidence. What they tell him in these matters he accepts and will continue to accept as final truth. There is some evidence recently that their attitude may change but new and attractive fields of special technology are constantly being developed and parents and their sons will for some time continue to seek them as speculative shortcuts to success. So long as they are willing to pay the price the temptation to meet their wishes, however unwise, is great. The scientific foundation of the student's education will be preserved and augmented. But the capable graduate of the new type will have been prepared to act wisely in a broader sphere of affairs. When a labor crisis arises out of the use of one of his labor-saving machines, for example, his background of history, and perhaps psychology, will enable him to see the industrial situation in a clearer perspective. When a social security program is proposed, perhaps by thoughtless politicians, he will be able to understand at least the basic biological significance as well as the fundamental economic implications bound up in it for the future of the human race. He will have a right conception of the ends of life. Such vital questions as women in industry, the liberty of the individual in society, and crime will present themselves to him not as simple problems, it is true, but as matters resolvable into their component parts in the broad light of the great fundamentals of biology, economics, and history. He will be competent to see his engineering activities in their proper background and perspective, that is, he will be an educated man and not merely a technician.

Certain superiorities inherent in engineering education will certainly be preserved in the new version. Engineering education is professional education; it is purposeful and definite. In its liberalized form it will continue to supply dynamic and purposeful motivation to the student. Through this focus of his mind he will integrate the liberalizing and humanistic studies which must accompany professional training.

The faults of the present engineering education are not inherent in it. They can be eliminated without sacrifice and with great gain. Let one first-class college cut through the meshes of its illiberal traditions and the inertia of its vested interests. Let it frankly and wholeheartedly abandon the training of technicians in behalf of the education of engineers. Such a college need not fear for its future. To it will inevitably be attracted both a faculty to provide sympathetic administration of its program and a student body capable of profiting thereby. They will come from the better backgrounds where engineering education is now increasingly condemned. But the first step must be to set up a sound and attractive program.

# Physics and the Engineering Curriculum

## "Instruction in physics has been not only the mother of engineering, but for the future must be the heart of its instruction—its guide, philosopher, and friend"

By O. W. ESHBACH
FELLOW AIEE

ENGINEERING was originally the despised child of science. At the time of its birth, which occurred in a period of invention, it was not very welcome. In the second stage of its development, that of curriculum building which followed through a concurrent period of commercialization of inventions, many mistakes were made; and now since the beginning of the twentieth century, when it has been accepted the tremendous development of new ideas brought about by research in both colleges and industry have so swamped the all-inclusive efforts of curriculum builders that there is a threat of filial ingratitude. No matter how great the pressures are to limit time devoted to this instruction, it seems to be a false step to subordinate the importance of instruction in physics and likewise its financial support.

In recent literature on engineering education 3 ideas predominate as possible ways out. The first is, instruction should be more fundamental; second, the curriculum should be longer; and third, graduate study must be developed. All are in progress. This contribution, if it may be so graced, is a plea for the effective use of time, and it is in this relationship that instruction in physics is discussed. The simile for this thesis is taken from the field of electric traction, the speed-time curve. The principle is physical, common, and simple—the speed at which one travels determines the distance one can go in a given time and also the time to go a given distance.

Effective instruction in physics determines the quality and tempo of engineering teaching. Two of the important portions of a speed-time curve are the periods of acceleration and the portion when, after the maximum accelerating force has been applied, the motor operates in accord with its own characteristic. The peak velocity it will reach in a given time, operating on this characteristic, is affected by its rate of acceleration. Likewise, the stimulation given during the first 2 years of an engineering curriculum will be the determining factor in the speed of comprehension and effectiveness of learning of students during the latter part of their courses when, to a large extent, their own characteristics should determine the dimensions of their education.

This truth is axiomatic, but what most educators would like to know is how to do it. Some have attempted, with success, to crowd the maximum of mathematics into the freshman year, thus forming the background for a more effective study of physics in the second year. Those who have tried to introduce physics during the first year have found the necessity of continuing the instruction through the sophomore year. In either case it becomes perfectly obvious that a knowledge of mathematics and how to get it soon enough are 2 of the principal problems involved. The solution would seem to lie in an effort at integrating the early instruction in both physics and mathematics, limiting the instruction in early years to those new concepts in each field which are basic to the understanding, and early introduction of instruction in the several professional branches of engineering. To stop with the mere organization of instruction along these lines is insufficient. It is just as important that a procedure be made for stimulating teaching through a stimulating environment of adequate physical facilities. And to stop *there* is insufficient, because it would merely relegate physics to a subordinate influence in the professional thinking of students in later years. It would seem necessary to continue more advanced instruction through the junior and senior years.

This probably would mean the elimination of some of the specialized courses or options in the professional branches. The loss would not be serious, however, if time were saved by allocating everything that properly belongs in physics to that department. If such a procedure were attempted, it could only be accomplished through a cooperative effort on the part of the teachers of physics, mathematics, and engineering, which I believe would have to result in the scrapping of much of our standard text material, the development of a new technique of teaching, and a more advanced approach to the applications of science to engineering practice. An attempt in this direction would bring about an early development of intellectual capacity, a much greater speed of learning, the acquisition of more knowledge in the present 4-year period, and ultimately a more competent and better-educated professional body.

There are many weaknesses in our present situation. First, there is a failure to capitalize the interest which has led the most promising freshmen to select engineering as a career. This could be accomplished by an early introduction to physical concepts through the familiar types of

Essential substance of a paper presented at a meeting of the Society for the Promotion of Engineering Education, Rutgers University, New Brunswick, N. J., May 15, 1937.

O. W. ESHBACH is special assistant, personnel department, American Telephone and Telegraph Company, New York, N. Y. He is a graduate of Lehigh University from which he received the degrees of electrical engineer (1915) and master of science (1920). For several years after graduation he was engaged in teaching at Lehigh, during which period he also served in the Army. In 1923 he joined the Bell telephone organization and was appointed to his present position in 1925. He has served on several AIEE committees, having been chairman of the committees on education (1935–37) and Student Branches (1935–36). He is a member of the Society for the Promotion of Engineering Education.

engineering apparatus, giving both exactness of concept and quantitative approach. Because of large numbers of freshmen and inadequate facilities both in laboratories and teaching staffs there is not the personal contact with individual students which could be used for guidance and stimulation in a period now one of the most discouraging in a college student's career. In short, the physics department may be the first vocational guidance agency of the college.

Second, as instruction in engineering is now organized, it too often lacks co-ordination with physics, which often results in duplication of effort. While repetition is a good thing, it does not seem reasonable to a student that a curriculum frequently should require instruction in exactly the same subjects at exactly the same time, in 2 different departments. Co-ordination can be accomplished only by sympathetic understanding and willingness on the part of the faculties of both groups, not only to get together occasionally, but through faculty meetings of each group to meet regularly.

The problem of the physics department of engineering schools may be regarded as embracing 3 general objectives:

1. To instruct undergraduates in those principles of physical science which are essential to an understanding of engineering practice, and develop an appreciation of the relationships in these fields which will encourage the further development of their application.

2. To develop physicists, in addition to engineers, who will be able to carry on the future work in education and research which this important branch of science demands.

3. To develop in all students, technical or nontechnical, an appreciation of the scope, place, and importance of physical science in the modern world.

Considering the question from the limited view of a service function of the physics department should not be construed as a lack of appreciation or resentment toward glorifying the study of exact science as a plane of higher intellectual learning, but rather facing the fact that much of engineering is synthetic in character and must meet compromising and temporizing reactions of economic and human forces. Putting it in another way the engineer takes a utilitarian or practical attitude toward the study and application of physical principles. This fact does not alter the selection or determination of what should be taught, but is a vital factor in the stimulation derived from the way it is taught.

For example, if one were to examine good textbooks in each of the several engineering courses and list the physical principles involved in the understanding of them, by summarizing the results one would still say, teach mechanics, heat, light, sound, and electricity to freshmen and sophomores. These are basic physical phenomena from which applications have arisen through innumerable combinations of principles. Further investigation together with consultation with the faculty of the engineering college should hold promise of advantageous adjustments in time and emphasis given to the several basic courses, but the greatest values are to be obtained from understanding the body of engineering knowledge with a thoroughness that makes possible the selection of projects and problems to vitalize instruction in fundamental principles. Bluntly put, teachers of physics to engineers need to study engineering.

Another phase of the topic may be emphasized by rather sketchy illustrations. Progress in engineering is not stationary; in fact, it is one of the most swiftly advancing professions. With it the body of scientific and engineering knowledge has grown to proportions where serious consideration must be given to the time element in undergraduate education. Whether the situation will result in an extension of time or a modification of curricula, with greater emphasis on subjects in the field of mathematics and pure science, remains to be seen. In the meantime, teachers who are preparing engineers for careers 10 or 15 years hence cannot overlook the changes going on in practice and must attempt to anticipate the relative importance of new developments and viewpoints in the field of science. This refers more to instruction beyond the scope of what in the past has been regarded as the minimum fundamentals.

For example, in electrical engineering the last student generation has been giving increasing attention to the development of electronics with accompanying interest in the understanding of the physical nature of matter. Atomic physics, radiation, and high-frequency current phenomena are, as a consequence, edging into every curricula; in mechanical engineering the orthodox instruction in thermodynamic principles and applications is under pressure, and involves better understanding of the phenomena of internal energy, heat, and heat transfer and insulation; the industry of heating and ventilating and air conditioning is in a state of change; design is affected by the development of the art of welding; in civil engineering building materials are changing—the theoretical approach to stress analysis and fluid mechanics are viewed with a broader technical approach, in which the subjects of dimensional analysis and model structures are of increasing importance; in aeronautical engineering there is the most complicated application of mechanics to structures and fluids. All this seems to point to the necessity of greater exactness in physical concepts and the importance of perspective in dealing with related fields of practice.

It would seem, therefore, that the objectives of service functions of the physics department to the engineers should be: first, to teach thoroughly the minimum fundamentals necessary or prerequisite to beginning engineering subjects; and second, to organize the advanced courses so as to anticipate future requirements. The balance or emphasis given the subject matter must come from a knowledge of engineering practice and trends, in which cooperation with the engineering faculty is essential.

In closing, there are 2 aspects of the human side of the problem which are a part of the service. The first has to do with levels of ability and interest and the second with flexibility of occupational opportunity. Many students would profit by an engineering education; only a portion of them, however, will make successful engineers in a professional sense, and some never should study engineering because they have less than the minimum of ability required to profit by it. Can physics teachers in their

instruction help the engineering division to solve these problems?

Regarding flexibility of opportunity, many engineers seem to be restricted in possibility of accomplishment by too early specialization, a good deal of which comes from a failure to appreciate the scope of application and co-ordination of technical knowledge in practice. Is it possible to bring under the influence of an independent department those subjects of engineering which are elementary, the co-ordination of which will broaden a student's viewpoint and stimulate his interest and curiosity? If there is any justification for such an attempt it would seem to be in the fact that industry is both a crucible and a catalyst for science, where personal opportunity easily can be hampered by premature decisions and prejudices.

# Use of the Slide Rule for Adding

## By combining its ability to perform addition with its other functions, the usefulness of the slide rule may be greatly increased

By E. B. FERRELL

AS IT commonly is used, the slide rule serves as a set of tables and as a multiplying device. As the latter it also is used in performing the inverse operation division. By combining the 2 functions one may perform such operations as division by a sine, or multiplication by the square of a tangent. For many users the technique of slide rule operation goes no farther than such simple combinations.

By the inclusion of one more concept, however, the technique can be extended to include many addition problems, and a whole new field of usefulness may be opened up. The idea may be illustrated by a simple example. Suppose 18 and 45 are to be added; this may be written

$$18 + 45 = 18\,(1 + 45/18)$$

This reduces a general addition problem to one involving division, multiplication, and a very special addition. The division and multiplication can be performed on the simple slide rule. The special addition can be performed mentally. The only thing remaining is to arrange the work conveniently.

It is helpful to look upon the problem as a continued proportion. A series, 1, $n$, $n + 1$, is set up such that its third term is the sum of the first two. Next any other series is set up whose terms are proportional to those of the first series. Then the second series also satisfies the condition that its third term is the sum of the first two. The setting up of such a continued proportion is one of the easiest things to be done on the slide rule. In the numbers of the example,

$$\frac{1}{18} = \frac{n}{45} = \frac{n+1}{63}$$

This ability of the slide rule to serve as an adding device may be combined with its ability to serve as a set of tables. Squares and reciprocals may be added. To the communication engineer this immediately suggests the combining of impedances, either in series or in parallel.

Suppose the value of the impedance resulting from connecting 5 ohms in parallel with $j4$ ohms is to be computed. Since this is a parallel combination, reciprocals are involved. Since it is a vector combination, squares also are involved. In particular, a series of 3 numbers, 5, 4, and $Z$, are to be set up such that the squares of their reciprocals will form one of those series whose third term is the sum of the first two. Now on the ordinary polyphase slide rule, the numbers on the $B$-scale are the squares

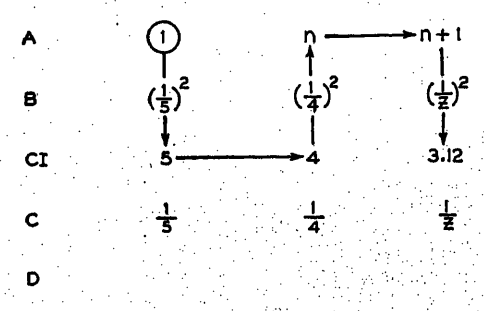

**Figure 1. Setting of the slide rule for computing the absolute value of the combination: 5 ohms in parallel with j4 ohms**

Written especially for ELECTRICAL ENGINEERING.

E. B. FERRELL is a member of the technical staff of the Bell Telephone Laboratories, Inc., New York, N. Y.

of the reciprocals of numbers on the *CI*-scale. And numbers on the *A*-scale are proportional to numbers on the *B*-scale. Therefore, the problem may be solved by reading the numbers 5, 4, and *Z* on the *CI*-scale so that the squares of their reciprocals, on the *B*-scale, lie opposite the series 1, *n*, *n* + 1, on the *A*-scale. The face of the slide rule as set up to perform the required operations is shown diagrammatically in figure 1. The letters at the left of the figure are the names of the scales involved. A vertical line indicates the alignment of 2 numbers on different scales, as may be done with the aid of the runner. The

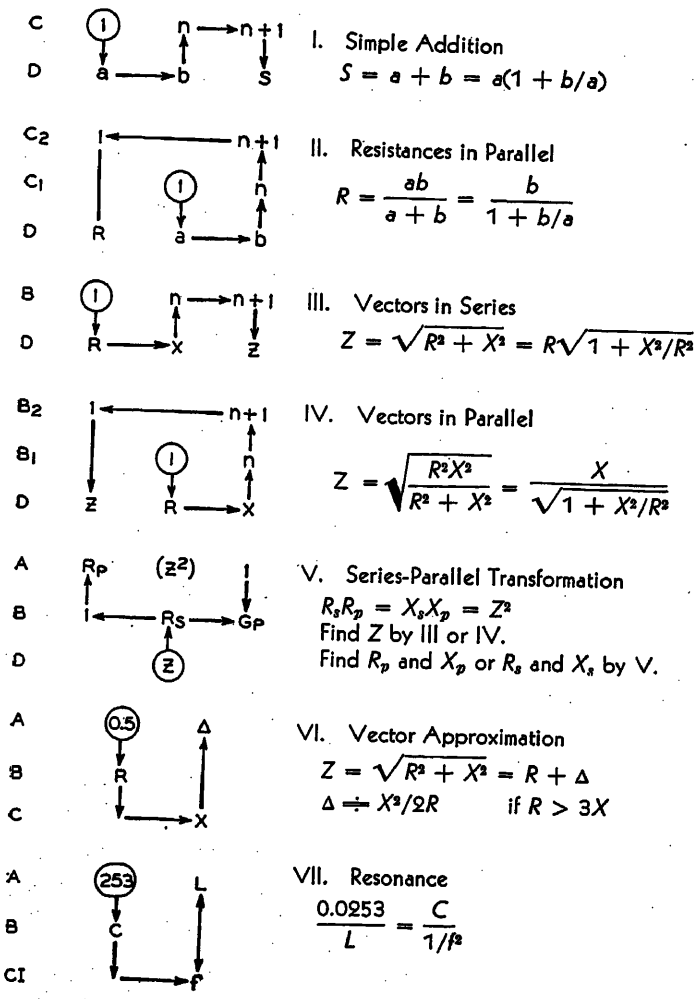

**Figure 2. Diagrams showing some of the operations that may be performed with a slide rule**

circle encloses the number first used and the arrows lead to the various numbers of the problem in the order in which they are used. No explicit use is made of the number $^1/_5$ on the *C*-scale, or the number $(^1/_5)^2$ on the *B*-scale.

In undertaking to apply this extended technique to various problems, there are several possible ways of performing the actual operations—just as there are several ways of performing a simple multiplication. The particular arrangement chosen for the last example, while good for purposes of illustrating the principle, has 2 disadvantages from the operating viewpoint. The result appeared on the slide, where it could not be used directly

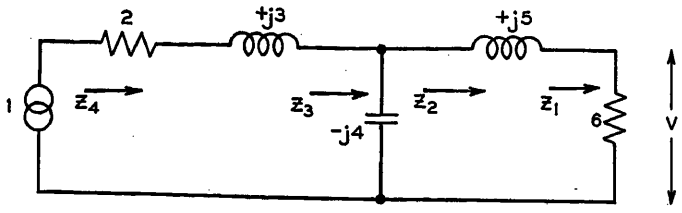

**Figure 3. Work sheet showing computations made with a slide rule**

The voltage *V* is computed from the constants given in the circuit diagram. Arrows are used to indicate equivalences, and show the order in which the operations are performed. The symbol ‖, an adaptation from elementary geometry, indicates "in parallel with"

$Z_1 = 6.00 \qquad = 6.00 \ \angle 0°$

$Z_2 = \dfrac{+j\,5.00}{6.00 + j\,5.00} \rightarrow 7.81 \ \angle +39.8° \rightarrow 10.17 \| + j\,12.20$

$Z_3 = 2.59 - j\,4.43 \leftarrow 5.14 \ \angle -59.6° \leftarrow \dfrac{-j\,4.00}{10.17 \| -j\,5.95}$

$Z_4 = \dfrac{2.00 + j\,3.00}{4.59 - j\,1.43} \rightarrow 4.81 \ \angle -17.3°$

$V = \dfrac{1 \times 5.14 \times 6.00}{4.81 \times 7.81} \angle 0° - (-17.3°) + (-59.6°) - (+39.8°) + 0°$

$= 0.820 \ \angle -82.1°$

for subsequent operations. The arrangement involves the use of the *CI*-scale which does not appear on the simple Mannheim rule.

The set of diagrams in figure 2 shows convenient methods of performing a few of the operations that may be of interest to the communication engineer. In some of these operations the slide, instead of the runner, is shifted. Successive positions of the movable scale are indicated by subscripts. It may be noted that only a single shift of either the runner or the slide, but not of both, is required to complete most of the operations indicated.

Nothing has been said about the location of the decimal point. Rigorous rules for this are both complicated and unnecessary. In vector work more help will be obtained from a visualization of the vector triangle.

No mention has been made of the phase angle. Unfortunately the trigonometric scales of the Mannheim rule are not located conveniently for inclusion in the technique described. Fortunately the angle itself is often not of great importance. When needed it can be found by a separate simple operation. But it may be noted that the "*n*" in either of the vector operations is the reciprocal of the tangent of the angle. If at the start the index always is set over the *smaller* of the 2 vectors, then only the addition of an inverted tangent scale on the face of the slide is required to make a full-fledged vector slide rule out of the simple Mannheim rule. The first decade of this scale is sufficient for most purposes.

In preparing this discussion the objective has been not the presentation of a new formula or a new trick, to be forgotten as easily as learned, but the encouragement of a viewpoint that would lead to wider and more satisfactory use of the simple slide rule.

# Protective Multiple Earthing in England

## From the results of an investigation conducted in 4 typical villages in England, recommendations for improving the protective earthing (grounding) of rural electric circuits in that country have been made

INVESTIGATIONS to ascertain to what extent consumers of electricity in rural areas of England are protected from risk of shock with methods of earthing at present in use, and what changes in practice might be desirable, with special reference to "protective multiple earthing," were reported in a paper by H. G. Taylor entitled "The Use of Protective Multiple Earthing and Earth-Leakage Circuit Breakers in Rural Areas" which was read before The (British) Institution of Electrical Engineers, April 14, 1937. The term "protective multiple earthing" as used here means the connection to earth of the neutral conductor at some or all consumers' premises and the connection of metal frameworks to the neutral, using a separate insulated earth-continuity conductor that is run through the house and connected to all metal-work of appliances, to a separate earth, and to the neutral service conductor on the service side of the fuses at the meter board.

The investigations show that present safeguards are inadequate. Recommendations are made which it is believed will lead to material improvement, but further experience and experiment are said to be necessary before the matter can be put on an entirely satisfactory footing. Figures 1 to 4, reproduced from figures 1, 2, 3, and 10, respectively, of the paper, give some of the principal results.

It has been realized for some time that in rural areas fed by overhead lines where no water mains exist the protection afforded by "ordinary earthing" is not entirely satisfactory. With this in mind an investigation was undertaken by the British Electrical and Allied Industries Research Association with a view to finding means for improving the situation. Alternative methods of protection are provided by earth-leakage circuit breakers, or the use of the neutral to carry the fault current. This latter method, known throughout the paper as "protective multiple earthing" is subject to the disadvantage that the frameworks of apparatus connected to the neutral rise to the same voltage above earth as the neutral conductor. It was found from field tests, however, that the voltage rise of the neutral did not exceed a value dangerous to human beings under normal operation, and that even animals would be protected if the statutory voltage drop were not exceeded. No interference with the satisfactory working of the telephone system was observed during any of the tests.

Other possible sources of trouble due to the use of the protective multiple earthing system were considered in some detail. An investigation also was made to find the tripping voltage of earth-leakage circuit breakers that have been in use for a period of about 2 years.

## Conclusions and Recommendations

The paper concludes with the following major deductions reached from the practical tests, conclusions re-

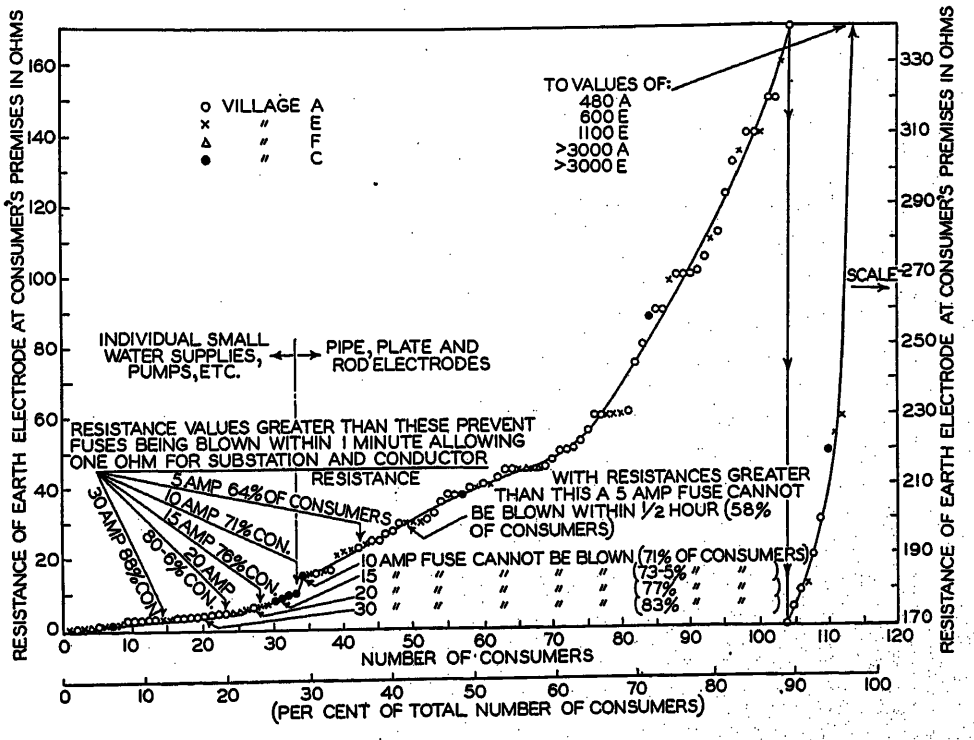

**Figure 1. Resistance of earth electrodes at consumers' premises**

In none of the villages does a general system of water mains exist, though in many cases it was found that consumers had a pump which drew water from a well in the garden, and these were generally used for earthing. The value was always 10 ohms or less, and the figure shows a clear discontinuity in the curve at 10 to 15 ohms, between the resistance of pumps, water systems, etc., and that of earth rods or plates

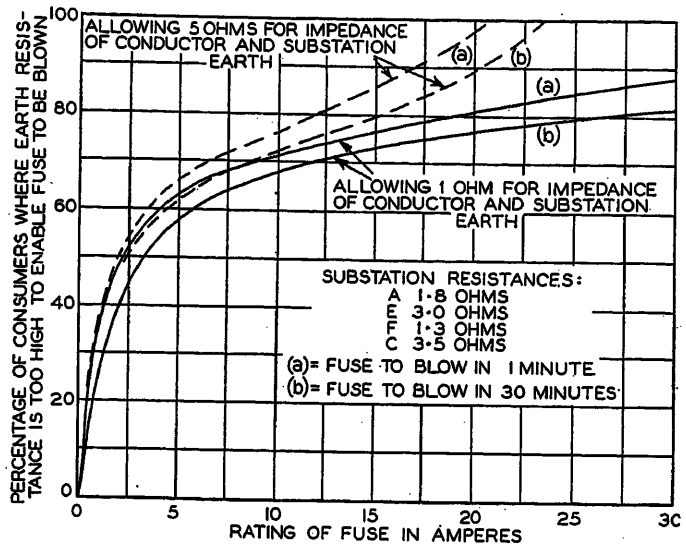

**Figure 2. Percentage of consumers at each of the villages where fuses of various sizes cannot be blown**

specting protective multiple earthing in general, and recommendations respecting existing and new installations and certain proposed conditions which should be complied with before protective multiple earthing is permitted:

### Conclusions on the Practical Tests

1. If the results of measurements made at 4 villages in different parts of the country may be regarded as typical, in $^2/_3$ of the installations in rural areas fed by overhead networks, where no water mains exist, fuses could not clear an earth fault due to an insulation breakdown on electrical appliances.

2. Tests in an area where the earth resistivity is high have shown that earth-leakage circuit breakers, while not in all cases functioning at a voltage below the danger limit (*viz.*, 30 volts), have contributed materially toward eliminating the risks of electric shock. Moreover, many of the tests were conducted on early types of circuit breakers, and with the improved types now available and the development of technique there is good reason to expect better results in the future.

3. Tests on protective multiple earthing have shown that the voltage-rise of the neutral with respect to earth under quite abnormal conditions of loading does not exceed 30 volts and is therefore not dangerous to human beings, though it may be dangerous to animals.

4. When using protective multiple earthing, immediately prior to the blowing of fuses the voltage rise of the neutral at the end of distributors and near the substation may be 60 volts to earth for a short period.

5. If the statutory limits of voltage variation are adhered to, the voltage rise of the neutral will not be dangerous to either human beings or animals.

6. The voltages picked up on pilot lines to test earths adjacent to power earths were smaller than would be required to produce false ringing of telephone bells in the C.B.S. No. 1 type of exchange, and listening tests on the telephone lines did not reveal any disturbance.

7. Substantial improvement could be effected in existing installations using the present method of earthing by—

(*a*) Ensuring that an electrode not less than 6 feet long and not less than $^3/_4$ inch in diameter is always used, and that, if necessary, 2 are used at least 6 feet apart.

(*b*) Making use of a small water-pipe system, if one exists in the village, as the earth for the neutral, instead of attempting to provide an earth of low resistance at the substation.

(*c*) Making greater use of a protective earth wire for interconnecting the metal-work in a group of houses, and joining it to earth at a house where a low earth resistance exists.

8. The effect of multiple earthing of the neutral is to reduce the voltage drop in the neutral and earth in parallel to a greater extent than would be expected from the change in resistance; at the same time the voltage-drop in the phase wire is increased.

9. Multiple earthing of the neutral does not appreciably improve the voltage regulation.

### Conclusions on Protective Multiple Earthing in General

1. If the connection between the protected metal-work and the (insulated) neutral is made only at the meter board, a fracture of the neutral wire inside the installation does not represent a hazardous condition—the appliance merely ceases to function. If a fault to frame exists, current returns through the neutral wire and the earth-continuity conductor in parallel, and entirely through the latter if a break in the neutral occurs. As this may constitute a fire hazard if it continues for any length of time, it is essential that no fuses or switches should exist in the neutral.

2. The voltage rise of protected metal-work in the event of a fracture of a neutral service conductor, without the phase wire, is determined by the connected load and the earth resistance at the consumer's premises. For example, on a 240-volt supply, if the resistance is 10 ohms and the load switched on is 1 kw the voltage rise is 36; if the resistance is 100 ohms the value is 152 volts. The voltage rise is in no case equal to the full supply voltage, which is the voltage which may occur on metal-work ineffectively earthed in the ordinary way, unless there is no earth at all on the consumer's installation.

3. In the event of a break in a neutral distributor without the phase wire all the metal-work on the system rises to a certain voltage with respect to earth, which is determined by the connected load on the remote side of the break from the substation, and the resistance to earth of the neutral on either side; if the break is near the substation the voltage on the frameworks of appliances connected to the sound section of the neutral is higher than that on those connected to the disconnected section; if the break is nearer the end of the distributor than the substation the reverse is the case. From the point of view of general danger the worst position for the break if the system possesses only a single distributor is at 30 to 40 per cent of the distance from the substation to the end of the distributor with a

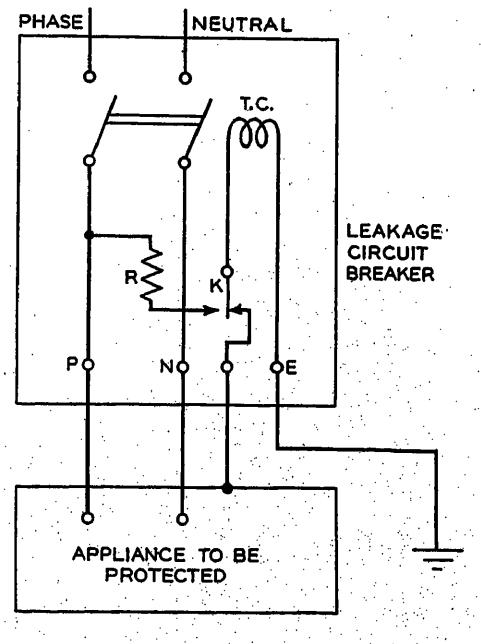

**Figure 3. Diagram of connections of earth-leakage circuit breaker**

uniformly loaded and symmetrically earth system. The lower the general resistance to earth of the neutral, the less the voltage rise.

4. Comparing the system of protection by earthing which is at present used, with protective multiple earthing, from the point of view of shock risk, it is estimated that the latter system is several times as safe as the former.

5. With protective multiple earthing, a line-to-neutral fault on the distributor of a 240-volt system would not result in a greater voltage than 60 volts on protected metal-work, provided precautions were taken in effecting the earth connections to ensure that the true neutral point is near the load center of the system.

6. A disadvantage of protective multiple earthing of the neutral is that current returning from an earth fault on the phase wire cannot be distinguished from normal neutral return current.

7. Existing installations may readily be converted to the protective multiple earthing system by connecting the earth-continuity conductor to the neutral at the meter board and linking across all neutral fuses.

### Recommendations

1. That protective multiple earthing be permitted, subject to compliance with the conditions laid down below.

2. That farm installations where animals may come into contact with protective metal-work should be treated differently from house installation, in view of the greater sensitivity of animals to shock than human beings.

3. Since small water systems frequently occur at farms it is suggested that such installations only continue to be earthed in the usual way, provided that the total resistance in the earth circuit at any time of the year is low enough to pass $2^1/_2$ times the current normally carried by the largest fuse on the installation. If this is not possible then earth-leakage circuit breakers should be used on each distinct piece of apparatus and *all* frameworks and metal-work in the installations, liable to become alive, should be protected, where there is danger of animals making contact with the metal-work. The trip-coils should operate at not more than 15 volts.

4. If undertakings decide to continue to rely on ordinary earthing, the resistance in the total earth circuit should be such that the earth current which will flow at any time of the year, in the event of an earth fault, will be $2^1/_2$ times the current normally carried by the largest fuse in the installation. If this cannot be ensured then ordinary earthing should not be relied upon, and protective multiple earthing or earth-leakage switches should be used.

5. If earth-leakage circuit breakers are used, care should be taken to ensure that *all* metal-work throughout the installation which is liable to become alive is protected.

6. That a British Standard Specification be prepared for earth-leakage circuit breakers.

7. That greater attention be given, in the construction of all electrical appliances, to the provision of a higher standard of insulation.

### Proposed Conditions Which Should Be Complied With Where Protective Multiple Earthing Is Used

1. The size of the neutral distributor should not be less than that of the phase wire, and both conductors should preferably not be less than 0.05 square inch.

2. The neutral should be connected to earth at all consumers' terminals—the earth electrode consisting of any water pipes that are available or a single 6-foot mild-steel rod of not less than $^3/_4$ inch diameter or a pipe of 1 inch diameter. The pipe or rod should be driven as nearly vertically as possible, and the connection to the electrode should be made above the ground surface so that it may be inspected.

3. The neutral distributors should be connected to earth at the base of poles at 4 points per route-mile, in addition to the earth at the substation. Including the substation the ratio of any 2 of these resistances should not exceed 4, and the greatest should not exceed 10 ohms,* and should preferably be considerably less.

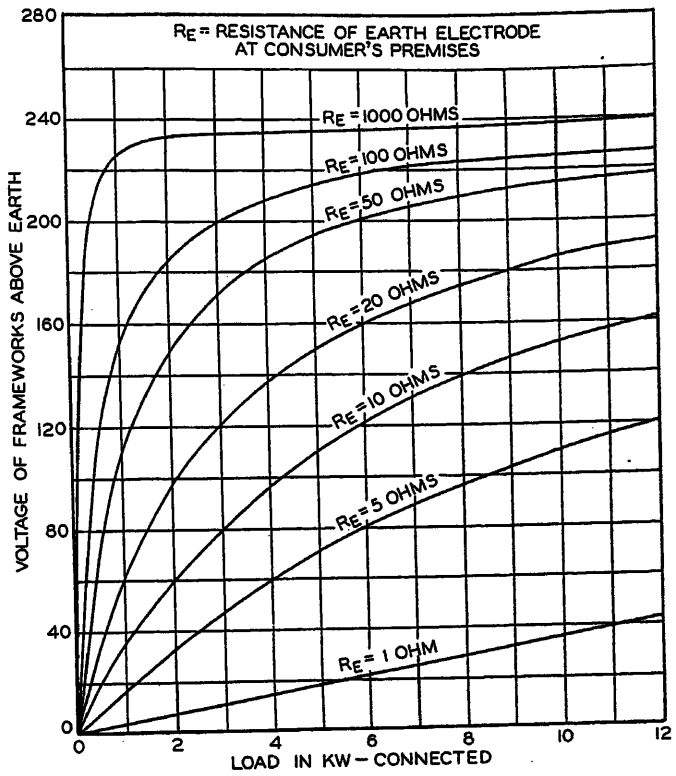

**Figure 4. Voltage above earth of protected frameworks for various values of earth resistance and installed capacity when a break occurs in a neutral service conductor**

4. Water mains should not be used for earthing at the substation.

5. An earth-continuity conductor should be used throughout each installation, and should be connected to the neutral conductor and earthing lead at the meter board.

6. No switch or fuse should be used in the neutral throughout the installation, but removable links may be provided for test purposes where required.

7. The resistance of the earth continuity conductor from any appliance to the meter board should not exceed 0.5 ohm, and this should be verified in each installation by means of a current of at least 10 amperes flowing for 5 minutes, before protective multiple earthing is used.

8. Two separate electrodes should be provided for earthing: (*a*) the high-voltage system neutral point and/or any metal-work related to the high-voltage system and electrically separate from the metal-work of the low-voltage system, e.g., the earth wire; and (*b*) the low-voltage system neutral point and the metal-work of the low-voltage system. These should be so situated that the low-voltage earth electrode is not within the resistance area of the high-voltage earth electrode. If this precaution were not taken, then a breakdown on the high-voltage system, causing current to flow through the high-voltage earth electrode, would result in the potential rise of the high-voltage earth electrode being communicated to the neutral of the low-voltage system and all apparatus frames connected to it.

9. The distribution system should be so protected that in the event of contact between a phase wire and neutral at any point up to the consumer's terminals the supply would be automatically cut off from the defective section.

* In areas where the resistivity is exceptionally high it may be necessary from economic considerations to permit a higher value of resistance than 10 ohms.

# A Review of Radio Interference Investigation

By F. E. SANFORD
MEMBER AIEE

WILLARD WEISE
NONMEMBER

Development of radiobroadcasting and reception has been paralleled by development and extensive use of devices that may cause interference with reception. The purpose of this paper is to review several factors of particular interest to the electric utilities, who supply service to both the radio and many of the interference sources. A relatively new form of interference effect—external cross modulation—is described. In conclusion, a parallel is drawn to the familiar co-ordination activities on wired communication lines and electric power systems.

RADIO has advanced from a little known hobby of 15 years ago to a publicly accepted source of entertainment, news, and education today. Modern receivers with high sensitivity, wide frequency coverage and high fidelity, represent an almost phenomenal development from the battery-operated sets of 10 years ago, and the crystal sets of a few years previous.

Self-contained, compact receivers, capable of being operated without special antenna and ground connections, have replaced the older sets which required a large cabinet, miscellaneous connections, and an outside antenna. A short piece of wire along the floor or wall for an antenna, and no connection to a ground post, are features of minimum installation trouble. A connection to the nearest electric outlet has replaced the batteries and eliminators.

Expectancy on the part of listeners for absolutely noise-free reception has increased the level of freedom from interference expected. In contrast to the thrill of hearing a distant station, even if only faintly and between crackling noises, is today's immediate annoyance at any snap, buzz, or break in good, clear reception. This attitude is, in itself, highly complimentary to those who have made it possible.

## Increase of Interference Sources

In this same period, development and increase in use of electrical appliances has paralleled radio development. Along with lights there are now in the same homes with radio receivers, one or more of the new appliances—electric refrigerators, mixers, cleaners, blowers on heating and cooling systems, oil igniters, stokers on furnaces, and now even electric razors. These devices employ motors, thermostats, control contactors, etc., which may contribute to radio-frequency disturbances.

High-frequency equipment, such as X-ray and therapeutic apparatus, formerly confined to hospitals, is now located in doctors' and dentists' offices in every commercial center. Flashing commercial neon signs are common and electric precipitators and other industrial devices may contribute to radio-frequency disturbances over a wide area.

In the majority of cases, interference from these sources is confined to the same building or room, but in other cases the disturbance may be severe enough to carry over electric service lines which are common to several buildings and reach receivers in the neighborhood. In particularly severe cases, the high frequency has been known to spread through space and over distribution circuits and cause interference over an area of several miles radius.

These conditions summarized briefly are:

(*a*) Sensitive, compact a-c receivers with short inside antennas.

(*b*) A wide band of frequencies to be received and an increasing interest in short-wave foreign broadcasts.

(*c*) A more discriminating and widespread group of listeners.

(*d*) A large increase in possible sources of interference and in the density of these sources.

## Utility Interest in Interference

Electric distribution equipment of the utilities was originally one of the principal causes of radio interference. Loose connections at cutouts, taps and terminals, and arcing at insulators and to grounds, were the principal causes encountered. Tests, inspections, laboratory research, design changes, and maintenance have, in general, removed this source as a widespread cause, but cases of loose and corroded connections and faulty equipment still occur often enough to require investigation of complaints. Investigation on the lines has now been largely reduced to locating individual cases of breakdown and repairing or replacing of defective parts.

Interference carried by distribution lines, service wires, and inside wiring, is of more importance now, partly because it is not so easily eliminated. Some of the interference from appliances is directly transmitted, but in other cases electric circuits serve to carry it. The principal rôle of the electric circuits is shifted from that of direct influence or cause to the field of carrier or coupling.

Investigation of radio interference complaints has generally been taken care of by the public utilities, in the United States. This rather liberal policy has been a gradual development and may be considered as promoting customer good will. The utility cannot say that its equipment is not causing trouble, without an investigation, because such cases still occur. The utility's inspector can

A paper recommended for publication by the AIEE committee on communication. Manuscript submitted July 23, 1937; released for publication August 17, 1937.

F. E. SANFORD is distribution engineer for the Cincinnati Gas & Electric Company, Cincinnati, Ohio; WILLARD WEISE is employed by the same company.

The authors wish to acknowledge the assistance given by W. J. Wuest and W. L. Thompson, Cincinnati Gas & Electric Company, in the interference inspection procedure outlined, and by the technical supervisors of Cincinnati radio stations, particularly R. J. Rockwell, of Crosley Radio Corporation, for co-operation which has led to a practical application of the co-ordination idea.

usually trace down the real cause at a moderate additional cost.

A less tangible result of public acceptance of radio is of inestimable value to the rest of the electrical industry. Radio has contributed to the public's knowledge and intimate familiarity with electrical apparatus. This must inevitably help to stimulate an interest in all electrical development.

Portable radio receivers have been used by a number of companies in line patrol work, to locate trouble in its initial stages. Investigation of radio interference complaints, which lead to the location of defective distribution and transmission line parts and loose connections before they develop far enough to result in line outages, may in itself go far to balance the cost of such investigation.

Where the utility's policy is to investigate all complaints received, an average of about 20 per cent justified complaints from power causes has been found during the past few years by The Cincinnati Gas & Electric Company. The number of power causes is only about 25 per cent of what it was in the first years of this investigation work. The frequency rate of complaints averages one complaint per year per 300–400 residential customers. The cost of these investigations to the utility, in general, approximate only about 1 or 2 per cent of the revenue derived from radio. Incidentally, Edison Electric Institute statistics show radio receivers as a consumer of total kilowatt-hours second only to electric refrigerators, among domestic appliances.

## Causes of Interference

Radio receivers respond to impulses of minute quantity, in the range of frequency for which they are designed and adjusted. Whether these impulses come entirely from a desired broadcast station, or partly from other nearby sources, determines the degree of freedom from interference. The ratio of signal strength to noise level is important. Radio interference is a purely relative situation. Many of the causes of interference today would have been entirely unnoticed with the old-type receivers and antenna installations.

Excluding natural or atmospheric static and set troubles, there are 2 common classes of interference, and a third class that is less known. The most common causes are those associated with load current passing through poor

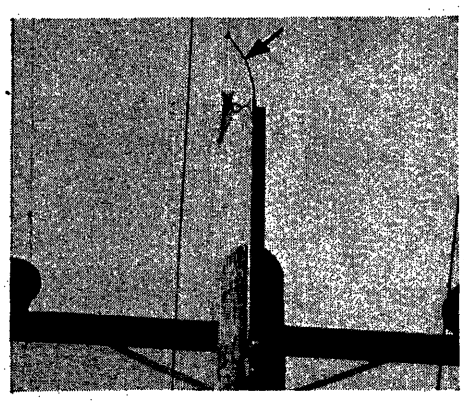

**Figure 1. Flexible jumper on swivel static clamp**

The loose connection of these clamps to ground the static wire is sufficient for lightning surges but not as a drain for radio-frequency energy picked up by the static acting as an antenna

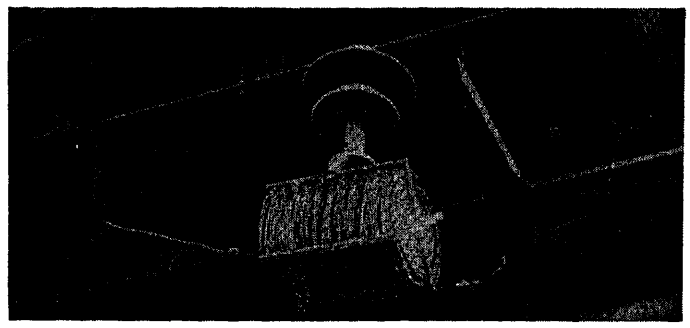

**Figure 2. Radio-frequency choke applied to an industrial precipitator**

Before this source of interference was located, interference had been found as far as 2 miles distant

or loose connections in circuits or equipment and generating radio-frequency energy.

Somewhat less common are the cases of static discharges to ground, from electrical conductors or charged bodies, but not associated directly with load current. External cross modulation is a relatively new class of interference, somewhat similar to static discharges but with other factors associated with broadcast energy.

Some of the more common causes associated with sparking or loose contact are: connections in the house wiring; at the appliance or outlet receptacle; in the entrance connections or outside in the service connections; secondary lines; or transformer installation equipment. Other causes include slip-ring and commutator sparking in motors; thermostatically controlled loads of all types, from the household aquarium heater of a few watts to the industrial electrical heaters of many kilowatts capacity; synchronous rectifiers of X-ray equipment and industrial precipitators; therapeutic devices; elevator controls; dial telephones; electric railway equipment, trolley and motors; and a host of others.

A few of the common causes of the static discharge type of interference are the alternate charging and discharging of household refrigerators by belt static; worn extension cords touching metallic frames; armored cable loosely touching against grounded piping and discharging whenever vibration causes contact. Primary distribution line causes include insulated conductor arcing to hardware; line wires arcing to guys or trees; street lighting fixture troubles; loose tie wires at insulators; and loose ground connections on overhead ground or static wires.

Fortunately, the majority of the more common causes of arcing type of troubles are fairly easy to locate and eliminate. Remedy may vary from tightening of connections to the application of chokes or condensers. Many electrical devices now have built-in capacitors which are very effective. Static discharge causes are eliminated by increasing clearances, by bonding, or solid grounding.

There is no "cure-all" type of corrective or mitigative measure, nor does there appear to be any general rule for the elimination of interference. Some of the commercial so-called interference eliminators have been nothing more than small condensers. Other "eliminators" ground the

receiver antenna terminal and use the house wiring for an antenna.

The conclusion may be stated that in most instances, elimination of severe interference requires location and correction at the source. Since, however, the absolute elimination of all sources does not appear feasible or practical, it is essential that receiver antennas should be properly installed, and free from, or shielded from, surrounding wires. Short inside antennas, which pick up the broadcast energy by reradiation from the house wiring, will naturally be much more susceptible to even slight influences.

## External Cross Modulation

This is a relatively new term in the field of interference investigation. The explanation is at present more theoretical than proven, although the evidence of it is definite enough. To the radio listener the effect is that one station is heard in the background when the receiver is tuned to another. In extreme cases, the background station may actually predominate. This form of interference must be differentiated from cross modulation within the receiving set itself.

External cross modulation is a field strength modulation produced by a strong signal in conjunction with another signal, where both act upon a system of wires or metallic structures in which there is a variable impedance element affected by the radio-frequency-current pulsations. This metallic system then reradiates the desired signal which, due to the variable impedance, contains the modulation of the other signal.

If the receiver antenna is in the field of the reradiated signal, there will be both direct radiated and reradiated energy entering the receiver. The severity of cross talk or cross modulation depends on the ratio of these 2 energies.

Rectification at a poor connection will also result in the generation of harmonics of the actuating frequencies, as well as heterodyne frequencies obtained by the addition and subtraction of fundamental frequencies and combination of fundamental and harmonic frequencies.

Elimination of this type interference requires properly installed antennas, solid grounding of neutral service wires, and clearing of loose connections in surrounding piping, plumbing, and metallic surfaces. Contact between any metal bodies of sufficient size, if the contact is oxidized, will cause rectification and hence cross talk or cross modulation.

## Investigation of Complaints

In the interest of service and good will, it is necessary that the electric utility investigate radio-interference complaints made by its customers. Considerable variation in the company policy is possible—from one of investigating every complaint, tracing the trouble to its source and correcting the condition regardless of its nature, to investigating only those assigned definitely to the utility by a competent radio service man. Efforts to curtail the field work involved have included letters listing several questions to be answered by the complainant before the investigation is made, as well as, in a few cases, a charge for investigations made that do not disclose a utility source of interference.

In some cases, an extremely liberal attitude has resulted in the utility becoming almost the first point of call for all sorts of radio trouble. This is, perhaps, as undesirable as the opposite extreme of having customers feel that the utility is barely willing to clear its own trouble to correct interference.

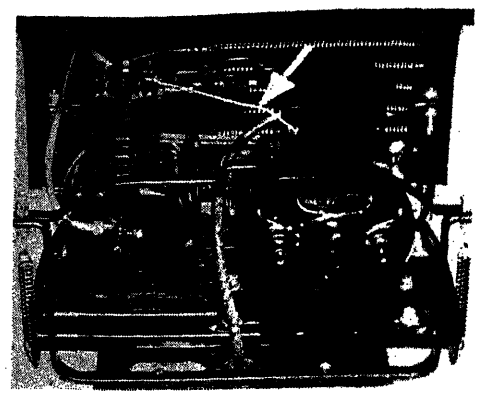

**Figure 3. Eliminating belt static in a domestic refrigerator**

A small copper-wire jumper is used to bond the motor and compressor

A moderate policy seems to be that the utility should have an inspector make personal contact as promptly as possible, identify the interference, classify its intensity, and locate the cause of trouble. If interference is found to be caused by utility equipment, the condition should be corrected, or mitigative measures applied. If the interference is found to be caused by appliances or devices owned and operated by utility consumers, an attempt should be made to either apply or suggest corrective or mitigative measures.

Cases of radio-receiver trouble should be referred to the customer's radio repairman. Many, and perhaps a large percentage of complaints will lead to trips by the inspector only to find that the interference was only on a short time and has disappeared, or that the complainant has found the trouble, or also called a service man to check the receiver. Here, as in cases of actual interference, tact and an attitude of personal interest on the part of the inspector, are a definite asset to the utility in maintaining consumer good will.

The most useful tool of the inspector in following this policy of investigation, is a standard receiver. Use of this set isolates the cases of receiver trouble. The procedure is then to follow back and by elimination of possibilities finally isolate the source of trouble. During this part of the investigation, the inspector should also check the antenna.

In most cases, it is permissible to open the entrance switch in residences, and a test made here with the test receiver connected on the line side of the switch, will definitely show whether the trouble is within the premises. If it is, the branch circuit can be located in a similar manner.

These first steps are made on the supposition that the

trouble is on the premises of the complainant. The average experience under the moderate policy outlined above, is that two-thirds of the total complaints received will be cleared or isolated at this point, including the cases of receiver trouble, unfounded complaints, and disappeared interference.

The next step in the remaining one-third of investigations, is outside the complainant's premises. Here the investigation becomes more technical in nature and follows along the lines of experience in the past. The principal point of difference under conditions of the last few years, compared to the earlier years of radio, is the very large proportion of complaints that can be eliminated without the use of special investigation equipment for use in the field.

It is important that a record be kept of each complaint received and the investigation made. It is helpful to have a method of classifying the complaints on this record, so that summaries may be made and the work reviewed. Instruments are available for technically classifying interference levels, but a practical method that is easily applied on the first investigation is to compare the signal to noise ratio, at various points on the dial. The essential information is field strength or intensity of the interference and its duration.

A notation $R_2\ ABC\ F_4$ on the complaint report, representing an interference that is equal in interference to station $ABC$ at the location of the test with the antenna system on the premises, and that the interference is continuous, gives a helpful record.

With this method of notation, $R_0$ is used to represent inaudible interference and the grading is up to $R_3$ where the interference blankets the signal. For time frequency notation, $F_0$ represents very infrequent, $F_1$ minutes per day, up to $F_4$ representing continuous.

This method is being used to replace exact data obtained from field-strength instruments and the notations are more easily understood in this form than in terms of microvolts per meter. This does not preclude, however, the necessity of accurate instruments for more technical field strength and interference investigations.

## Radio Co-ordination

Radio-interference elimination is essentially to co-ordinate this use of electricity with its other uses for light, heat, power, and transportation, in order that the growth of each may not be restricted by the requirements of the other.

The complete elimination of all radio interference would involve an enormous sum of money. A reasonable level, which is economically feasible, is the best that can be hoped for. Ratio of broadcast field strength to noise level field strength, both natural static and man-made interference, is an important part of the problem.

Legislation has, in a few instances, been provided by states and cities in the United States. Serious enforcement of such laws and ordinances would be cumbersome and expensive. Individual offenders who knowingly and persistently operate interference-producing devices and refuse to co-operate in application of necessary remedial measures, are rare.

A highly effective approach to the inductive interference problem caused by proximity of telephone communication circuits and power circuits, has been through recognition of 3 subdivisions of the factors involved: (1) inductive influence of the power circuit, (2) inductive susceptiveness of the telephone circuit, and (3) inductive coupling between the 2 types of circuits.

A similar approach to the radio-interference factors is practical. The approach is much more complicated in its broad aspects, however. In the one case, it involved a telephone utility and electric utility working together, or national committees representing the 2 interests, working out a program for investigation and research. In the present problem, equivalent interests are widely scattered and following widely divergent lines.

1. Reliable manufacturers of appliances have given attention to radio-interference effects of their products. In other cases, the same care has not, evidently, been given. A thermostatically controlled fish-aquarium heater selling for about $1.00 has in several instances been found to cause radio interference in neighboring houses. Freedom from radio interference is a general, if not yet universal, indication of merit.

2. Radio-receiver manufacturers have devoted a great deal of research and experimental work to proper shielding from outside influences. When all these influences are compared to radiobroadcast waves, in field intensity, it may be said a good job has been done. In too many cases, however, careless installations have been allowed to offset these efforts. Further co-operation along this line is in order, to reduce the factor of susceptiveness.

3. In this consideration, the rôle of the electric circuits may be shifted from that of influence to one of coupling. While the primary

**Table I. Classification of Interference Sources**

Found by Cincinnati Gas & Electric Company Investigation (1936)

| | Per Cent | |
|---|---|---|
| Disappeared or unfounded | 43.0 | |
| Receiver trouble | 18.0 | |

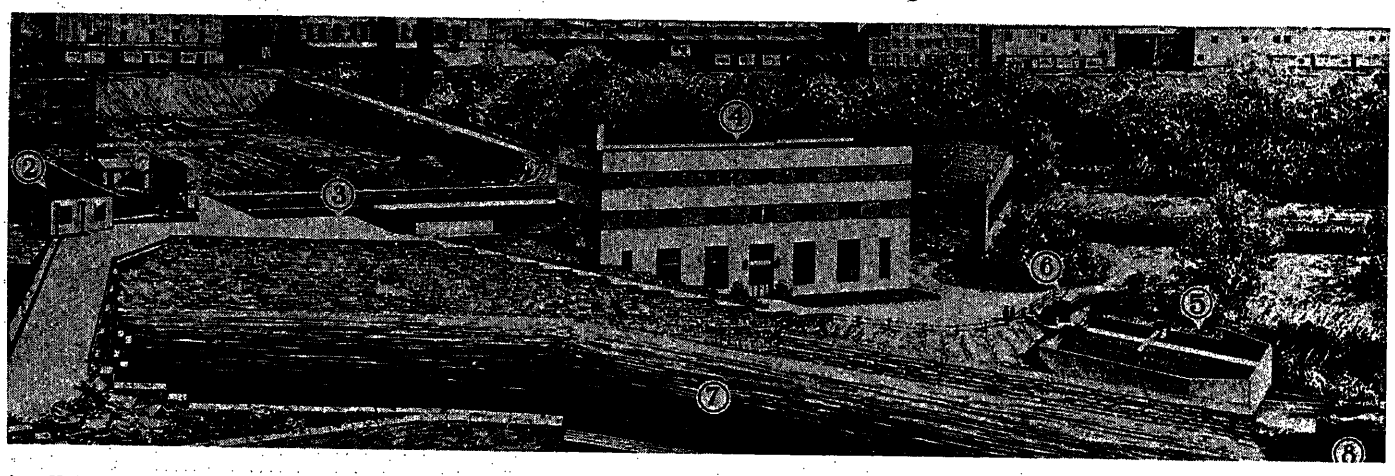
| Miscellaneous | 3.0 | |
| Outside sources other than electric utility | | 10.5 |
| Loose connections of primary circuits | 5.0 | |
| Secondary connections and grounds | 2.0 | |
| Loose static wire connections | 3.5 | |
| Defective equipment | 1.0 | |
| Electric distribution lines and equipment | | 11.5 |
| Miscellaneous | | 2.5 |
| | | 100.0 |

lines are most important in the influence field, both in inductive co-ordination and where electric lines cause radio interference, the secondary circuits are usually most important in the coupling effect. It is important to note that secondary circuits include house wiring. Even in cases of exceptionally strong influences, the radio frequency waves do not pass through the impedance of transformers to the primary.

A very important possibility for co-operation in this field includes a workable understanding among the 3 groups in any particular locality, most interested in good radio reception, namely:

(*a*) Radio and appliance commercial group and repairmen.

(*b*) Radiobroadcast technical group.



(*c*) Utility distribution engineers and inspectors.

In Cincinnati, where there are 5 broadcast stations, joint efforts of this group and the utility group has led to a procedure for the elimination or alleviation of individual cases of external cross modulation. This information has been put in the hands of all radio service men. Considerable research and field inspection work has been carried on by both groups.

Care is exercised by inspectors on the general and outside influence end, not to step into the field of the service men, whose proper sphere includes correction of any faults in the receiver installation as well as other efforts on the complainant's equipment. On the other hand, there is no attempt to avoid the responsibility of interference elimination when it is caused by outside influences.

There can hardly be a question of the value of joint efforts toward co-ordination of: (1) influence, (2) susceptiveness, and (3) coupling, in the field of electric appliances, radiobroadcast and reception, and electric service. Continued co-operation will lead to control of interference and lessen the need for mitigation and individual corrective measures.

## Minnesota Hydraulic Laboratory Being Constructed

NEAR the headwaters of the Mississippi River, 90 miles from its Lake Itasca source, the United States Works Progress Administration is constructing at St. Anthony's Falls a large-scale hydraulic laboratory for the college of engineering of the University of Minnesota. Located on Hennepin Island, in the heart of Minneapolis and near the center of the city's famous milling district, the laboratory will be primarily an experimental and research institution. Its function will be to promote greater knowledge of the use of water power, together with the improvement of hydroelectric machinery, and its facilities will be used by all students studying hydraulics at the University of Minnesota. Reproduced from an artist's drawing of the laboratory as it is expected to be when completed, the figure on this page shows: (2) the intake to the laboratory and the gate-control house; (3) main experimental laboratory for open-channel experiments and river hydraulics; (4) hydraulic machinery and turbine laboratory; (5) discharge measuring basin; (6) wasteway; and (7) tail-water pool.

Because a head of 48 feet is available at the site at all times the location is unusually good for a hydraulics laboratory. A long horseshoe-shaped weir constructed above the falls provides close regulation of head, and facilities are being provided to handle discharges of more than 300 cubic feet of water per second.

The building has been designed to utilize approximately half of the available head for model rivers and other experiments on flow in open channels, the level of the main experimental floor being 20 feet below the main headwater level. The remainder of the drop in the experimental plant permits large-scale volumetric measurements of flow, for which twin basins supplied with pneumatically operated cylinder valves are to be constructed.

The Hennepin Island laboratory is said to be the only one in the United States in which the testing of a full-size turbine will be possible. Its possibilities already have attracted national attention in the field of hydraulics, and experimental work is being planned in co-operation with federal, state, and commercial interests. Much of the research on sediment transportation by rivers being conducted in the University's existing hydraulic laboratory will be transferred to the new quarters when they are completed.

# Lightning Strokes in Field and Laboratory—II

By P. L. BELLASCHI
MEMBER AIEE

THE LIGHTNING-STROKE generator has made possible the investigation of lightning-stroke phenomena in the laboratory.[1,2] This paper deals with the fundamental aspect of the problem, particularly with the characteristics of the lightning-stroke channel. The data and findings here presented reveal further the nature of the channel core and of the resulting column.[3] Field observations are also indicated for comparison, to enhance the value of the laboratory investigation.

## Test Method

The lightning-stroke generator consists of a high-voltage generator, a heavy-current generator, and a "microsecond switch." A steep-fronted high-voltage impulse from the voltage generator initiates flashover or dielectric breakdown of the test object. Then, within a time measured in microseconds the current generator is switched on thus supplying to the test object a current of lightning-stroke intensity and duration.

A lightning-stroke test is illustrated in figure 2. The voltage generator first breaks down the 36-inch rod-to-plate gap, this occurring on the front which rises at somewhat more than 3,000 kv per microsecond (figure 1*D*). Then, as oscillogram *A* shows, the "microsecond switch" operates and in 5 microseconds the current generator begins discharging across the gap a current which reaches 57,000 amperes and of a total duration of 100 microseconds or more. More rapid and slower follow-up of the current occurs, respectively, for oscillograms *B* and *C*. A lightning-stroke to a distribution-line wood pole appears in figure 9 in which case the voltage to break the pole down rises to 2,500,000 volts, followed by the current of lightning-stroke intensity and duration. These tests are typical of the lightning-stroke testing in this investigation.

## Characteristics of Lightning Channel

### Tests on Paper and Similar Materials

The results from tests on paper and similar materials are summarized in table I. In these tests a large sheet would be mounted on an insulated wood frame and inserted in the path of the discharge as in figure 2. Test samples indicating the area "blown" are shown in figure 3.

For rather strong, yet quite thin, white paper (first 8 samples), the average area "blown" for a current of 53,000 amperes (average) is close to 0.15 square inch. One test at 23,500 amperes gives an area of 0.07 square inch. On thicker paper (samples 12, 13, and 21) the area is 0.16 square inch for 55,000 amperes. At higher currents, tests on the heavier paper only were possible because of tearing. An area of 0.24 square inch is obtained with 74,000 amperes (samples 15 and 16). The areas "blown" in the paper for currents of 24,000, 54,000, and 74,000 amperes are then, respectively, 0.07 square inch, 0.15 square inch,

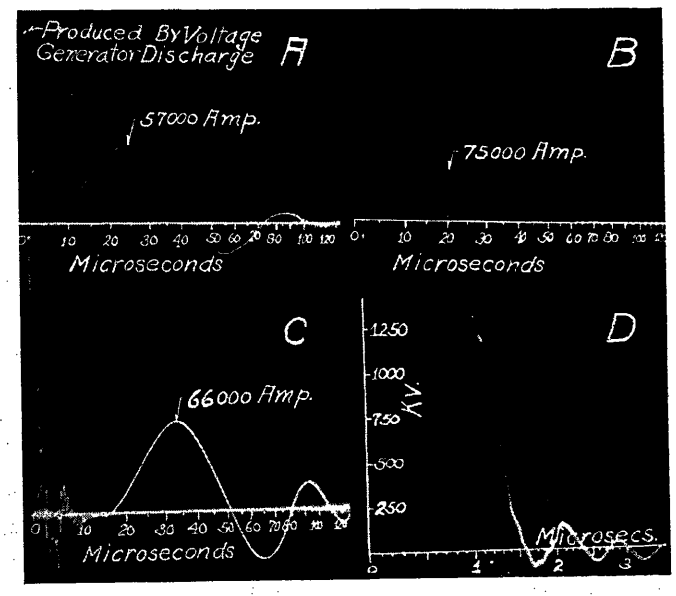


**Figure 1. Voltage and current oscillograms of lightning-stroke tests**

and 0.24 square inch, that is, the area is proportional to the current of the discharge.

A blast effect is also present on the specimens. It is in the nature of a surface "erosion" resulting from the combined action of the blast and the associated high temperature. This blast effect extends out radially from the area "blown" and can be seen best on the photograph of the glassine-paper (sample *H* of figure 3), where it assumes a $1\frac{3}{4}$-inch diameter at the outer edge. The blast action appears also on the photograph of the discharge in figure 2; here the average diameter of the incandescent column measures close to 3 inches for a current of 55,000 amperes.

Tests were made on tracing cloth. This consists of cloth as a base and a filler material solidly enclosing all interstices between threads. In these tests a dozen small holes are found within a circle of approximately $\frac{1}{8}$ inch diameter (sample *G* in figure 3). "Burning" at the surface

A paper recommended for publication by the AIEE committee on power transmission and distribution. Manuscript submitted March 24, 1937; released for publication July 30, 1937.

P. L. Bellaschi is section engineer in transformer engineering, Westinghouse Electric and Manufacturing Company, Sharon, Pa.

The author acknowledges the assistance in securing the data and in preparing the material for the paper, particularly of the following: Doctor R. C. Mason (Westinghouse Electric and Manufacturing Company) for the derivation in the appendix and other constructive criticism; Doctor M. L. Manning (Westinghouse Electric and Manufacturing Company) for his helpful assistance and criticism; M. Ch. Morel (Switzerland) and J. K. Hodnette (Westinghouse Electric and Manufacturing Company) for specific field data respectively on the core and channel of the lightning stroke; and to the staff of the Sharon high-voltage laboratory for carrying out the tests.

1. For all numbered references, see list at end of paper.

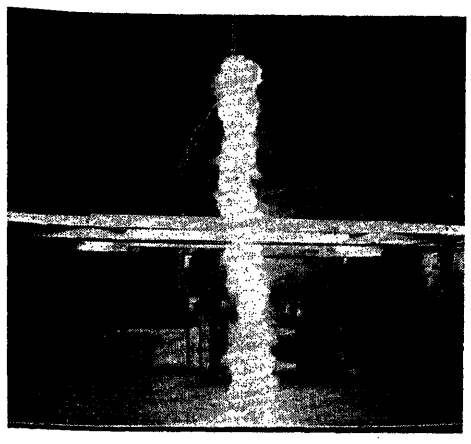

**Figure 2. Lightning-stroke discharge through paper sheet**

is concentrated within this circle, which indicates that the "core" is maintained here during part of or the whole current discharge then expanding abruptly into the column (figure 2). This explosive expansion of the core into the column is also evidenced from the paper specimens and from the radial tearing of the paper out from the area "blown." It should be noted from the small area "blown" that the current is restricted in its passage through the tracing cloth to some 5 per cent of the area indicated for the core (table I).

The area "blown" in the specimens is generally circular in form, this configuration being even more prevalent for the resulting column. The area "blown" is not always a single hole; at times it would be the combination of a large hole and smaller holes all closely huddled together. The path or paths of breakdown are established by the voltage discharge. The current associated with it, as can be seen from the area "blown" in sample *E* (figure 3), is relatively small compared to the current of lightning-stroke intensity which follows the voltage breakdown (samples *D* and *F*). In 2 cases distinct paths were established, about 10 inches apart, as evidenced from the large "twin" holes of equal size on the specimen (samples $I_1$ and $I_2$).

### Tests on Surface of Insulation

In these tests the sample was inclined so the discharge would hug the surface (figure 5) leaving thereon a "record." On porcelain the "burning" of the thin glaze, as in figure 4, comprises the record. From table II, the width of the "burning" is $1^1/_4$ inch for a discharge of 60,000 amperes (average). On photographs the incandescent column measured approximately 4 inches in width. At the center part of the burning in figure 4 the glaze is flaked, this effect indicates that the highest temperature has been maintained there. Away from the center the "burning" becomes progressively less. Upon rubbing the hand along the length of the "burned" surface the flakes are removed leaving a $^1/_2$-inch "core." In this "core" region the more intense "burning" appears to have been concentrated at the center part within a $^3/_8$-inch band.

The tests on Micarta gave records on the glossy layer of the surface such as in figure 6. The parts of the record where the discharge hugged the surface are particularly pertinent. They indicate an "inner core" $^3/_{32}$- to $^1/_8$-inch wide and a thinner shell enclosing it, then a sheath or "outer core" $^1/_2$- to $^5/_8$-inch on the outside and finally the region of the column extending outward to the total width of $1^3/_4$ to 2 inches. The explosive action of the "core" into the column is evidenced from the indications appearing on the surface (figure 6) as well as on the photograph of a similar test in figure 5. On the photograph the intense part of the channel is approximately 2 inches; however, the incandescent gases extend out a total width of some 5 to 6 inches. The current in these tests was close to 50,000 amperes.

The "records" in figures 6 and 4, though primarily the result of temperature and bombardment effects on the surface layer, suggest nevertheless that the "core" is apparently a complex of parts and processes. The current varying with time complicates somewhat further the mechanism and structure of the lightning discharge. Even then, without entering into the complex formulation of the detail phenomena which may occur, an estimate of the pressure and temperature in the "core" of the lightning channel should be possible from relatively simple considerations of the experimental findings presented hereto.

The expansion of the "core" from $^1/_2$-inch diameter or even less to the resulting channel of 3 to 4 inches diameter or more suggests a pressure in the "core" some 40 to 60 times the atmospheric. The corresponding gas temperature in the "core" would then be in the range of 11,000 degrees to 17,000 degrees Kelvin (absolute). These are estimates; for a closer determination, account should be taken in the gas formula of the process of expansion such as the turbulent interaction of incandescent gas and air (see photographs), the recombination into molecular form of the atomic elements, the positive and negative ions, besides other effects.

From a consideration of the electromagnetic force on

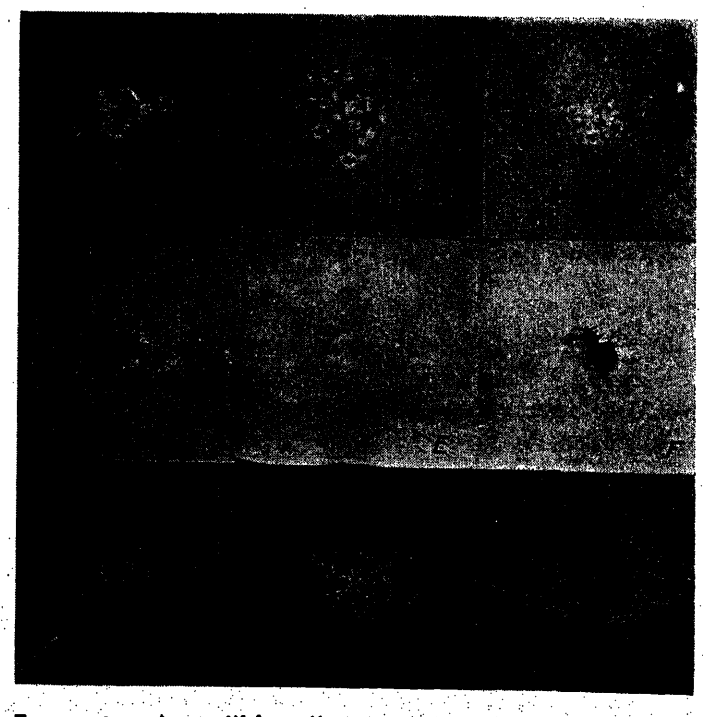

**Figure 3. Area "blown" in paper and similar materials (see table I)**

the current elements (the electrons comprise the bulk of the current flow), a further approach may be obtained on the internal pressure and whether this compression force accounts in part or all for the balancing of the gas pressure in the core. Both the circular form of the core and its abrupt expansion as the current ceases to flow are consistent with the rôle of the electromagnetic force balancing the gas pressure in the core during the current flow. Considering a current $I$ (abamperes) uniformly distributed in a core $R$ centimeters in radius, the "electromagnetic pressure" at $x$ centimeters from the center is (see appendix)

$$P = \frac{I^2}{\pi R^2}\left(1 - \frac{x^2}{R^2}\right) \text{ dynes per square centimeter} \qquad (1)$$

The deduction of interest from equation 1 is that the electromagnetic force can account for a pressure on the current elements (electrons) in the order of the estimated gas pressure and thus appears as a major factor in balancing the gas pressure in the core. The "electromagnetic pressure" is applied directly to the electrons as these comprise the bulk of the current flow. Furthermore, the "electromagnetic pressure" decreases with increasing distance from the core center so other processes both internally and at the surface of the core play a part in the general equilibrium of forces, charges, and matter. Attempts to analyze rigorously these processes have been made[4] and in this connection the experimental data presented in the paper should be a guide to such theoretical analyses.

From a consideration of the large force acting on a relatively small mass, the time for the core to expand into the column estimates to be in the order of microseconds. The large impact resulting from this expansion explains the concussion experienced by persons that have been hit or were within a few feet of the lightning discharge. This explosive action likewise explains the detonation or thunder produced by lightning, either in the field or in the laboratory.

## Negatives of Photographs

The lightning discharge, when analyzed from the photograph negatives, appears as a white streak (the core) surrounded by a dark sheath (the resulting column), such as shown in a measure in figures 7 and 8. These are, respectively, photographs of the negatives of figures 2 and 5. The white streak is about one inch wide, the more intense part is $1/2$ inch or less. This intense part comprises the core proper where the temperature is highest and maintained longer.

The negatives indicate some expansion of the core proper, partly perhaps due to the variation of the current during the discharge, besides a natural expansion, and in part possibly due to the apparent photographic effect of the high temperature of the core. The abrupt or explosive expansion of the core into the column is also indicated on the negatives. The temperature of the gases appear to suffer a considerable reduction with this expansion. A determination of the relative or absolute temperature in the core and in the resulting parts of the channel may be possible from further study of the effects appearing on negatives.

**Figure 5. Lightning-stroke discharge on Micarta surface**

## Tests on Wood Poles and With the Rotating Camera; Deionization of Lightning Channel

Not all poles struck by lightning are damaged, for as long as the discharge is external of the pole, relatively small splintering results. When the discharge is internal, as in a seasoned crack (figure 9), then the pole is generally badly damaged (figure 10) due to the explosive force of the core. In the photograph of figure 9 the source of light for the exposure came from the flash of the core and from the incandescent column which persists for some time after the discharge. Figure 10 was taken after the test and shows fully the resulting damage to the pole. From these and similar other photographs it is amply apparent that the mechanical effects produced by lightning are impulsive in character.

In the process of the shattering of the pole, a force $F$ is applied to the wood mass $m$ for a time $t$. A part of the momentum

$$\int F\,dt$$

is consumed to "blow out" the wood mass; the remaining momentum $mv$ imparts motion $v$ to the wood mass. Considering the relative magnitude of force $F$ and considering the time $t$ with mass $m$ of the wood blown as indicated in figure 10, even though the momentum

$$\int F\,dt$$

were consumed largely in imparting motion alone, some hundredths of a second appear necessary to displace the mass of wood blown a few centimeters away from the

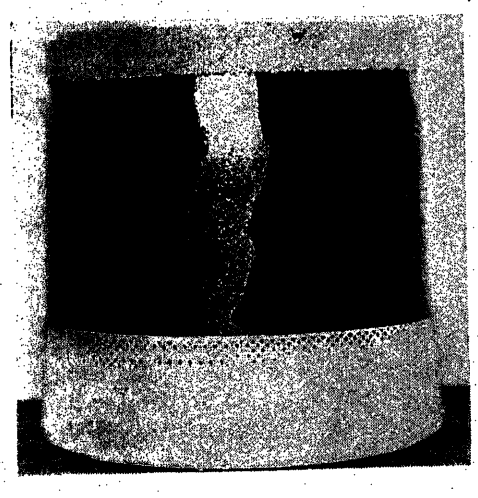

**Figure 4. "Record" on glaze of porcelain (see table II)**

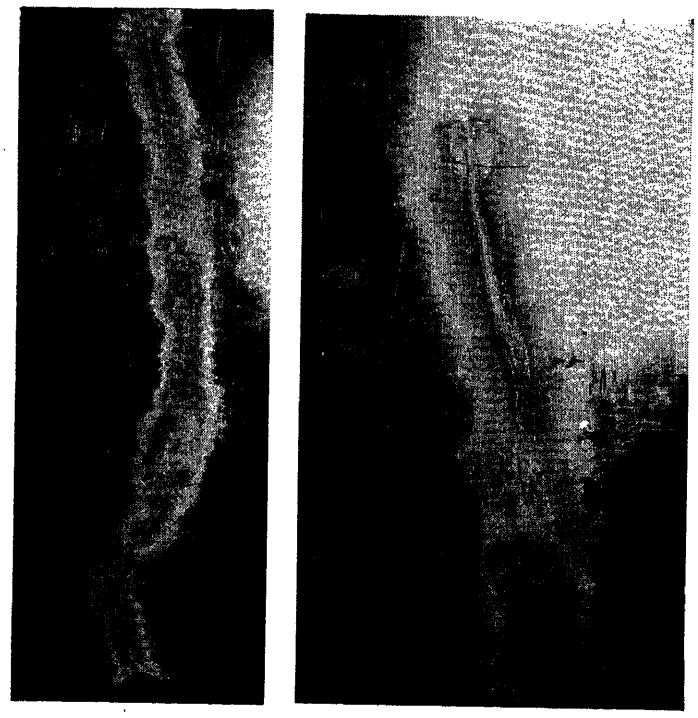

**Figure 6. Surface effect on Micarta indicating character of lightning channel (see table II)**

**Figure 7. The lightning channel from negative of figure 2**

pole proper as shown in figure 9. It can be seen then from the relatively small displacement of the wood blown during the time the column is incandescent (figure 9) that the lightning channel remains ionized for some hundredths of a second and more.

To establish more fully the deionization process of the lightning discharge, photographs were recorded with a rotating camera. The camera employed consists of a fixed lens and a 10-inch diameter circular film rotating one revolution in 0.02 second. A photograph of the discharge between the rod and plate (figure 2) is shown in figure 11*A*. In this test the lens is approximately 7 feet from the discharge. The voltage discharge appears first, followed in 15 to 20 microseconds by the indication of heavy current. The column is particularly intense during the first 50 microseconds due to the heavy current discharge (figure 1). It remains relatively intense for some 300 microseconds, diminishing continuously to a much reduced intensity at 0.002 second. Only a faint trace remains on the negative at 0.005 second. Incandescence at the electrode ends persists longer but all traces of incandescence in the column completely disappears in 0.01 second.

Two other photographs are shown in figure 11*B* and *C*. In these tests the camera was moved closer to the arc and the lens was opened wider, so naturally these records are more intense throughout than the first one. All 3 records indicate essentially the same process of deionization. The combined results of 8 records establish that incandescence of the channel completely disappears in 0.01 to 0.02 second after the lightning-current discharge. Therefore, the path of the lightning discharge reaches an advanced stage of deionization in this order of time.

### Tests on Fiber Tubes and Metal Surfaces

Tests on fiber tubes were briefly reported in the first paper.[3] The tubes were from 2 to 3 feet in length and $^1/_4$ to $1^1/_4$ inches inside diameter. Wall thicknesses ranged from 0.2 to 0.6 inch. Lightning currents from 100,000 to 130,000 amperes and of some 200 microseconds duration to one-half value were discharged through the tubes. In these tests the discharge was initiated with a fine copper wire. It was found that the tubes would discharge these severe lightning currents without shattering when the internal diameter of the tube exceeded approximately $^3/_4$ inch. For the smaller diameter tubes shattering would result but even then the ends of the thicker tubes remained intact for several inches. These tests suggested the relatively small size of the core and the explosive action produced from its expansion.

Tests comprised of discharging a current by a fine copper wire (0.08 in diameter) to the center of smooth copper plates were then conducted. A very small hole was bored at the center of the plate to carry the fine wire straight through. The averages from 10 tests are summarized in table III. These tests indicate that the area of the surface "fused" by the discharge is proportional to the current. A core of 0.60 inch in diameter is indicated in figure 12 for a current discharge of 134,000 amperes. The column resulting from the explosion of the core measured from 4 to 6 inches in diameter on photographs. A close examination of the fusion in figure 12 indicates that the fused metal on the surface is beaded quite uniformly with some grading on approaching the edge of the circle. The beads covering the center part of the circle are somewhere in the order of a hundredth of an inch. The surface fusion terminates quite abruptly at the edge

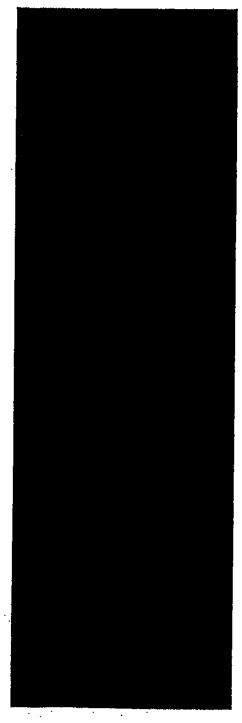

**Figure 8. The lightning channel from negative of figure 5**

of the circle. These observations confirm further that the core is sustained for the greater part of the whole duration of the current discharge and they also indicate some expansion or variation in the size of the core. A series of concentric regions appear just beyond the core circle. These apparently indicate a uniformly circular expansion of the gases in the initial stages and they suggest from the graded colors of the copper oxide the relative

in one case 4 centimeters and in the other 2 centimeters approximately. In a report on airplanes hit by lightning,[8] holes the size of a penny, or larger ones where the fabric would be torn, were found. Fulgurites in dry sand are described[5] that take "the shape of vertical tubes which may be nearly half an inch in diameter and several feet long. Externally they are rough somewhat whiter than the surrounding sand; inside they are enamel-like, from

**Table I. Effects Produced by Lightning Discharging Through Paper and Similar Materials***

| Sample Number | Material | Lightning Current** (Amperes) | Area "Blown" in Sample by Discharge (Square Inches) | Diameter of Blast Visibly Indicated on Surface of Sample (Inches) | Comments |

** (*a*). Wave form of current for tests on samples 1, 2, 3, 4, 6, 7, 8, 12, 13, 17, 18, 19, 20, 21, and 22 given in figure 1*A*.
(*b*). Wave form of current for tests on samples 9, 10, 11, 15, and 16 given in figure 1*B*.
(*c*). Wave form of current for test on sample 5 is aperiodic, rising to crest in some 7 microseconds and receding close to zero in 60 microseconds.
(*d*). In the tests on samples indicated in (*a*) and (*c*) the spacing between the rod and plate (see figure 2) was 36 inches with the sample 14 to 17 inches from the plate. In the tests on samples indicated in (*b*) and for sample 14 the spacing between rod and plate was 18 inches with the sample 10 inches from the plate.
(*e*). In the test on sample 14 the voltage generator alone discharged. The current associated with the voltage generator discharge is relatively small in amplitude and duration compared to the lightning currents (column 3).
(*f*). The voltage initiating breakdown of the 36-inch gap is shown in figure 1*D*.

temperature drop. The irregular "blotches" of oxidized surface beyond these concentric regions confirm that in the later stages of the abrupt expansion of the core into the column, the expansion process is of a turbulent character.

## Field Records Compared With Laboratory Data

Considerable field data on lightning[11-24] are now available but observations bearing on the lightning stroke channel are rather limited yet. A few typical instances will be considered for comparison with the laboratory data.

Holes have been "blown" in windows by lightning. In one case[5] the hole was in the order of a couple centimeters. The edges of the hole were melted. Two interesting observations have been reported recently to the writer by M. Ch. Morel (see also references 6 and 7). In these 2 instances the holes "pierced" in window panes measured the glassy surface of fused silicon." Rock blasted by lightning indicates a fusion streak some one-half inch wide marking the path of discharge. These experiences alone show good agreement on the size and general characteristics of the core of the lightning strokes in the field with the corresponding though more complete measurements in the laboratory.

The explosive character and damaging effects of lightning discharges are well known.[3,6,7] Wood poles splintered by lightning evidence the same character of damage and explosive effects as have been found from the laboratory tests.

The size of the lightning-stroke channel has been measured from photographs or estimated from visual observation. Considering the heaviest lightning flash, Walter estimates[9] by photographs the breadth of the channel to be only 10 centimeters. In one case recently

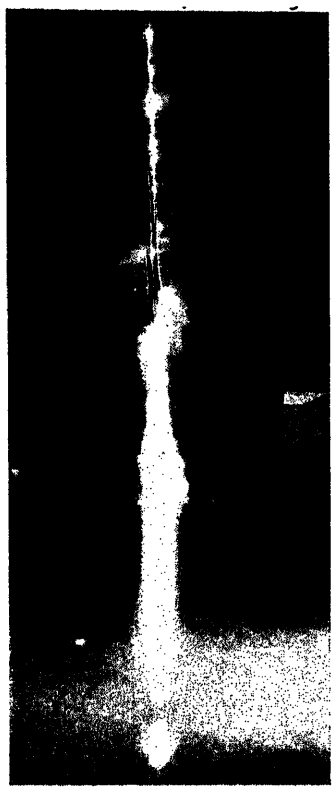

Figure 9. Lightning stroke to distribution-line wood pole

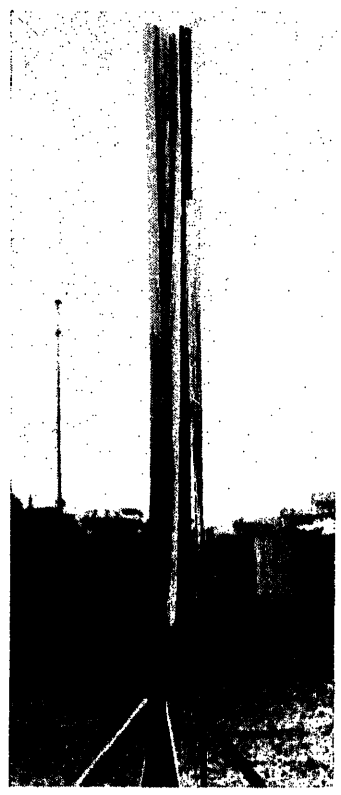

Figure 10. Resulting damage of wood pole from test in figure 9

called to the writer's attention, the observer was at about 50 feet in direct line of vision from a tree struck by lightning. Number 18 copper wire was hanging from midway of the tree to several feet above ground. Lightning splintered the top of the tree, following the copper wire then to ground. The current in this stroke is estimated to not exceed 50,000 amperes, since the copper wire was fused in segments but not completely volatilized.[10] The size of the channel by comparison to the trunk of the tree was estimated at 15 to 20 centimeters. Even these few cases are quite indicative that the dimensions of the lightning channel observed in the field are comparable to those measured in the laboratory.

A recent contribution by Doctor B. F. J. Schonland has come to the author's attention entitled: "The Diameter of the Lightning Channel," *Philosophical Magazine*, series 7, page 503, March 1937. A photograph of a lightning flash consisting of 11 discharges is discussed therein which shows the first and last separate strokes of the discharge to have had their channels shifted a distance exceeding 3.7 meters by the wind. It is found that the average diameter of the lightning stroke channel is about 16 centimeters. The heaviest stroke gave a diameter of 23 centimeters and the weakest branch one of 11 centimeters.

## Summary

1. The lightning-stroke effects on paper, tracing cloth, porcelain, Micarta, and photograph negatives indicate an area (circular) for the core proportional to the current in the lightning discharge. This apparent area is, respectively, 0.08, 0.16, and 0.24 square inch for currents of 25,000, 50,000, and 75,000 amperes. Tests on fiber tubes at 140,000 amperes indicate an area of 0.44 square inch.

2. The surface fusion on copper plates, the photograph negatives, the glaze burning on porcelain, the record on Micarta, and other effects all show that the core is sustained the greater part of or the whole duration of the lightning-current discharge. The center part, some two-thirds or one-half, of the above-mentioned area comprises the core proper where the temperature is highest and maintained longer. Some expansion or variation in the core proper takes place during the discharge apparently resulting in the larger area. The actual current in the discharge (electrons for the greater part) naturally occupies but a fractional part of the core. The above records and observation suggest that the core structure is a complex of parts and processes.

3. When or as the current ceases the core then expands abruptly or explodes into the column. The expansion appears from the records relatively uniform (circular), the gases suffering a corresponding temperature drop with expansion. The later stages of the expansion process be-

Table II. Effects Produced by Lightning Discharging Along Surface of Insulation Materials*

(*b*). Wave form of current for test on sample 28 similar to figure 1*C* except period is 20 per cent longer.

come turbulent in character. Thus for a current discharge of 50,000 amperes, uniform expansion apparently extends some one to 2 inches in diameter. Turbulent action then follows and the totally expanded incandescent column (measured on photographs) approximates a 3-inch diameter. For a current discharge of 140,000 amperes the incandescent column measures on photographs 4 to 6 inches in diameter.

4. The expansion of the core into the size of the channel suggests a pressure in the core some 40 to 60 times the atmospheric and a corresponding gas temperature in the range of 11,000 degrees to 17,000 degrees Kelvin (absolute). A more rigorous determination would require that account be taken of the turbulent interaction of the expanding incandescent gas with the surrounding air, the recombination of disrupted elements and ions (positive ions and electrons) into molecular form, besides a consideration of the complex core structure and other effects.

5. The electromagnetic force produced by the current can account for a pressure on the current elements (electrons) in the order of the estimated gas pressure deduced from the expansion. Thus the "electromagnetic pressure" (directed centrally inward) appears as a major factor in balancing the gas pressure in the core (directed outward). Other processes both internally and at the surface of the core play a part in the general equilibrium. The experimental data and findings presented in the paper offer the basis for more extensive theoretical analysis.

6. From a consideration of the large force acting on the relatively small mass of the core, the time for the core to expand into the column is estimated to be in the order of microseconds. The experimental findings confirm the estimate. The large impact resulting from the expansion accounts for the concussion experienced by persons that have been hit by or were within a few feet of the lightning discharge. This explosive action likewise explains the detonation or thunder produced by lightning.

7. The shattering of wood poles and similar destructive effects show that the mechanical forces and impact produced by lightning are impulsive in character. It can be deduced from these tests and the corresponding photographs that the lightning channel remains incandescent (ionized) for some hundredths of a second.

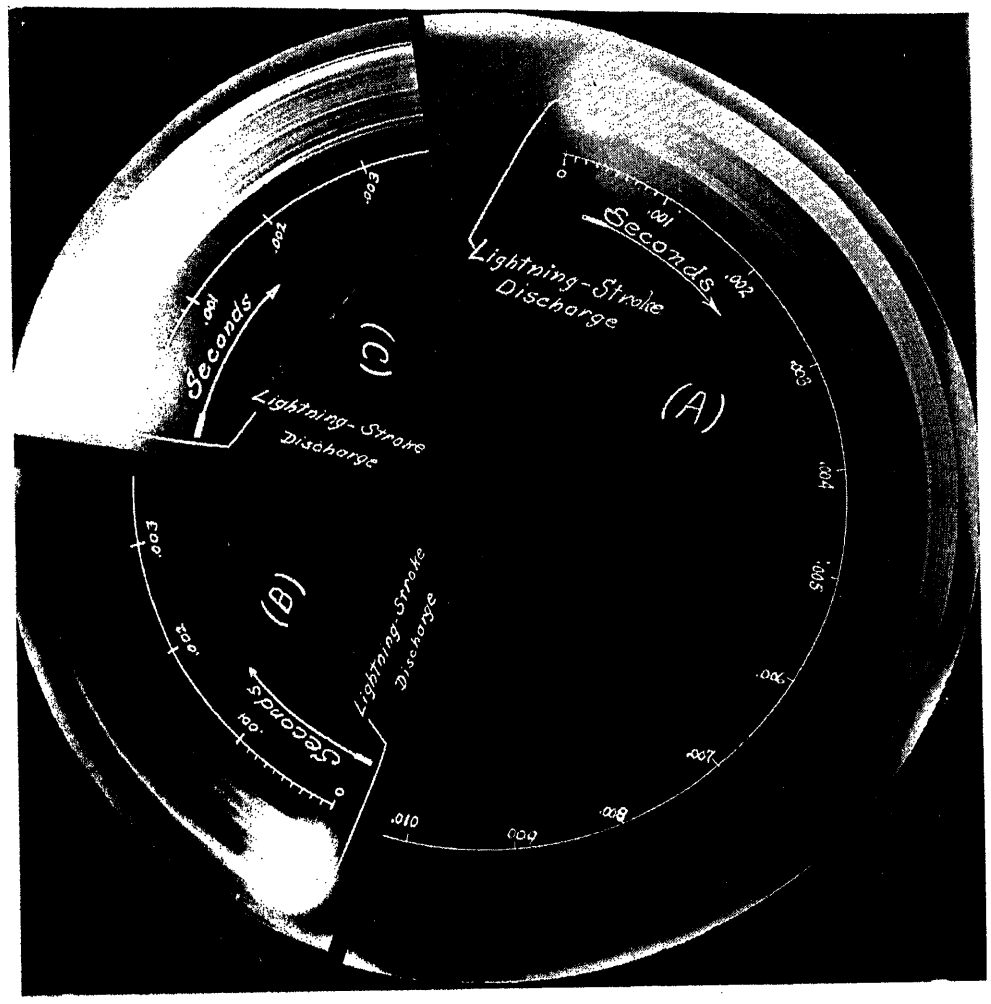

Figure 11. Photographs of lightning flash with the rotating camera to determine duration of incandescence (deionization of lightning path)

8. Records of the lightning flash with a rotating camera establish that the lightning path is particularly intense during the current discharge (50 to 100 microseconds). The established channel remains relatively intense for some 300 to 500 microseconds, diminishing continuously to a much reduced intensity in about 0.002 second. The results of 8 records establish that incandescence of the channel completely disappears in 0.01 to 0.02 second after the lightning-current discharge. Therefore, the path of the lightning stroke reaches a stage of advanced deionization in this order of time, a finding well in accord with the field data on the time interval between repetitive strokes.

9. The field records and data on the core and channel of the lightning stroke, though relatively few, indicate general accord with the more extensive laboratory findings here presented.

## Appendix

The derivation of equation 1 is based on the following fundamental consideration: To be in equilibrium the pressure gradient

$$-\frac{\partial P}{\partial x}$$

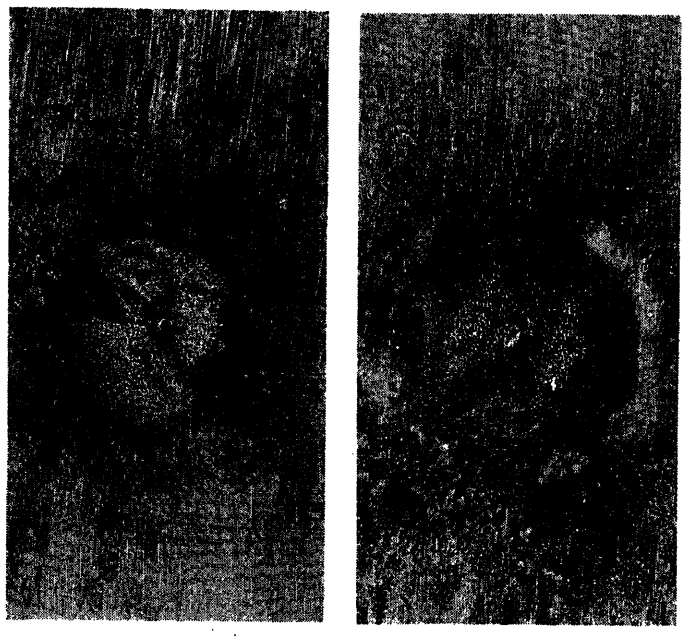

**Figure 12. Surface "fusion" on copper plates indicating nature of core and resulting channel of lightning stroke (see table III)**

**Table III. Surface Fusion Produced by Lightning Discharge to Polished Copper Plates**

| Number of Samples | Lightning Current | Diameter of Core (Inches) | Diameter of Blast Indicated on Surface (Inches) |
|---|---|---|---|
| Four | 134,000 | 0.61 | 1 1/2 |
| Two | 105,000 | 0.51 | 1 1/8 |
| Two | 79,000 | 0.46 | 1 |

at any point $x$ must balance the volume forces acting on the gas. The equation is derived elementarily by considering a shell of the core of radius $x$ centimeters and thickness $dx$. The current $I$ (abamperes) is considered uniformly distributed in the core of $R$ centimeters in radius.

The magnetic force (volume force) on the shell per centimeter length is the product of the magnetic field at $x$ and the current in the shell, i.e.,

$$2\Delta\pi x \cdot \Delta 2\pi x dx$$

where

$$\Delta = \frac{I}{\pi R^2}$$

is the current density.

The force on the shell due to variation in gas pressure balances the magnetic force, so

$$-\frac{\partial P}{\partial x} 2\pi x dx = 2\Delta\pi x \cdot \Delta 2\pi x dx$$

$$-\frac{\partial P}{\partial x} = 2\Delta^2\pi x$$

i.e., pressure gradient equals volume force. Then,

$$p = -\Delta^2\pi x^2 + \text{constant}$$

From the boundary conditions $p = 0$ when $x = R$, thus making $p$ merely excess over atmospheric pressure at the outer boundary of the core,

$$p = \Delta^2\pi R^2\left(1 - \frac{x^2}{R^2}\right)$$

or since $\pi\Delta R^2 = I$, equation 1 is obtained:

$$p = \frac{I^2}{\pi R^2}\left(1 - \frac{x^2}{R^2}\right) \text{ dynes per square centimeter} \qquad (1)$$

At $x = 0$

$$p_{(max)} = I\Delta$$

Substituting the experimental data of a core section 0.15 square inch for 54,000 amperes, then

$$p_{(max)} = \frac{5400 \times 5400}{6.45 \times 0.15} = 30 \times 10^6 \text{ dynes per square centimeter}$$

or about 30 atmospheres.

Even at $\frac{x}{R} = 0.9$, $p = 30\ (1\text{–}0.81) \cong 6$ atmospheres.

# A System Out of Step and Its Relay Requirements

By LESLIE N. CRICHTON
MEMBER AIEE

## Synopsis

This is a study of the current, voltage, and power values throughout a simple transmission system when machines are operating out of step. The investigation was made to determine the proper relay protection for some large frequency changers which supply power to an electrified railroad. The object was to find means for protecting machines that had already fallen out of step or, if possible, to prevent them from falling out due to overload.

The treatment of the problem is geometric, probably the easiest method to comprehend. The assumed conditions have been kept as simple as possible, but it is hoped that the method of treatment is complete enough to permit anyone interested in the subject easily to apply it to more complex problems. It is to be particularly observed that the common method of assuming that a system consists of pure reactance leads to errors that are noticeable on 25-cycle systems where the reactance is low.

As a by-product of the study of machine protection, it was discovered that the behavior of different types of line-sectionalizing relays under out-of-step conditions can be easily predetermined and proper adjustments made to obtain a more desirable performance of such relays.

## Two Machines Fall Out of Step

WHEN A GENERATOR and a motor are connected together and the motor is loaded, the generator poles advance and the motor poles retard, the angular difference being a measure of the power transfer. This angular difference produces a flow of current which tends to keep the 2 machines in step. The accompanying series of small sketches show what happens as the motor pole lags farther and farther until it is definitely out of step and until it comes back into step again after completing one full revolution, that is, after it has slipped 2 poles. The sketches shown in figures 1*A* to 1*J* form a sort of primer on the elementary conditions which exist when 2 machines are out of step. Figure 1*A* shows that if the motor poles lag behind the generator poles, the voltage which induces interchange of current between the 2 machines is $E_G - E_M$. These voltages are generated voltages and are not the quantities which are ordinarily measured at machine terminals. Figure 1*B* shows that the voltage difference between the 2 machines is the greatest when the poles are 180 degrees out of phase but as the motor continues to lag behind the generator, it comes back into step with the next pole as shown in figure 1*C*. Whether or not the motor will slip another pair of poles in the same manner depends upon the conditions existing in the system. The resultant voltage, as shown in figure 1*D*, increases from a zero value when the poles are exactly in step to its maximum when they are 180 degrees out of step and back to zero again following a circle as a locus. As will be observed, the shift in phase angle of this resultant does not go through a 360-degree cycle but only through 180 degrees. Also at the start and at the finish position the voltage value is zero. Since a complete slip

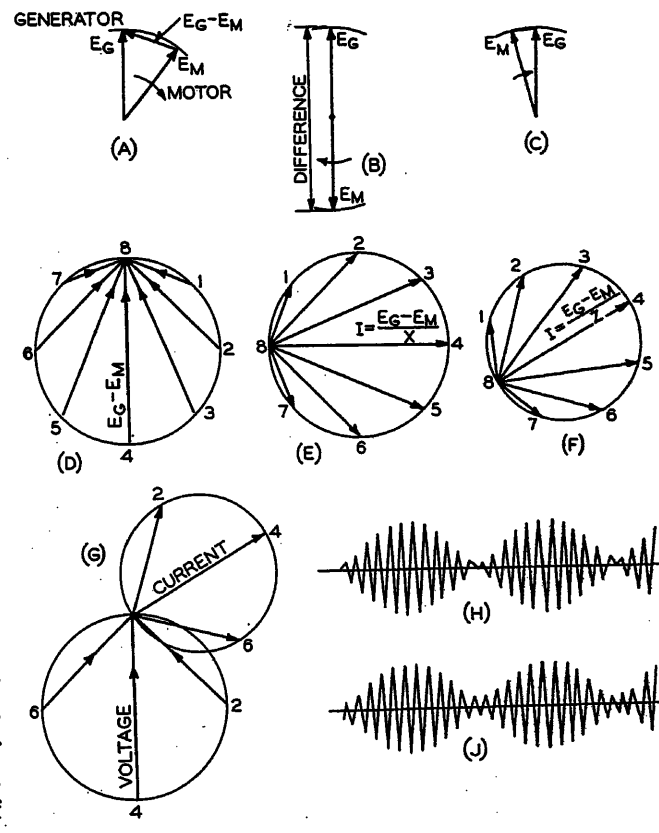

**Figure 1. Two machines out of step**

*A*—As the motor lags, the voltage difference increases until—

*B*—It reaches a maximum when the poles are 180 degrees out of phase

*C*—As the lagging pole continues around the circle, the difference approaches zero again

*D*—The voltage ($E_G - E_M$) moves around this circle through a complete cycle of 180 degrees

*E*—The current that flows between the 2 machines is at right angles to the voltage (resistance neglected)

*F*—Resistance in the circuit decreases the current and tilts the axis of the circle

*G*—The combined diagram

*H*—The current surges if the machines have equal excitation

*J*—If the excitations are unequal

A paper recommended for publication by the AIEE committee on protective devices. Manuscript submitted August 2, 1937; released for publication August 27, 1937.

LESLIE N. CRICHTON is an engineer in the meter engineering department of the Westinghouse Electric & Manufacturing Company, Newark, N. J.

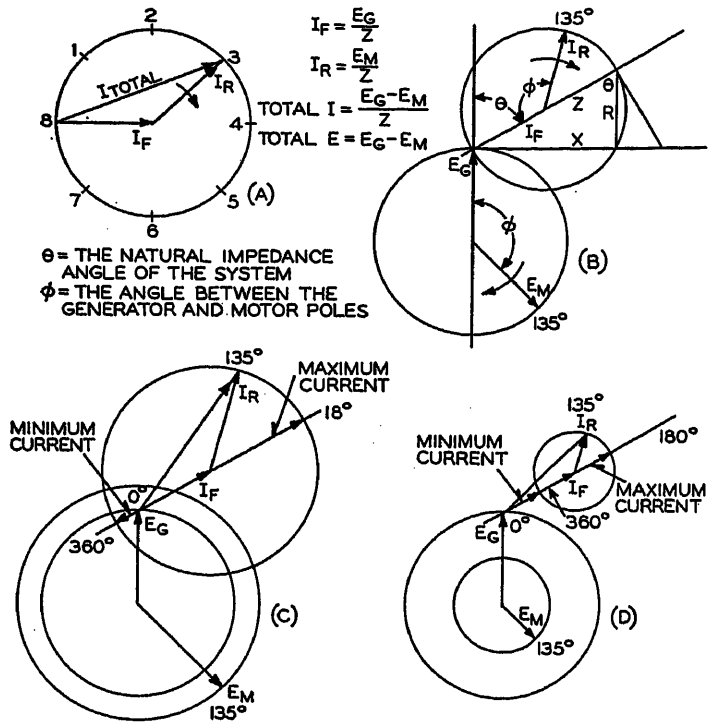

**Figure 2. Analysis of the current through the system and the voltage difference between the generated voltages at each end of the line**

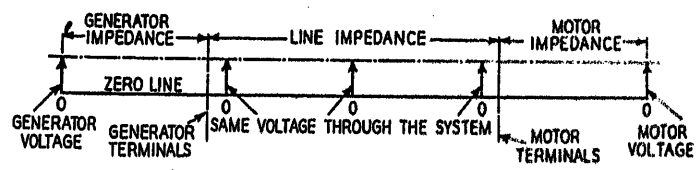
*A*—A current or voltage vector oscillating through 180 degrees may be resolved into 2 components, one fixed and the other rotating through 360 degrees in step with the slipping pole

*B*—This is another way of representing figure 1*G*. $E_G = E_M$

*C*—If the generator and motor voltages are not equal, the current will never become zero. Here the motor voltage is higher



*D*—Here the motor voltage is lower and the difference greater, hence the minimum current is greater

cycle of 360 degrees of the poles results in a shift in phase in the resultant voltage of only 180 degrees, confusion will be avoided by applying the angle in degrees always to the slip of the poles. In the figures the pole slip is also shown in positions, 1, 2, etc., so that simultaneous current and voltage vectors can be readily compared.

The behavior of the current is the same as that of the voltage except that the current lags behind the resultant voltage by an angle determined by the natural power factor of the system. This angle is the same as the angle which the current lags behind the generated voltage under short-circuit conditions. In figure 1*E* the current is shown lagging 90 degrees behind the voltage. This, of course, cannot exist in practice, although there are some generators where the short-circuit current can lag as much as 88 degrees. In figure 1*F* is shown the conditions in a system having an angle of 60 degrees. It will be convenient to use these 2 angles, namely, 60 and 90 degrees, for purposes of illustration throughout this discussion.

The current locus and the voltage locus for a 60-degree system are combined in figure 1*G* to show that the angle between the current and the voltage is the same, throughout all points of the slip cycle, although their values vary from zero to zero. The current surge, which occurs in the system under out-of-step conditions, is shown in figure 1*H*. These are the values shown in figures 1*E*, 1*F*, and 1*G* and is a similar picture to that given by the ordinary oscillogram taken on a system which is out of step. This is also the shape of the voltage pulsation through the system, but does not represent the voltage between wires or across the terminals of any machine. For purposes of comparison, a current surge in figure 1*J* is given to show what happens if the excitation of the 2 machines is unequal This will be explained later.

In order to analyze more thoroughly the conditions throughout a system consisting of 2 machines at each end of a transmission line, it is convenient to separate the current and voltage vectors into 2 components. For example, $E_{(total)} = E_G - E_M$. Here $E_G$ is a fixed quantity and $E_M$ is a rotating vector. It will, therefore, be convenient at other places on the system to refer to the voltage between wires as $E_{(total)} = E_F - E_R$ where $E_F$ is a fixed and $E_R$ is a rotating vector. Similarly, the current vector, as shown in figure 2*A*, can be resolved into 2 components and $I_{(total)} = I_F + I_R$. It will be observed that the voltage vector is a difference of 2 components and the current vector a sum of 2 components. As will be shown later, this means that at any particular point on a

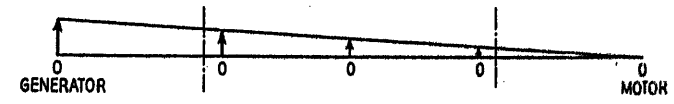


**Figure 3 (top). Machines in step—no load—equal excitation**

**Figure 4 (bottom). Motor without excitation, showing the impedance drop in the system**

system the current value is a maximum when the voltage between conductors is a minimum. In figure 2*B* the the quantities that were previously shown in figure 1*G* have been broken up into their 2 components. There are, therefore, 2 voltage vectors and 2 current vectors or a total of 4 quantities instead of a total of 2 quantities. A reason for doing this becomes immediately apparent in the next figure.

In studying out-of-step conditions the effect of changes in field strength is usually of primary importance. In figure 2*C* the generator and motor voltages have been laid out, and corresponding values of $I_F$ and $I_R$ have been added to the diagram. The value of these vectors has been determined from the equations given in figure 2*A*. It will be observed that the locus of the current does not go through the zero point. This is because the 2 generated voltages are unequal. The interpretation of this is easily made—the machine having the greater field strength (in this figure, the motor) supplies a constant magnetizing current to the other machine. This is probably more easily understood in figure 2*D* where the motor voltage is less than the generated voltage and consequently the ro-

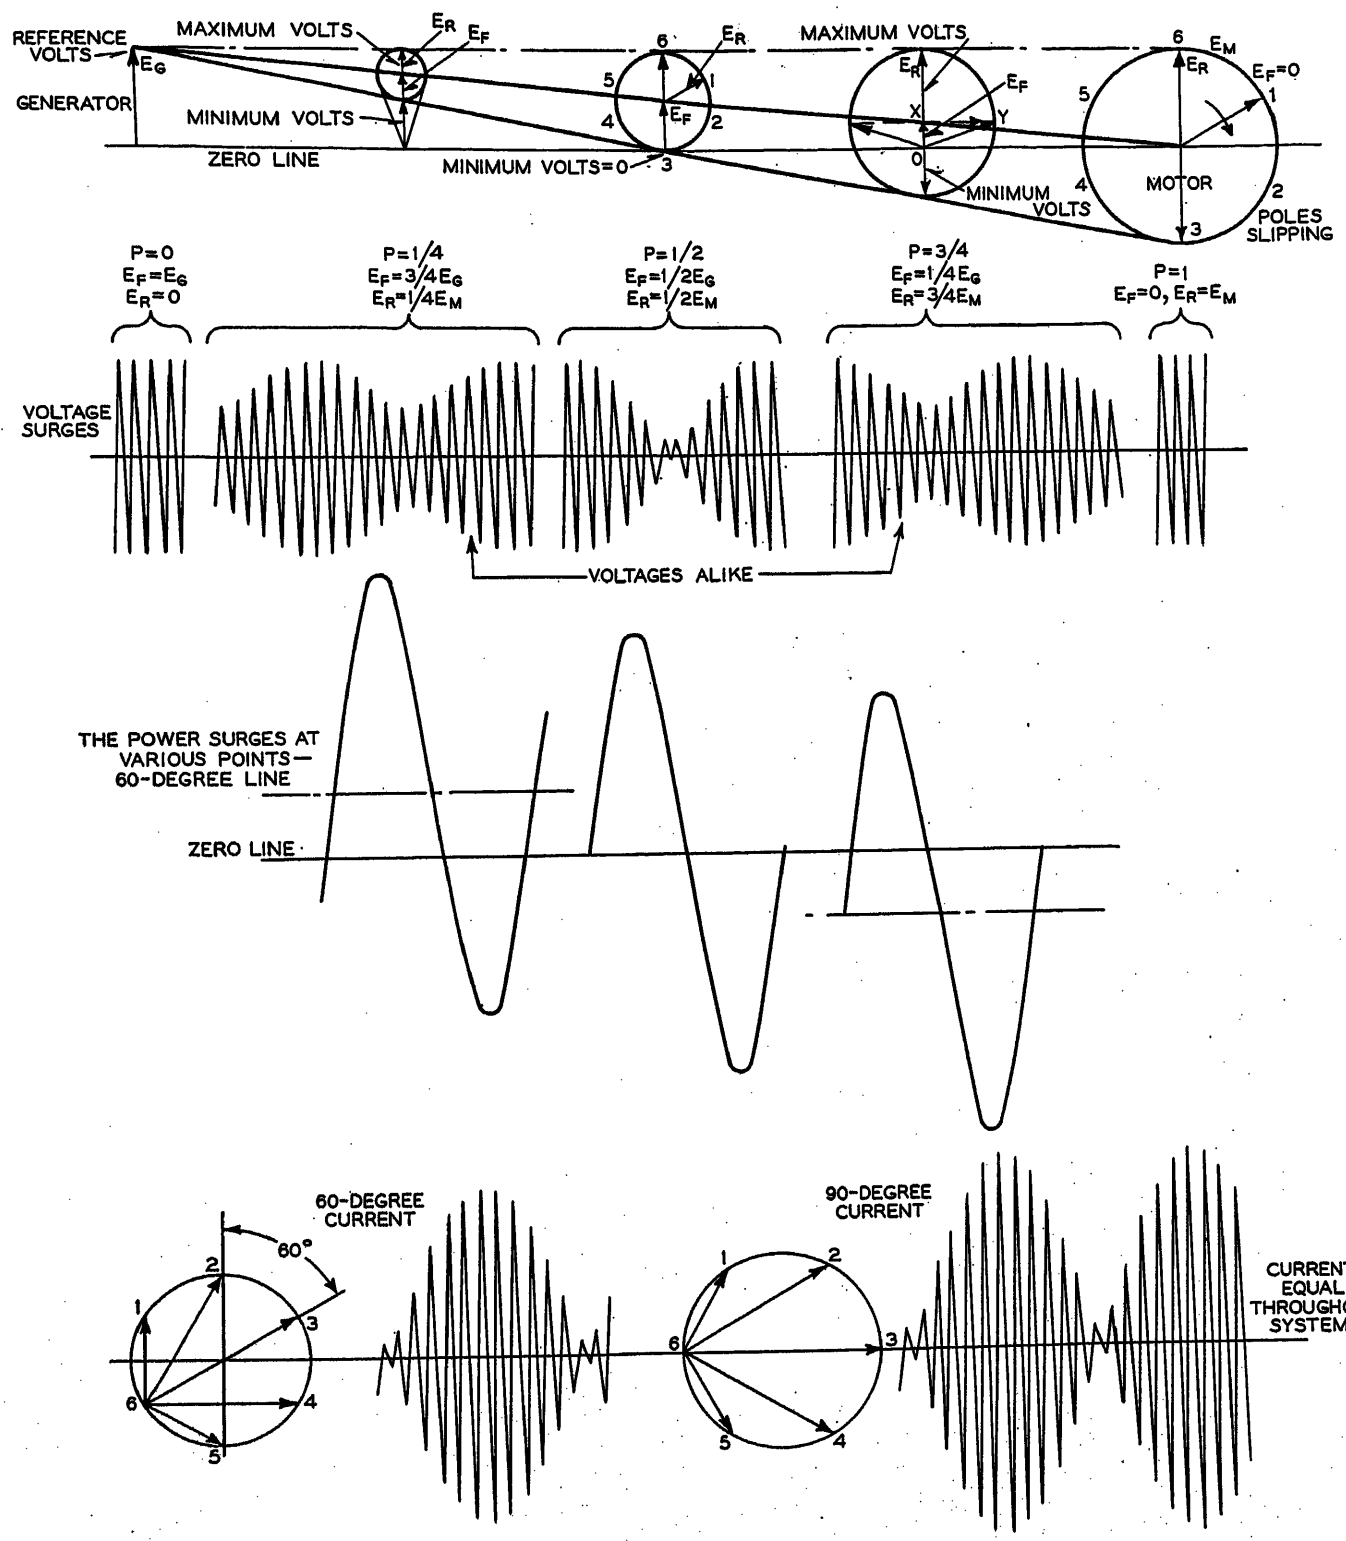

**Figure 5. The voltage, current, and power surges on a system where the generator and motor voltages are equal**

tating current vector less than the fixed vector. The conditions shown in both figures 2*C* and 2*D* produce a current surge such as that shown in figure 1*J*.

A study of figures 1 and 2 has shown the following conditions to exist:

1. The flow of current between the machines is not a sinusoidal pulsation but it varies from zero to zero through only 180 degrees.

2. The same thing is true of the voltage difference between the 2 machines.

3. Each of these variables can be resolved by geometric methods into a fixed component and a rotating component. The fixed current component is dependent on the fixed voltage component and likewise the rotating current component is determined by the rotating voltage.

4. If there is assumed to be no resistance in the circuit the current vectors will be 90 degrees behind their respective voltages. Resistance in the circuit will decrease this angle and also decrease the magnitude of both the current components.

5. A change in generated voltage of either of the machines affects

the value of the fixed or the rotating current and voltage vectors. This is the factor which must be given particular consideration when studying the protection of machinery because it is most likely to affect some of the protective methods which have been considered in the past.

It should be borne in mind that the voltages shown in this series of sketches (figures 1 and 2) are internal generated voltages. These will differ from terminal voltages or voltage values available out on the line in the manner shown in the second series of diagrams.

## Two Machines With a Transmission Line Between Them

The series of vector diagrams, figures 3 to 6, showing what happens on this simple system is useful because it can be applied in different ways. By way of illustration, some of the figures represent the machine terminals to be at a point $^1/_4$ of the distance from each end of the system. In practice, however, other points may be readily assumed to be machine terminals. Also, a number of machines may be grouped together to represent the "generator" of this simple system. In these figures the neutral of the generator has been taken as the zero point and all distances measured from that point to the neutral of the motor, and the complete distance being assumed to be one unit. Any measurement of distance will, therefore, be given as a fraction, *P*.

The figures previously discussed dealt only with internal generated voltages—quantities which are not ordinarily read by switchboard instruments. The zero line may be considered to be the neutral point of the entire system or it may be considered merely the reference point from which voltage is measured at any one location. It applies just as well to a delta voltage as to a star voltage measurement, but in these illustrations the star voltage is represented in its proper relation to the current.

In figure 3 is illustrated a simple system having the machines equally excited and carrying no load. The voltage will, therefore, be equal throughout the system and will everywhere be the same as the generated voltage. If one of these machines has no field, the conditions shown in figure 4 will exist. If all the different parts of the system have the same relative resistance and reactance, the voltage between wires will decrease uniformly along the line from the center of the generator to the center of the motor and will have the same phase relation throughout. The reason for showing the conditions in figure 4 becomes apparent in the next figure where, to the condition first shown are added the rotating vector conditions of the second machine. Here circles are drawn at 3 different points on the system for $^1/_4$, $^1/_2$, and $^3/_4$ of the distance

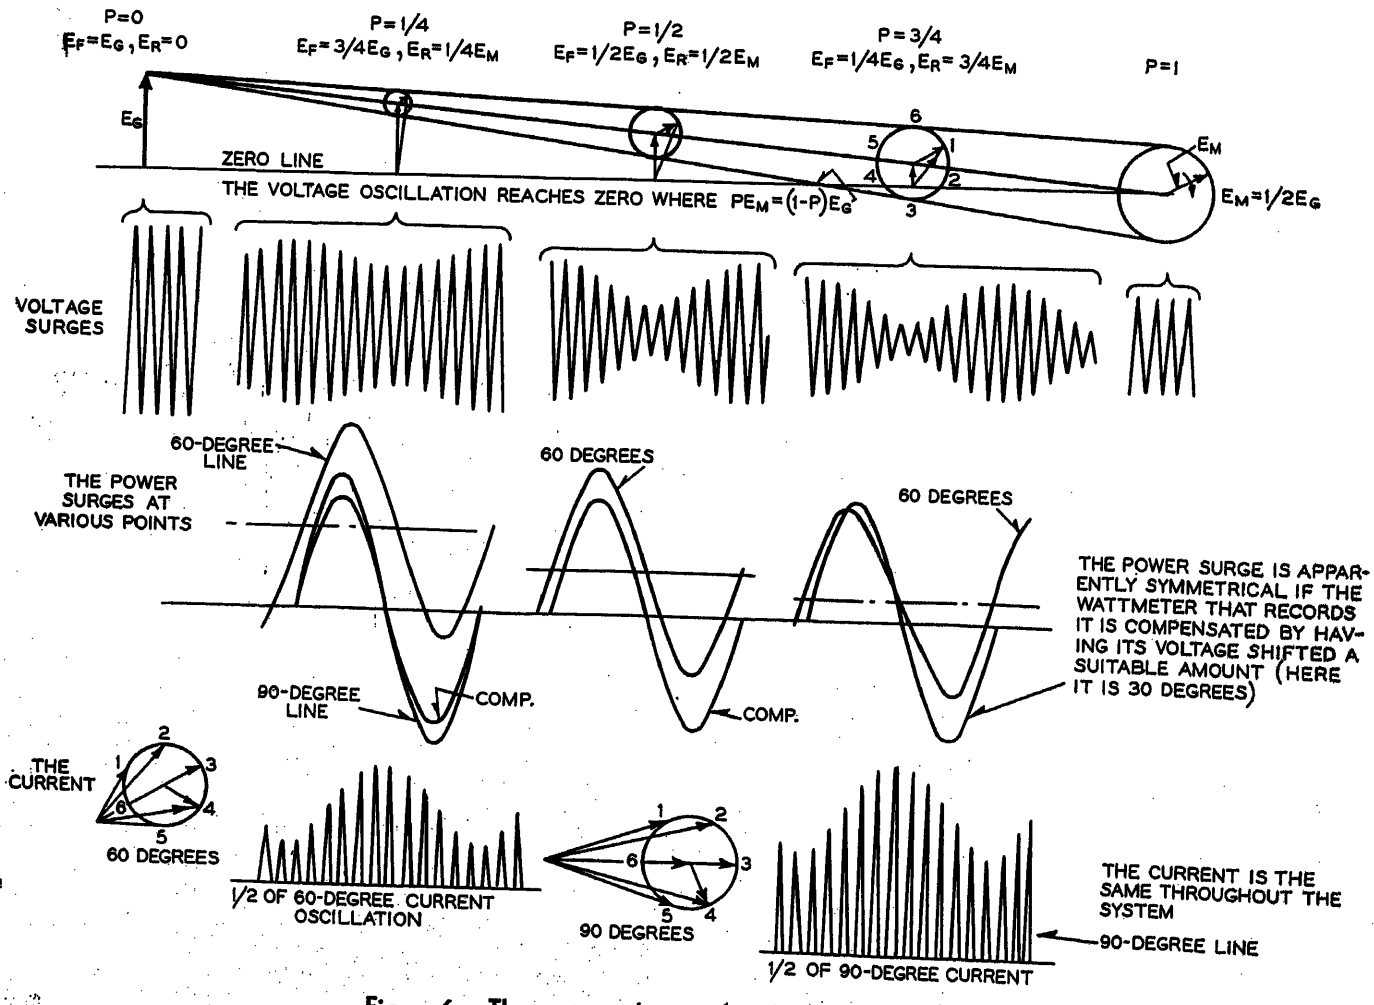

**Figure 6. The motor voltage is $^1/_2$ the generator voltage**

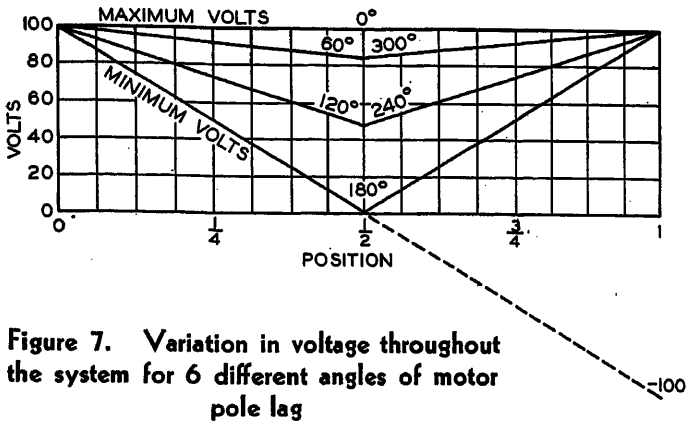

**Figure 7. Variation in voltage throughout the system for 6 different angles of motor pole lag**

between the generator neutral and the motor neutral.

Below each of these points is shown a cycle of the voltage oscillation at that point. It will be observed that the voltage oscillates to zero only at one point on the system which will be the center of the line if the 2 generated voltages are equal. If the voltages are unequal, as shown in figure 6, the point of zero voltage occurs in some other location on the system. Another way of showing this is by the curves in figures 7 and 8. These 2 figures will be of importance in studying the performance of line sectionalizing relays, particularly those of the distance-measuring type. Since minimum voltage and maximum current occur at the same time, it will be possible from these figures to determine what line relays are in danger of tripping during out-of-step conditions.

This system, with generator and motor voltages equal, is symmetrical and at first sight it seems strange that the vectors where $P = {}^1/_4$ appear to be so different from those where $P = {}^3/_4$. However, closer inspection will show that the resultant vectors are the same. It will be observed that although the swing of the vectors is different in the 2 positions, their absolute values are equal at any given time of reference. When they are plotted as scalar values they will be equal, as is shown in the voltage wave plotted below each point.

This is a good time to again emphasize that these are not vectors of instantaneous values. For example, in figure 5 the vector $OY$ is the sum of the vector $OX$ and $XY$ and this sum never reaches zero. This is shown in the voltage waves below the diagrams. The following additional facts concerning the current and voltage surges may be summarized:

1. When 2 machines are out of step there is only one point on the system where the effective voltage between wires drops to zero.

2. The position of zero voltage depends upon the relative excitation of the 2 machines.

3. The current will not become zero unless the excitation of the 2 machines is equal.

4. The system can be assumed to be symmetrical even though the machines may have different reactance values. Under such conditions, the terminals of the 2 machines are assumed to be at different distances from their centers.

5. Similarly, in considering a large generator or a group of generators connected to a small motor, the center of the system may be within the motor windings.

6. In this latter case there is no point outside of the machines where the voltage between wires will drop to zero during out-of-step conditions.

## Determining Power Surges

The most interesting part of this study is the analysis of the power flow. It has been generally recognized that the power oscillations are not the same throughout the system, but the way in which the oscillations vary at different points has been hard to understand.

The current is, of course, the same throughout the system, but the voltage is different at every point. As mentioned previously, the current vector consists of an unchanging quantity plus a rotating component which rotates with the slipping pole. The same thing is true of the voltage vectors. The flow of power between the centers of the 2 machines at any point is the product of the current and voltage vectors and the cosine of the angle between them. These vector diagrams for several points on the system are shown in figures 5 and 6. Below each of the vectors showing the voltage variations is plotted the envelope of the voltage pulsation at that point. Below this is plotted the average value of the power surge. This has been obtained by multiplying the current and voltage values by the cosine of the angle between them for various positions. Corresponding points on the current and the voltage reference circles have been marked 1, 2, 3, etc. The angles between corresponding voltage and current values are not shown, but they can easily be determined from the various figures by simple manipulations of a straight-edge and a triangle.

When plotting a power surge, a table should be prepared having the following headings:

| $\phi$ | $I$ | $E$ | Angle Between $E$ and $I$ | Cosine Angle | Watts |
|---|---|---|---|---|---|

This is about as easy a method as any. A trigonometric formula for the power surge at any point has been derived, but the final quantity that is obtained consists of the sum of a numerical term, a cosine term, and a sine term. The addition of these 3 quantities, if they are to be plotted, is usually more laborious than the method outlined above.

The formula mentioned is:

$$\text{Watts} = \frac{R}{Z^2}(E_G^2 - PE_G^2 - PE_M^2) + \frac{R}{Z^2}(2P - 1)E_G E_M \cos\phi + \frac{X}{Z^2} E_G E_M \sin\phi$$

where:

$R$ = resistance, $X$ = reactance, $Z$ = impedance of the conductor from the neutral of one machine to the neutral of the other
$E_G$ = internal voltage of the generator
$E_M$ = internal voltage of the motor
$\phi$ = the angle of separation between the poles of the 2 machines
$P$ = point where the watts are being measured

The meaning of the symbols is shown in figure 5. If the system is assumed to have no resistance, the first 2 terms vanish, leaving only the expression:

$$\text{Watts} = \frac{E_G E_M}{X} \sin\phi$$

This is the only condition where the flow of power is equal in each direction. Its value is also the same throughout the system because there is no resistance to consume power.

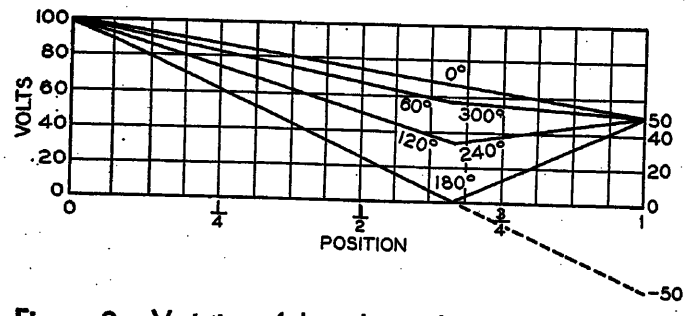
The value of the watts depends upon the product of the 2 voltages. If one of the voltages is decreased to $^1/_2$, the power interchange is decreased by the same amount. If one of the voltages is decreased to zero, the power interchange becomes zero.

As to the actual angle of a real system, there are probably none having a natural angle of more than 85 degrees. Many have an angle of around 80 degrees and more of 75 degrees. Systems of 60 degrees or even 45 degrees do exist. On such a system the power surges are not equal in the positive and negative direction, except at its center.

By reference to figures 5 and 6, it will be observed how this value varies at different points on the system under different conditions of excitation. The assumed angle in all these diagrams is 60 degrees.

Several different power curves are shown in figure 6. First, are the 3 normal curves for a 60-degree system having its motor excited to half voltage. Second, there is shown the symmetrical power wave which exists on a similar line having no resistance. The 2 sets of current vectors for these 2 different cases are shown on the diagram for comparison. Third, a set of compensated power curves is shown.

These compensated curves have particular application to the relay problem of protecting synchronous machinery. It has previously been shown that the voltage surges at a



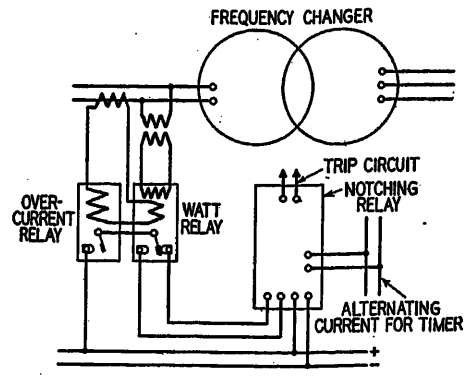


**Figure 8. Variation of the voltage when the motor voltage is 50 per cent of the generator voltage**

definite point cannot be predetermined if the excitation of the 2 machines varies in an unknown manner. The same is true of the current surges. But the power waves can be compensated so they are symmetrical. The reason for the symmetrical wave on the ideal system having no resistance is that the axes of the voltage diagram and of the current diagram are at right angles to each other. On a system where the current lags less than 90 degrees, the same effect can be obtained by compensating the wattmeter or the watt relay so that it has its zero torque at the natural angle of the system. On a 60-degree system this can be easily done by connecting the watt relay to utilize the star current and the delta voltage of the phase which is leading by 30 degrees. This differs from the usual arrangement of watt relays for line protection in that such

**Figure 9. Protecting frequency changers from operating out of step**

relays are connected to the star current and the voltage that lags by 30 degrees.

It is of interest to observe that the power wave has the same frequency as the voltage and current surges—not double frequency, as would be the case, if it were the product of 2 sine waves.

## Constants Used in the Calculations

The resistance and reactance of the transmission lines can be obtained from standard transmission line tables. The per cent resistance of the windings of machines and transformers may be assumed to be one per cent at their rated kilovolt-amperes. Synchronous machines have several different reactance values. The one that should be used in these calculations is the one now known as the transient reactance ($X_d'$). The following table of typical 60-cycle values is copied from the "Relay Handbook."

Turbine generator (2 pole): 12–22 per cent
Turbine generator (4 pole): 20–29 per cent
Salient-pole machines: 21–50 per cent
Condensers: 30–60 per cent
Power transformers:
up to 66 kv 5–7 per cent
88 to 110 kv 6–9 per cent
132 to 154 kv 8–10 per cent
187 to 220 kv 10–14 per cent

There are, of course, many factors which cannot be easily evaluated such as the effect of the load on the system and the proper method of grouping separated machines in order to simplify the setup. There is also an uncertain factor in the induction motor effect of the starting windings of the motors. Presumably, this will throw the power curve off the zero line.

Another variable is the effect of short circuits—the most common cause of out-of-step conditions. An unbalanced short circuit may cause machines to fall out of step before it is cleared. A 3-phase short circuit may, in effect, separate the machines during the time that it exists and, when the trouble is cleared by the proper breakers, the machines will be out of step. Sometimes they will pull back into step but often they will not.

## Out-of-Step Relay Protection

A synchronous machine can run out of step indefinitely and damage has been done to several machines of various types from this cause. One result of out-of-step operation

is overheating of the damper or starting windings. Another possible trouble with frequency changers and turbine generators is mechanical resonance of the rotor and the shaft, which form a torsion pendulum, with the out-of-step surges. Because of the rapidity with which dangerous resonant forces might conceivably be built up, some machines have been protected by out-of-step relays that will quickly disconnect a machine after it has slipped a definite number of poles, say 3 or 4 pairs.

The few installations of out-of-step protection with which the writer is familiar all use an out-of-step relay which actuates a notching relay. The notching relay in turn trips the breaker after the set number of notches has been registered.

Several forms of out-of-step relays have been used. On one system where it is desired to open sectionalizing breakers near the center of the system and at the lower capacity generating points, a low-voltage relay is used—a so-called "dip counter." This device can be applied when the out-of-step conditions, for which it must operate, are accompanied by dips in voltage below normal by a sufficient amount for operation of the actuating voltage relay once during each slip cycle.

Notching relays operated by current impulses are more common but it is probable that they will not fit all operating conditions. Such a current relay must be set high enough so that it will not operate if the machine is hunting—particularly after a short circuit has cleared. This high setting may be too high to allow operation under all values of field strength. Conditions may be such that the current relay will pick up and stay up because the current does not drop to a low enough value; or if the field is weak, the relay may not pick up at all.

An out-of-step relay that satisfies all of the conditions so far raised consists of a duodirectional watt relay and an overcurrent relay with their contacts in series. The watt relay can be compensated to have its zero-torque position agree with the angle of the line. This is done in the design of the relay itself when the angle to be compensated for is small. Such a relay will follow the power oscillations and make contact alternately in the positive and negative direction and step up the notching relay on each impulse.

The overcurrent relay should be set low, possibly below full load current. Its object is to insure that the watt relay will not operate when the machine is hunting. If the motor is lightly loaded the watt element may oscillate each side of zero but the current element contacts will be open. If, however, the motor is loaded so heavily that the current contacts are closed, the effect of hunting will be to cause the power to surge up and down without crossing over the zero line and becoming negative. A schematic diagram of the relay combination is shown in figure 9.

The notching relay may be a mechanical device or it may be constructed from a counting chain of auxiliary relays arranged so that each link will notch up in succession as successive impulses are given to it by the out-of-step relay. Any notching relay will be given a single energizing impulse whenever a short circuit occurs on the system. It is, therefore, necessary to reset the device after every short circuit on the system and it will also be convenient to reset it after every disturbance where it has stepped up a few notches but not enough to trip the breaker. This function may be performed automatically by means of a timing device which is set in motion by the first notch and will reset the relay, if the notching sequence is not completed within a specified time. In one commercial design of notching relay this timer can be adjusted for any value between zero and 10 seconds.

## Line Sectionalizing Relays Under Out-of-Step Conditions

The analysis given in this paper will be particularly useful in the study of transmission line relays where it is desired to prevent them from operating when the system is out of step. The factors involved are numerous and special attention must be given to every different type of relay installation. It is possible to determine the performance of the directional elements of the relays at every point taking into account the phase connection of the voltage terminals of the relay. The performance of impedance and reactance relays can likewise be determined for each location. From such a study it should be possible to prevent undesirable performance during out-of-step operation or to arrange the relays so that the line can be sectionalized at any desired point when out-of-step conditions exist. Although the principles herein outlined have been presented in a simple manner, they are fundamental and should serve as a useful guide in the study of any relay problems where out-of-step conditions are encountered.

# Use of Electricity to Treat Disease Fulfills Half-Century-Old Prophecy

A PROPHECY made over half a century ago, that electricity would be used in treating disease, has come true, and the scientist who made it is still alive to see his then rash statement justified.

The scientist is the 86-year-old Professor A. D'Arsonval, of Paris, whose galvanometer is familiar to every high school physics student. He recalled his early statement in a message to the first International Conference on Fever Therapy recently held in New York. Professor D'Arsonval is honorary president of the French committee of the conference.

"I am forgiven today," Professor D'Arsonval concludes his message, "for the phrase which I am proud of having written in 1882 and to which, at the time, I owed the animosity of doctors and pharmaceutical chemists.

" 'I am persuaded,' I said, 'that the therapeutic of the future will employ, as a curative means, the physical modificators, heat, light, electricity, and other agents still unknown . . . and that the most poisonous drugs of chemistry will have to give place to these imponderables that have the advantage of introducing no poison into the organism.' "

# Alternator Short-Circuit Currents Under Unsymmetrical Terminal Conditions

By A. R. MILLER
ASSOCIATE AIEE

W. S. WEIL, JR.
ENROLLED STUDENT AIEE

## General Introduction

IN A PREVIOUS PAPER[1] the solution for the ideal alternator under symmetrical terminal conditions was developed. In this paper the application of the equations developed in this previous paper are used, together with symmetrical components of currents, to obtain the solution of currents in the armature and field circuits of an alternator under unsymmetrical fault conditions. These equations and solutions are applied to a 3-phase alternator having a line-to-ground and a line-to-line fault condition, under various conditions. Oscillograms and calculated graphs are compared to check the method used in this solution, and excellent results are obtained. Due to the inclusion of resistance simultaneously in the armature and field circuits, the frequency of the harmonics in the circuits are seen to be somewhat different than usually given under less approximate assumptions. Also, the effect of resistance is more closely determined by this method of solution.

## Application of Symmetrical Components

The rigorous solution of the polyphase alternator assumes symmetrical terminal conditions of current. That is, the current in each phase was the same as that in every other phase, except for the difference in phase relationship.

This symmetrical terminal solution is extended to the solution of unsymmetrical fault conditions by assuming that the customary symmetrical components of positive-, negative-, and zero-sequence currents are simultaneously applied in such a fashion of phase and magnitude as will give the terminal conditions as actually exist. It is possible to so arrange these sets of sequence currents to duplicate any terminal condition chosen. Thus in a line-to-line fault, these currents (including the so-called "steady-state" and "transient" components of the solution) when added together in the open phase must give no current in that phase. Likewise, in a line-to-ground fault, the 2 open phases will have no current when the sequence currents obtained for these phases are added. The first case will require only positive- and negative-sequence components of current, while the latter will require positive-, negative-, and zero-sequence components. These statements refer not only to the fundamental component of current, but to harmonic components as well.

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted June 25, 1937; released for publication August 7, 1937.

A. R. MILLER is assistant professor of electrical engineering at Lehigh University, Bethlehem, Pa.; W. S. WEIL, JR., is employed by the General Electric Company.

1. For all numbered references, see list at end of paper.

Using these component symmetrical currents, the equivalent impedance of the alternator will need to be known for each. In general, in case harmonic armature and field currents are set up, the impedance to the fundamental and all related harmonics must be known, when flowing simultaneously.

Limiting the discussion to a line-to-line and line-to-ground fault, it would in general be expected that the impedance to the negative-sequence set of symmetrical currents would be different for the 2 cases. In the line-to-line fault the positive and negative fundamental components of current must cancel each other in the open phase; however, the negative-phase-sequence currents give rise to third harmonic currents, which in turn will require positive- and negative-sequence components that cancel each other in the open phase and so on. Since positive- and negative-sequence components of currents are involved, the impedance to the fundamental negative-sequence current will be dependent on these only. In the case of a line-to-ground fault, harmonics of positive, negative, and zero-sequence are set up by the fundamental negative-sequence component current. Because of this difference in the harmonics, depending upon the type of fault, different harmonics encountered require a different value of negative-sequence impedance. For the cases calculated in this paper, these impedances are discussed at some length in appendix $A$.

## Review of 3-Phase Short-Circuit Solution

In a previous paper by the authors[1] there were developed equations for finding the armature and field currents upon the application of a 3-phase short circuit to an alternator. There were also developed a number of equations for a 3-phase machine that could be applied for various conditions. These equations are important and will be repeated here although no derivation will be given.

$$e_d = -p\psi_d - \psi_q\,(p\theta) - i_d R \tag{1}$$

$$e_q = -p\psi_q + \psi_d\,(p\theta) - i_q R \tag{2}$$

$$E_{fd} = p\psi_{fd} + I_{fd}R_{fd} \tag{3}$$

$$\psi_{fd} = X_{ffd}I_{fd} + X_{fad}i_d \tag{4}$$

$$\psi_d = X_{afd}I_{fd} + x_d i_d \tag{5}$$

$$\psi_q = x_q i_q \tag{6}$$

These equations have been set up assuming that there is only the main field winding in the direct-axis rotor circuit and no windings on the quadrature-axis rotor circuit.

In order to solve for a 3-phase short circuit the 6 equations above are combined into the following 3 equations.

$$e_d = -(R + px_d)i_d - x_q i_q - pX_{afd}I_{fd} \quad (7)$$

$$e_q = x_d i_d - (R + px_q)i_q + X_{afd}I_{fd} \quad (8)$$

$$E_{fd} = pX_{fad}i_d + (R_{fd} + pX_{ffd})I_{fd} \quad (9)$$

These equations solved simultaneously by means of determinants give the following equations for the unknown currents.

$$\left.\begin{aligned} i_d &= [e_q(x_q R_{fd} + px_q X_{ffd}) - e_d(p^2 x_q X_{ffd} + px_q R_{fd} + pRx_{ffd} + RR_{fd}) - E_{fd}X_{afd}(p^2 x_q + pR + x_q)]/D(p) \\ i_q &= [e_d(pX_{afd}X_{fad} - px_d X_{ffd} - x_d R_{fd}) + E_{fd}(RX_{afd}) - e_q(p^2 x_d X_{ffd} - p^2 X_{afd}X_{fad} + pRX_{ffd} + pR_{fd}x_d + RR_{fd})]/D(p) \\ I_{fd} &= [E_{fd}(p^2 x_d x_q + pRx_q + pRx_d + R^2 + x_d x_q) - e_q(pX_{fad}x_q) + e_d(p^2 x_q X_{fad} + pRX_{fad})]/D(p) \end{aligned}\right\} \quad (10)$$

where

$$D(p) = p^3(x_d x_q X_{ffd} - X_{afd}X_{fad}x_q) + p^2(x_q x_d R_{fd} + Rx_d X_{ffd} + Rx_q X_{ffd} - X_{afd}X_{fad}R) + p(RR_{fd}x_d + RR_{fd}x_q + R^2 X_{ffd} + x_d x_q X_{ffd} - X_{afd}X_{fad}x_q) + (R^2 R_{fd} + x_d x_q R_{fd})$$

The currents in the various phases are found from the following equations.

$$i_a = i_d \cos\theta + i_q \sin\theta \quad (11)$$

$$i_b = i_d \cos(\theta - 120) + i_q \sin(\theta - 120) \quad (12)$$

$$i_c = i_d \cos(\theta + 120) + i_q \sin(\theta + 120) \quad (13)$$

where

$$\theta = t + \theta_0 \quad (14)$$

Also

$$e_d = \frac{2}{3}[e_a \cos\theta + e_b \cos(\theta - 120) + e_c \cos(\theta + 120)] \quad (15)$$

$$e_q = \frac{2}{3}[e_a \sin\theta + e_b \sin(\theta - 120) + e_c \sin(\theta + 120)] \quad (16)$$

and

$$x_{d'} = x_d - \frac{X_{afd}X_{fad}}{X_{ffd}} \quad (17)$$

## Theory of Single-Phase Solution

In order to satisfy terminal conditions in a line-to-ground fault, it is necessary to have positive-, negative-, and zero-sequence currents equal to each other and in-phase in phase $a$. The value of positive-sequence current is found by applying the voltage to a circuit consisting of positive-, negative-, and zero-sequence reactances in series. The sum of these reactances in the direct and quadrature axes will be $x_{dT}$ and $x_{qT}$ referred to as totalized reactances. The value of $x_2$ to be used is discussed in appendix $A$. These totalized values of direct- and quadrature-axis reactances are now used in equations 10 for the solution of a 3-phase short circuit and solutions will be obtained for $i_d$, $i_q$, and $I_{fd}$.

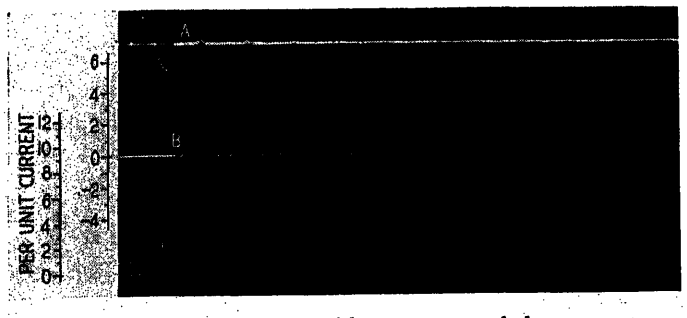

**Figure 1. Oscillogram of line-to-ground short circuit**

*A*—Phase a voltage; *B*—Armature current; *C*—Field current

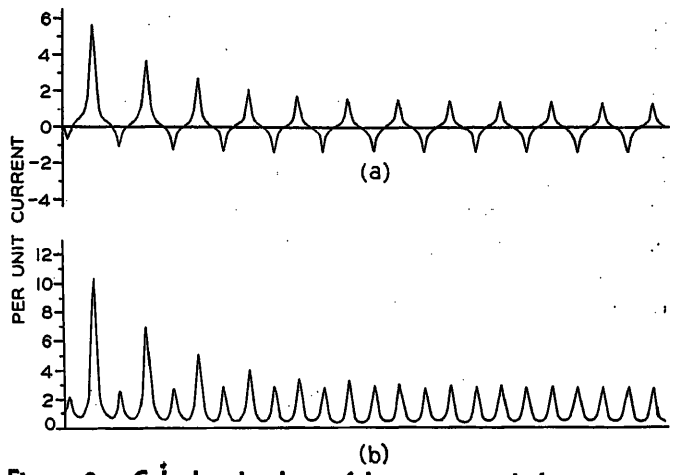

**Figure 2. Calculated values of line-to-ground short circuit**

(a) Armature current

$$i_a = \frac{0.396\sin(\omega t + 242°38') + 0.733\epsilon^{-0.09\omega t}\sin(\omega t + 242°38')}{1.224 - 0.946\cos(2\omega t + 288°)} + \frac{0.061\epsilon^{-0.103\omega t}\sin(1.991\omega t + 132°31')}{1.224 - 0.946\cos(2\omega t + 288°)} + \frac{1.109\epsilon^{-0.103\omega t}\sin(0.009\omega t + 59°40')}{1.224 - 0.946\cos(2\omega t + 288°)}$$

(b) Field current

$$I_{fd} = 1 + 1.84\epsilon^{-0.09\omega t} + 1.84\epsilon^{-0.103\omega t}\sin(0.991\omega t + 269°15') - \frac{0.946\sin(2\omega t + 201°6') + 0.447}{1.224 - 0.946\cos(2\omega t + 288°)} + \frac{[1.757\sin(2\omega t + 201°6') + 0.830]\epsilon^{-0.09\omega t}}{1.224 - 0.946\cos(2\omega t + 288°)} - \frac{[0.875\sin(2.991\omega t + 18°47')]\epsilon^{-0.103\omega t}}{1.224 - 0.946\cos(2\omega t + 288°)} + \frac{[1.82\sin(1.009\omega t + 22°11')]\epsilon^{-0.103\omega t}}{1.224 - 0.946\cos(2\omega t + 288°)} + \frac{[1.271\sin(0.991\omega t + 87°26')]\epsilon^{-0.103\omega t}}{1.224 - 0.946\cos(2\omega t + 288°)}$$

The armature currents that are found by this solution are only the fundamental-frequency positive-phase-sequence currents flowing in the armature, so that the value of $i_a$ obtained from the above values of $i_d$ and $i_q$ is ${}_1i_{a1}$. For a line-to-ground short circuit the total short-circuit current in phase $a$ is equal to 3 times the sequence current due to the fact that positive-, negative-, and zero-sequence currents are equal so that the true value of ${}_1i_a$ is equal to 3 times ${}_1i_{a1}$.

The fact that there is negative-sequence current flowing in the armature produces currents of frequency 2 higher than the fundamental solution, and gives rise to several series of terms of higher frequencies. These series will be

referred to as harmonic series throughout this paper although it will be seen that the series are not made up of harmonics but of a series of terms each of frequency 2 higher than the term that preceded it. In order to obtain the solution for the actual armature currents, the harmonics that go with ${}_1i_a$ must be found and added to it. The actual process of obtaining the total short-circuit current, including these harmonics, is given in appendix *B*.

The solution of $I_{fa}$ as found from equation 10 is, in a manner similar to the solution for armature current, only a

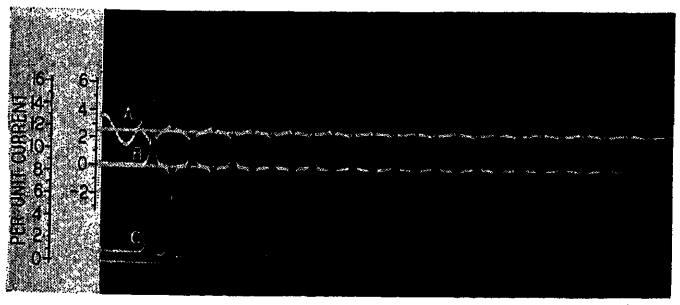

**Figure 3. Oscillogram of line-to-line short circuit**

*A*—Phase *a* voltage; *B*—Phase *b* current; *C*—Field current

part of the total current. The harmonics in the field current arise from the harmonic currents flowing in the armature. Therefore the harmonics in the field are calculated from the total $i_a$ flowing in the armature by solving equation 9 for $I_{fa}$.

Letting $E_{fa} = 0$

$$I_{fa} = \frac{pX_{fad}i_a}{R_{fa} + pX_{ffa}}$$

The series are geometric in form so that once 2 terms have been found the rest of the series is determined.

The same process is used to obtain the solution for a line-to-line short circuit. In this case there are no zero-sequence currents and the equation for $x_2$ will be different than that used in the line-to-ground solution.

## Conclusions

By the application of symmetrical components of currents to polyphase-alternator short-circuit solutions it has been possible to include the resistance in both the armature and field circuits in a much more satisfactory manner than is usually found in unsymmetrical alternator short-circuit solutions. In order to shorten the numerical calculations, some approximations have been made in the inclusion of the resistances of the machine circuits, but these approximations have only a negligible effect. Moreover, these solutions are similar to the general 2-reaction theory as developed for symmetrical short-circuit solutions, and give solutions which agree experimentally. The oscillograms included in the paper were taken on a small laboratory machine; even closer results could be obtained on larger commercial machines, in which the constants were known.

## Appendix A

NEGATIVE-SEQUENCE REACTANCE

By applying the constant-flux-linkage theorem to a line-to-ground fault, Doherty[2] has shown that the initial value of the fundamental component of current is

$$i = \frac{2e_0}{x_D' + \sqrt{x_D'x_Q'}} \tag{1a}$$

By the principle of symmetrical components, this is also equal to

$$i = \frac{3e_0}{x_d' + x_2 + x_0} \tag{2a}$$

Therefore

$$\frac{3}{x_d' + x_2 + x_0} = \frac{2}{x_D' + \sqrt{x_D'x_Q'}}$$

Park[3] has shown that the following relations exist between the single-phase static constants and the 3-phase constants.

$$x_D' = \frac{x_0 + 2x_d'}{3}$$

$$x_Q' = \frac{x_0 + 2x_q'}{3}$$

Substituting and solving for $x_2$

$$x_2 = \frac{\sqrt{(x_0 + 2x_d')(x_0 + 2x_q')}}{2} - \frac{x_0}{2} \tag{3a}$$

Park has shown that for a line-to-line fault the relation between single-phase and 3-phase constants differ from the line-to-ground relations.

$$x_D' = 2x_d'$$

$$x_Q' = 2x_q'$$

Thus the initial value of the fundamental current during a line-to-line fault as given by Doherty becomes

$$\frac{2\sqrt{3}e_0}{x_D' + \sqrt{x_D'x_Q'}} = \frac{\sqrt{3}e_0}{x_d' + \sqrt{x_d'x_q'}}$$

But by symmetrical components this current is also

$$\frac{\sqrt{3}e_0}{x_d' + x_2}$$

Now equation the 2 expressions and solving for $x_2$

$$x_2 = \sqrt{x_d'x_q'} \tag{4a}$$

Thus it is seen that $x_2$ varies with the kind of fault.

For a line-to-ground fault the external reactances of the sequence network are $x_2$ and $x_0$ in series.

Therefore

$$x_{dT} = x_d + x_2 + x_0$$
$$x_{qT} = x_q + x_2 + x_0$$

Similarly

$$x_{dT}' = x_d' + x_2 + x_0$$
$$x_{qT}' = x_q' + x_2 + x_0$$

For a line-to-line fault, the external reactance is only the negative-sequence reactance and the totalized impedances are

$$x_{dT} = x_d + x_2$$
$$x_{qT} = x_q + x_2$$
$$x_{dT}' = x_d' + x_2$$
$$x_{qT}' = x_q' + x_2$$

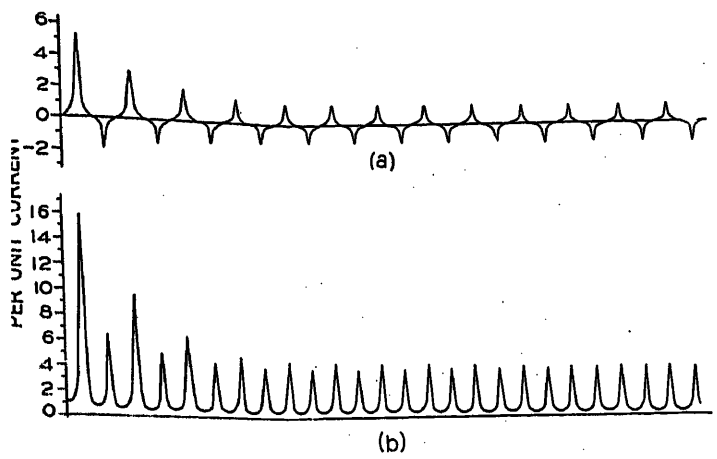

**Figure 4. Calculated values of line-to-line short circuit**

(a) Armature current

$$i_b = \frac{0.208 \sin(\omega t + 345°1') + 0.599\epsilon^{-0.123\omega t}\sin(\omega t + 345°1')}{1.342 - 1.170\cos(2\omega t + 132°)} +$$
$$\frac{0.064\epsilon^{-0.101\omega t}\sin(1.991\omega t + 248°22')}{1.342 - 1.170\cos(2\omega t + 132°)} +$$
$$\frac{0.798\epsilon^{-0.101\omega t}\sin(0.009\omega t + 161°1')}{1.342 - 1.170\cos(2\omega t + 132°)}$$

(b) Field current

$$I_{fd} = 1.0 + 2.88\epsilon^{-0.123\omega t} + 2.884\epsilon^{-0.101\omega t}\sin(0.991\omega t + 271°26') -$$
$$\frac{1.17\sin(2\omega t + 44°23') + 0.681}{1.342 - 1.170\cos(2\omega t + 132°)} +$$
$$\frac{[3.37\sin(2\omega t + 44°23') + 1.96]\epsilon^{-0.123\omega t}}{1.342 - 1.170\cos(2\omega t + 132°)} -$$
$$\frac{[1.68\sin(2.991\omega t + 224°35')]\epsilon^{-0.101\omega t}}{1.342 - 1.170\cos(2\omega t + 132°)} +$$
$$\frac{[2.87\sin(1.009\omega t + 224°26')]\epsilon^{-0.101\omega t}}{1.342 - 1.170\cos(2\omega t + 132°)} +$$
$$\frac{[2.657\sin(0.991\omega t + 89°25')]\epsilon^{-0.101\omega t}}{1.342 - 1.170\cos(2\omega t + 132°)}$$

If any impedance external to the machine is present, it must be added to $x_d$, $x_2$, and $x_0$, etc. Thus for an external impedance of $x_{ex}$ in a line-to-ground fault

$$x_{dT} = x_d + x_2 + x_0 + 3x_{ex} \tag{5a}$$

Similar equations must be written for $x_{qT}$, and for the transient reactances $x_{dT}'$ and $x_{qT}'$.

An external impedance in a line-to-line fault is taken into account similarly except that $x_0$ is not present; therefore only $2x_{ex}$ must be added.

$$x_{dT} = x_d + x_2 + 2x_{ex}, \text{ etc.} \tag{6a}$$

In order to see the formation of higher frequency currents, let a negative-sequence voltage of frequency $n$ be impressed.

$$e_a = \sin nt$$
$$e_b = \sin(nt - 120)$$
$$e_c = \sin(nt + 120)$$

And then from equations 15 and 16

$$e_d = \sin(n+1)t$$
$$e_q = -\cos(n+1)t$$

From equations 1 and 2

$$e_d = -p\psi_d - \psi_q(p\theta) - i_d R$$
$$e_q = -p\psi_q + \psi_d(p\theta) - i_q R$$

But using the totalized reactances

$$\psi_d = x_{dT}' i_d$$
$$\psi_q = x_{qT}' i_q$$

With $p\theta = 1$ and neglecting $R$

$$e_d = \sin(n+1)t = -p\,x_{dT}' i_d - x_{qT}' i_q$$
$$e_q = -\cos(n+1)t = -p\,x_{qT}' i_q + x_{dT}' i_d$$

Solving for $i_d$ and $i_q$

$$i_d = \frac{\cos(n+1)t}{n\,x_{dT}'}$$

$$i_q = \frac{\sin(n+1)t}{n\,x_{qT}'}$$

Then from equation 11 the value of $i_a$ becomes

$$i_a = \frac{1}{2n}\left(\frac{1}{x_{dT}'} + \frac{1}{x_{qT}'}\right)\cos nt + \frac{1}{2n}\left(\frac{1}{x_{dT}'} - \frac{1}{x_{qT}'}\right)\cos(n+2)t \tag{7a}$$

From equation 7a the formation of higher frequencies can readily be seen. A negative-sequence current of frequency $n$ will produce a positive-sequence current of frequency $(n + 2)$. That this is a positive-sequence current can readily be checked by finding the currents $i_b$ and $i_c$ similar to equation 7a. The important part of this equation is the relation of the magnitude of the 2 currents. This ratio is

$$\frac{\left(\frac{1}{x_{dT}'} - \frac{1}{x_{qT}'}\right)}{\left(\frac{1}{x_{dT}'} + \frac{1}{x_{qT}'}\right)} = \frac{x_{qT}' - x_{dT}'}{x_{qT}' + x_{dT}'} \tag{8a}$$

Therefore if a negative-sequence current of frequency $n$ is flowing there will also be flowing a positive-sequence current of frequency $(n + 2)$ whose amplitude bears the ratio to the first current as given by equation 8a.

## Appendix B

ARMATURE CURRENT

From the theory of symmetrical components, the current that will be found by dividing the voltage by the network impedance for a line-to-ground fault is only the positive-sequence current.

$$i_{a1} = \frac{E}{x_1 + x_2 + x_0}$$

However there is also flowing a negative- and zero-sequence current equal to this value of $i_{a1}$. It is a known fact that harmonics exist

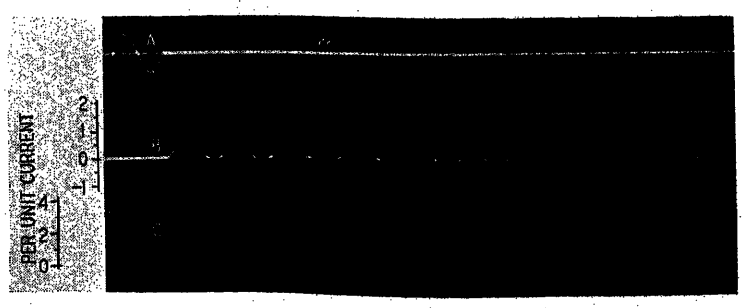

**Figure 5. Oscillogram of line-to-ground short circuit with external reactance**

A—Phase a voltage, B—Armature current, C—Field current

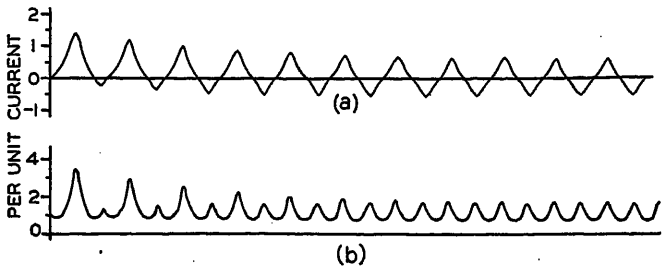

**Figure 6. Calculated values of line-to-ground short circuit with external reactance**

(*a*) Armature current

$$i_a = \frac{0.333 \sin(\omega t + 280°18') + 0.201\epsilon^{-0.051\omega t}\sin(\omega t + 280°18')}{1.053 - 0.462\cos(2\omega t + 10°)} +$$

$$\frac{0.022\epsilon^{-0.075\omega t}\sin(1.999\omega t + 180°)}{1.053 - 0.462\cos(2\omega t + 10°)} +$$

$$\frac{0.525\epsilon^{-0.075\omega t}\sin(0.001\omega t + 98°)}{1.053 - 0.462\cos(2\omega t + 10°)}$$

(*b*) Field current

$$I_{fd} = 1.0 + 0.60\epsilon^{-0.051\omega t} + 0.60\epsilon^{-0.075\omega t}\sin(0.999\omega t + 268°37') -$$

$$\frac{0.46\sin(2\omega t + 283°19') + 0.106}{1.053 - 0.462\cos(2\omega t + 10°)} -$$

$$\frac{[0.277\sin(2\omega t + 283°19') + 0.064]\epsilon^{-0.051\omega t}}{1.053 - 0.462\cos(2\omega t + 10°)} -$$

$$\frac{[0.137\sin(2.999\omega t + 107°5')]\epsilon^{-0.075\omega t}}{1.053 - 0.462\cos(2\omega t + 10°)} -$$

$$\frac{[0.60\sin(1.001\omega t + 102°51')]\epsilon^{-0.075\omega t}}{1.053 - 0.462\cos(2\omega t + 10°)} +$$

$$\frac{[0.170\sin(0.999\omega t + 89°24')]\epsilon^{-0.075\omega t}}{1.053 - 0.462\cos(2\omega t + 10°)}$$

in the armature so the current as found above shall be referred to as fundamental positive-sequence current in phase *a*, or, ${}_1i_{a1}$.

$${}_1i_{a1} = A\sin(\omega t + \theta_0 + \alpha) = A\sin(\theta + \alpha)$$

where $\theta_0$ is the angle between phase *a* and the direct axis at the instant of short circuit and $\alpha$ is the angle of lag of the armature circuit. This angle $\alpha$ is only slightly less than $-90$ degrees.

It was shown in appendix *A*, equation 8*a*, that if a negative-sequence current is flowing in the armature, there is set up a positive-sequence current of frequency 2 units higher and bearing a ratio to the original current of $\frac{x_{qT}' - x_{dT}'}{x_{qT}' + x_{dT}'}$. This ratio will be called *b* for convenience.

Now

$${}_1i_{a1} = A\sin(\theta + \alpha)$$
$${}_1i_{a2} = A\sin(\theta + \alpha)$$
$${}_1i_{a0} = A\sin(\theta + \alpha)$$

and

$${}_1i_a = 3A\sin(\theta + \alpha) \qquad (1b)$$

but ${}_1i_{a2}$ sets up a positive-sequence third harmonic current, ${}_3i_{a1}$, such that

$${}_3i_{a1} = b\,x\,{}_1i_{a2} = bA\sin(3\theta + \alpha)$$

and since

$${}_3i_{a1} = {}_3i_{a2} = {}_3i_{a0}$$
$${}_3i_a = 3bA\sin(3\theta + \alpha)$$

Now if

$${}_3i_{a2} = bA\sin(3\theta + \alpha)$$
$${}_3i_{a1} = b^2A\sin(5\theta + \alpha)$$

In similar manner there must be ${}_3i_{a0}$ and ${}_3i_{a0}$ and thus

$${}_3i_a = 3b^2A\sin(5\theta + \alpha)$$

or

$$i_a = 3A[\sin(\theta + \alpha) + b\sin(3\theta + \alpha) + b^2\sin(5\theta + \alpha) + \text{etc.}\ldots] \qquad (2b)$$

FIELD CURRENT

From equation 9

$$I_{fd} = \frac{E_{fd} - p\,X_{fad}\,i_d}{R_{fd} + pX_{ffd}}$$

$E_{fd}$ has the same value before and after the instant of short circuit so that in calculating any additional field current $E_{fd}$ is neglected.

$$I_{fd} = -\frac{p\,X_{fad}\,i_d}{R_{fd} + p\,X_{ffd}}$$

Neglecting $R_{fd}$

$$I_{fd} = -\frac{X_{fad}}{X_{ffd}}\,i_d \qquad (3b)$$

Therefore, in order to find the series of terms in $I_{fd}$, the series of terms in $i_d$ must be found.

$$i_d = \frac{2}{3}[i_a\cos\theta + i_b\cos(\theta - 120) + i_c\cos(\theta + 120)]$$

$$i_b = i_c = 0$$

therefore

$$i_d = \frac{2}{3}\,i_a\cos\theta \qquad (4b)$$

Putting in the value of $i_a$ term by term as found above gives for the first term

$${}_1i_d = \frac{2}{3} \times 3A\sin(\theta + \alpha)\cos\theta$$

$$= A\sin(2\theta + \alpha) + A\sin\alpha$$

In similar manner

$${}_3i_d = bA\sin(4\theta + \alpha) + bA\sin(2\theta + \alpha)$$

and

$${}_5i_d = b^2A\sin(6\theta + \alpha) + b^2A\sin(4\theta + \alpha)$$

or

$$i_d = A\sin\alpha + (1 + b)A[\sin(2\theta + \alpha) + b\sin(4\theta + \alpha) + b^2\sin(6\theta + \alpha) + \ldots] \qquad (5b)$$

To find the total armature current the harmonics due to negative-sequence current were found and added to the solution of ${}_1i_a$ as found from equation 1*b*. Therefore only the harmonics in the field current that come from the negative-sequence fundamental current must be added to the solution of $I_{fd}$ from equation 10.

$${}_1i_{a1} = A\sin(\theta + \alpha)$$

$${}_1i_{d1} = \frac{2}{3}[{}_1i_{a1}\cos\theta + {}_1i_{b1}\cos(\theta - 120) + {}_1i_{c1}\cos(\theta + 120)]$$

$$= A\sin\alpha$$

$${}_1i_{d2} = \frac{2}{3}[{}_1i_{a2}\cos\theta + {}_1i_{b2}\cos(\theta - 120) + {}_1i_{c2}\cos(\theta + 120)]$$

$$= A\sin(2\theta + \alpha)$$

Thus it is seen that in the equation for $i_d$ the first term $A \sin \alpha$ comes from the fundamental positive-sequence current and is not part of the additional harmonics. Therefore in order to get $I_{fd}$ only the terms in the bracket are applied to equation 3b. The additional terms of $I_{fd}$ are then

$$I_{fd} = -\frac{X_{fad}}{X_{ffd}}(1+b)\,A\,[\sin(2\theta+\alpha) + b\sin(4\theta+\alpha) + b^2\sin(6\theta+\alpha) + \ldots] \qquad (6b)$$

To obtain the total solution of $I_{fd}$, equation 6b must be added to the solution of $I_{fd}$ from equation 10.

### Harmonic Series

It is very inconvenient to plot the series term by term. For that reason the development of an expression for the sum of each series is now given.

The series that occur in the armature and field currents are both of the following general form where $X$ equals the sum.

$$X = \sin(n\theta+\alpha) + b\sin[(n+2)\theta+\alpha] + b^2\sin[(n+4)\theta+\alpha] + b^3\sin[(n+6)\theta+\alpha] + \ldots$$

Let $b = a^2$ and multiply both sides by $a^n$.

$$a^nX = a^n\sin(n\theta+\alpha) + a^{n+2}\sin[(n+2)\theta+\alpha] + a^{n+4}\sin[(n+4)\theta+\alpha] + \ldots$$

now

$$\sin(n\theta+\alpha) = \frac{\epsilon^{jn\theta}\epsilon^{j\alpha} - \epsilon^{-jn\theta}\epsilon^{-j\alpha}}{2j}$$

Writing the series with a summation sign

$$a^nx = \frac{1}{2j}\sum_{k=0}^{k=n}(a^{2k+n}\,\epsilon^{j(2k+n)\theta}\epsilon^{j\alpha} - a^{2k+n}\epsilon^{-j(2k+n)\theta}\epsilon^{-j\alpha})$$

but

$$\sum_{k=0}^{k=n} a^{(2k+n)} = \frac{a^n}{1-a^2}$$

$$a^nx = \frac{1}{2j}\left[\frac{\epsilon^{j\alpha}a^n\epsilon^{jn\theta}}{1-a^2\epsilon^{j2\theta}} - \frac{\epsilon^{-j\alpha}a^n\epsilon^{-jn\theta}}{1-a^2\epsilon^{-j2}}\right]$$

$$= \frac{1}{2j}\left[\frac{\epsilon^{j\alpha}a^n\epsilon^{jn\theta} - a^{n+2}\epsilon^{j\alpha}\epsilon^{j(n-2)\theta} - \epsilon^{-j\alpha}a^n\epsilon^{-jn\theta} + a^{n+2}\epsilon^{-j\alpha}\epsilon^{-j(n-2)\theta}}{1-a^2(\epsilon^{j2\theta}+\epsilon^{-j2\theta})+a^4}\right]$$

$$= \frac{1}{2j}\left[\frac{a^n(\epsilon^{j\alpha}\epsilon^{jn\theta} - \epsilon^{-j\alpha}\epsilon^{-jn\theta}) - a^{n+2}(\epsilon^{j\alpha}\epsilon^{j(n-2)\theta} - \epsilon^{-j\alpha}\epsilon^{-j(n_2)\theta}}{1-a^2(\epsilon^{j2\prime}+\epsilon^{-j2\theta})+a^4}\right]$$

$$a^nX = \frac{a^n\sin(n\theta+\alpha) - a^{n+2}\sin[(n-2)\theta+\alpha]}{1-2a^2\cos 2\theta + a^4}$$

$$X = \frac{\sin(n\theta+\alpha) - a^2\sin[(n-2)\theta+\alpha]}{1+a^4-2a^2\cos 2\theta}$$

but $a^2 = b$, therefore

$$X = \frac{\sin(n\theta+\alpha) - b\sin[(n-2)\theta+\alpha]}{1+b^2-2b\cos 2\theta}$$

where $\sin(n\theta+\alpha)$ is the first term of the series. Remembering that $\theta = \omega t + \theta_0$

$$\text{Sum} = \frac{\sin[n(\omega t+\theta_0)+\alpha] - b\sin[(n-2)(\omega t+\theta_0)+\alpha]}{1+b^2-2b\cos 2(\omega t+\theta_0)} \qquad (7b)$$

## Appendix C

### Line-to-Ground Short Circuit

Appendices $C$, $D$, and $E$ illustrate the method of calculating various types of faults on a small laboratory machine, the constants of which are given below.

| | | |
|---|---|---|
| $R_{fd} = 1.0$ | $x_d = x_q = 2.80$ | norm. $e_a = 63.5\sqrt{2}$ |
| $X_{afd} = 1.0$ | $X_{fad} = 81.7$ | $i_a = 10\sqrt{2}$ |
| $R = 0.073$ | $X_{ffd} = 31.5$ | $E_{fd} = 1.68$ |
| | $x_0 = 0.34$ | $I_{fd} = 13.95$ |

$$x_d' = x_d - \frac{X_{afd}X_{fad}}{X_{ffd}} \qquad (17)$$

$$= 2.8 - 2.59 = 0.21$$

$$x_2 = \frac{\sqrt{2x_d'+x_0)(2x_q'+x_0)}}{2} - \frac{x_0}{2} \qquad (3a)$$

$$= \frac{1}{2}\sqrt{(0.42+0.34)(5.6+0.34)} - 0.17 = 0.89$$

The totalized reactances are then

$$x_{qT}' = 2.80 + 0.34 + 0.89 = 4.03$$
$$x_{dT}' = 0.21 + 0.34 + 0.89 = 1.44$$

$$b = \frac{4.03-1.44}{4.03+1.44} = \frac{2.59}{5.47} = 0.473$$

Assuming that the 3 sequence resistances are equal

$$R = R_1 + R_2 + R_0 = 3 \times 0.073 = 0.22$$

Now, using $x_{dT} = 4.03$ instead of $x_d = 2.80$ and $R = 0.22$ in the equations for a 3-phase short circuit,

$$i_{d1} = -0.248 - 0.459\epsilon^{-0.09\omega t} + 0.705\epsilon^{-0.103\omega t}\cos(0.991\omega t - 2°34')$$

$$i_{q1} = 0.0135 + 0.0248\epsilon^{-0.09\omega t} + 0.250\epsilon^{-0.103\omega t}\cos(0.991\omega t - 98°46')$$

$$I_{fd} = 1.0 + 1.84\,\epsilon^{-0.09\omega t} + 184\epsilon^{-0.103\omega t}\sin(0.991\omega t + 269°\ 15')$$

From the oscillogram $\theta_0 = 324°$

$$i_{a1} = i_{d1}\cos(\omega t+\theta_0) + i_{q1}\sin(\omega t+\theta_0)$$

and the fundamental value of $i_a$ becomes

$$_1i_a = 3\,i_{a1}$$

$$_1i_a = 0.745\sin(\omega t + 237°6') + 1.38\,\epsilon^{-0.09\omega t}\sin(\omega t+237°6') + 0.687\epsilon^{-0.103\omega t}\sin(1.991\,\omega t + 54°47') + 1.43\epsilon^{-0.103\omega t}\sin(0.009\omega t + 58°11')$$

Each of these 4 terms is followed by a series of harmonics but the term $(\omega t + \theta_0)$ must be factored out of $(\omega t + 237°6')$, etc. Thus for the first term of $_1i_a$

$$0.745\sin(\omega t+237°6') = 0.745\sin[(\omega t+324°) - 86°54']$$

The series of harmonics following the first term is

$$0.745(\sin[(\omega t+324°) - 86°54'] + b\sin[3(\omega t+324°) - 86°54'] + b^2\sin[5(\omega t+324°) - 86°54'] + \text{etc.})$$

The first term is in the form $\sin[n(\omega t+\theta_0)+\alpha]$ and the equation developed in appendix $B$ can be used to get the sum.

$$\text{Sum} = \frac{\sin[n(\omega t+\theta_0)+\alpha] - b\sin[(n-2)(\omega t+\theta_0)+\alpha]}{1+b^2-2b\cos 2(\omega t+\theta_0)} \qquad (7b)$$

For the series following the first term of $_1i_a$

$b = 0.473$ $\quad n = 1$ $\quad (\omega t+\theta_0) = (\omega t+324°) = \theta$
$\alpha = -86°54'$

$$\text{sum} = 0.745\,\frac{[\sin(\theta - 86°54') - 0.473\sin(-\theta - 86°54')]}{1.224 - 0.946\cos(2\omega t+288°)}$$

$$= 0.745\,\frac{[0.532\sin(\theta - 81°22')]}{1.224-0.946\cos(2\omega t+288°)} = \frac{0.396\sin(\omega t+242°38')}{1.224-0.946\cos(2\omega t+288°)}$$

In a similar manner the sum of the series following the second term is

$$= 1.38\epsilon^{-0.09\omega t}\,\frac{[0.532\sin(\theta - 81°22')]}{1.224 - 0.946\cos(2\omega t + 288°)} = \frac{0.733\epsilon^{-0.09\omega t}\sin(\omega t + 242°38')}{1.224 - 0.946\cos(2\omega t + 288°)}$$

The same denominator will appear in all of the terms and for convenience it will be replaced by a symbol $D(1)$, where

$$D(1) = 1.224 - 0.946\cos(2\omega t + 288°)$$

In order to use the equation for the sum developed in appendix $B$, it is necessary to get the first term of each series in the form of

$$\sin[n(\omega t + \theta_0) + \alpha]$$

The third term of ${}_1i_a$ can be written

$$0.687\epsilon^{-0.103\omega t}\sin(1.991\omega t + 54°47') = 0.687\epsilon^{-0.103\omega t}\sin[1.991(\omega t + 324°) + 129°42']$$

where

$$\alpha = \phi - n(\theta_0) = 54°47' - 1.991\,(324°) = 129°42'$$

In similar manner for the fourth term

$$\alpha = 58°11' - 0.009\,(324°) = 55°16'$$

and

$$1.43\epsilon^{0.103\omega t}\sin(0.009\omega t + 58°11') = 1.43\epsilon^{0.103\omega t}\sin[0.009\,(\omega t + 324°) + 55°16']$$

The third and fourth term series become respectively

$$\text{Third} = \frac{0.687\epsilon^{-0.10\omega t}}{D\,(1)} \times \frac{[\sin(1.991\theta + 129°42') - 0.473\sin(-0.009\theta + 129°42')]}{D(1)}$$

$$\text{Fourth} = \frac{1.43\epsilon^{-0.103\omega t}[\sin(0.009\theta + 55°16') - 0.473\sin(-1.991\theta + 55°16')]}{D(1)}$$

These two can be combined in the following manner.

$$0.687\ \angle 129°42' + 0.473 \times 1.43\ \angle -55°16' = 0.061\ \angle 207°26'$$

$$1.43\ \angle 55°16' + 0.473 \times 0.687\ \angle -129°42' = 1.109\ \angle 56°45'$$

and the combination of the third and fourth term series gives

$$\text{Third + fourth} = \frac{0.061\epsilon^{-0.103\omega t}\sin(1.991\theta + 207°26')}{D(1)} + \frac{1.109\epsilon^{-0.103\omega t}\sin(0.009\theta + 56°45')}{D(1)}$$

Substituting $\theta = \omega t + \theta_0$

$$\text{Third + fourth} = \frac{0.061\epsilon^{-0.103\omega t}\sin(1.991\omega t + 132°31')}{D(1)} + \frac{1.109\epsilon^{-0.103\omega t}\sin(0.009\omega t + 59°40')}{D(1)}$$

Then the complete expression for the armature current becomes

$$i_a = \frac{0.396\sin(\omega t + 242°38') + 0.733\epsilon^{-0.09\omega t}\sin(\omega t + 242°38')}{1.224 - 0.946\cos(2\omega t + 288°)} + \frac{0.061\epsilon^{-0.103\omega t}\sin(1.991\omega t + 132°31')}{1.224 - 0.946\cos(2\omega t + 288°)} + \frac{1.109\epsilon^{-0.103\omega t}\sin(0.009\omega t + 59°40')}{1.224 - 0.946\cos(2\omega t + 288°)}$$

The value of $i_d$ can be found from each term of $i_a$ by using the following equation.

$$i_d = \frac{2}{3}\,i_a\cos(\omega t + \theta_0) \qquad (4b)$$

$$= \frac{2}{3} \times 0.745\sin(\theta - 86°54')\cos\theta$$

$$= 0.248\sin(2\theta - 86°54') - 0.248$$

Using equation 5*b*, the $i_d$ resulting from the first term of $i_a$ and its series is

$$i_d = -0.248 + 0.248(1 + b)[\sin(2\theta - 86°54') + b\sin(4\theta - 86°54') + b^2\sin(6\theta - 86°54') + \text{etc.}]$$

$$I_{fd} = -\frac{X_{fad}}{X_{ffd}}\,i_d \qquad (3b)$$

$$I_{fd} = -2.59\,i_d$$

As was shown in appendix $B$, the harmonics in $I_{fd}$ are found by using only the bracketed terms of $i_d$.

The first term of the series is in the form

$$\sin[n(\omega t + \theta_0) + \alpha]$$

where

$$n = 2 \qquad \alpha = -86°34' \qquad b = 0.473$$

$$\text{sum} = \frac{-2.59 \times 0.248 \times 1.473[\sin(2\theta - 86°54') - 0.473\sin(-86°54')]}{D(1)} = \frac{-0.946\sin(2\omega t + 201°6') - 0.447}{D(1)}$$

In similar manner the sum of the next series becomes

$$-2.59 \times \frac{1.38}{3} \times 1.473\epsilon^{-0.09\omega t} = \frac{[\sin(2\theta - 86°54') - 0.473\sin(-86°54')]}{D(1)} = \frac{-1.757\epsilon^{-0.09\omega t}\sin(2\omega t + 201°6') - 0.830\epsilon^{-0.09\omega t}}{D(1)}$$

For the third sum

$$n = 2.991 \qquad b = 0.473 \qquad \alpha = 129°42'$$

$$\text{sum} = \frac{-2.59 \times \frac{0.687}{3} \times 1.473\epsilon^{-0.103\omega t}[\sin(2.991\theta + 129°42') - 0.473\sin(0.991\theta - 129°42')]}{D(1)}$$

For the fourth sum

$$n = 1.009 \qquad b = 0.473 \qquad \alpha = 55°16'$$

$$\text{sum} = \frac{-2.59 \times \frac{1.43}{3} \times 1.473\epsilon^{-0.103\omega t}[\sin(1.009\theta + 55°16') - 0.473\sin(-0.991\theta + 55°16')]}{D(1)}$$

$$\text{Third sum} = \frac{[-0.875\sin(2.991\omega t + 18°47')]\epsilon^{-0.103\omega t}}{D(1)} + \frac{[0.413\sin(0.991\omega t + 90°47')]\epsilon^{-0.103\omega t}}{D(1)}$$

$$\text{Fourth sum} = \frac{[-1.82 \sin (1.009\omega t + 22°11')]\epsilon^{-0.103\omega t}}{D(1)} - \frac{[0.861 \sin (0.991\omega t + 265°49')]\epsilon^{-0.103\omega t}}{D(1)}$$

$$0.413 \angle 90°47' - 0.861 \angle 265°49' = 1.271 \angle 87°26'$$

Therefore

$$\text{Third + fourth sums} = \frac{[-0.875 \sin (2.991\omega t + 18°47') - 1.82 \sin (1.009\omega t + 22°11')}{D(1)} + \frac{1.271 \sin (0.991\omega t + 87°26')]\epsilon^{-0.103\omega t}}{D(1)}$$

To these series must be added the 3 terms obtained from the original equations and the total field current becomes

$$I_{fd} = 1 + 1.84\epsilon^{-0.09\omega t} + 1.84\epsilon^{-0.103\omega t} \sin (0.991\omega t + 269°15') - \frac{0.946 \sin (2\omega t + 201°6') + 0.447}{1.224 - 0.946 \cos (2\omega t + 288°)} + \frac{[1.757 \sin (2\omega t + 201°6') + 0.830]\epsilon^{-0.09\omega t}}{1.224 - 0.946 \cos (2\omega t + 288°)} - \frac{[(0.875 \sin (2.991\omega t + 18°47') + 1.82 \sin (1.009\omega t + 22°11')]\epsilon^{-0.103\omega t}}{1.224 - 0.946 \cos (2\omega t + 288°)} + \frac{[1.271 \sin (0.991\omega t + 87°26')]\epsilon^{-0.103\omega t}}{1.224 - 0.946 \cos (2\omega t + 288°)}$$

Figure 1 is an oscillogram of a line-to-ground fault on a small wound-rotor induction motor, the rotor of which was excited by direct current. The calculated curve of armature current is shown as figure 2*a*, the calculated curve of field current is figure 2*b*.

But for a line-to-line fault

$$_1i_b = -j\,1.732\ {}_1i_{a1} = 1.732\ {}_1i_{a1}\ \angle 270°$$

$$_1i_b = 0.494 \sin (\omega t + 338°23') + 1.426\epsilon^{-0.123\omega t} \sin (\omega t + 338°23') + 0.707\epsilon^{0.101\omega t} \sin (1.99\omega t + 158°35') + 1.210\epsilon^{-0.101\omega t} \sin (0.009\,\omega t + 158°\,26')$$

The angle $\theta_0 = 156$ degrees was reckoned on the basis of current in phase $a$ and as the short circuit has been assumed to occur in phases $b$ and $c$ it is necessary to convert $\theta_0$ over to phase $b$ in order to obtain the correct series for $i_b$. Since $i_b$ lags $i_{a1}$ by 90 degrees, it is necessary to subtract 90 degrees from $\theta_0$ to get the correct value to use for $i_b$.

$$\text{correct } \theta_0 = 156° - 90° = 66°$$

Now in a similar manner as was done in the line-to-ground case the summation of each series is found. Thus for the first term

$$0.494 \sin (\omega t + 338°23') = 0.494 \sin [(\omega t + 66°) + 272°23']$$

$$\text{sum} = 0.494 \frac{\sin[(\omega t+66°)+272°23'] - 0.575 \sin [-(\omega t+66°)+272°23']}{1.342 - 1.170 \cos (2\omega t + 132°)} = 0.494 \frac{0.420 \sin [(\omega t+66°)-80°59']}{1.342-1.170 \cos (2\omega t+132°)} = \frac{0.208 \sin (\omega t+345°1')}{1.342-1.170 \cos (2\omega t+132°)}$$

and the total short-circuit current in phase $b$ becomes

$$i_b = \frac{0.208 \sin (\omega t + 345°1') + 0.599\epsilon^{-0.123\omega t} \sin (\omega t + 345°1')}{1.342 - 1.170 \cos (2\omega t + 132°)} + \frac{0.064\epsilon^{-0.101\omega t} \sin (1.991\omega t + 248°22')}{1.342 - 1.170 \cos (2\omega t + 132°)} + \frac{0.798\epsilon^{-0.101\omega t} \sin (0.009\omega t + 161°1')}{1.342 - 1.170 \cos (2\omega t + 132°)}$$

## Appendix D

LINE-TO-LINE SHORT CIRCUIT

$$x_2 = \sqrt{x_d' x_q'} \qquad (4a)$$

$$= \sqrt{2.8 \times 0.21} = 0.75$$

$$x_{qT}' = 2.80 + 0.75 = 3.55$$

$$x_{dT}' = 0.21 + 0.75 = 0.96$$

$$b = \frac{3.55 - 0.96}{3.55 + 0.96} = \frac{2.59}{4.51} = 0.575$$

$$R = R_1 + R_2 = 2 \times 0.073 = 0.146$$

The constants for use in equations 10 are

| | | | |
|---|---|---|---|
| $R_{fd}$ | = 1.0 | $x_{dT} = x_{qT}$ | = 3.55 |
| $X_{afd}$ | = 1.0 | $X_{fad}$ | = 81.7 |
| $R$ | = 0.146 | $X_{ffd}$ | = 31.5 |

The voltage shown on the oscillogram is that of phase $b$ and since the equations require the angle between the direct axis and the axis of phase $a$

$$\theta_0 = (36° + 120°) = 156°$$

The solution obtained in a manner similar to line-to-ground case is

$$I_{fd} = 1.0 + 2.88\epsilon^{-0.123\omega t} + 2.884\epsilon^{-0.101\omega t} \sin (0.991\omega t + 271°26')$$

$$_1i_{a1} = 0.285 \sin (\omega t + 68°23') + 0.824\epsilon^{-0.123\omega t} \sin (\omega t + 68°23') + 0.414\epsilon^{-0.101\omega t} \sin (1.991\omega t + 248°35') + 0.699\epsilon^{-0.101\omega t} \sin (0.009\omega t + 248°26')$$

Care must be taken in calculating the value of $i_d$.

$$i_d = \frac{2}{3} [i_a \cos \theta + i_b \cos (\theta - 120°) + i_c \cos (\theta + 120°)]$$

$$i_a = 0 \quad \text{and} \quad i_c = -i_b$$

$$\cos (\theta - 120°) = \cos (\omega t + \theta_0 - 120°)$$

where the $\theta_0$ here refers to the current in phase $a$, but the $\theta_0$ in the series must be the one with reference to phase $b$.

$$(\omega t + \theta_0 - 120°) = (\omega t + 156° - 120°) = (\omega t + 66° - 30°) = (\omega t + \theta_0 - 30°) = (\theta - 30°)$$

In order to use the value of $\theta_0 = 66$ degrees, the equation for $i_d$ becomes

$$i_d = \frac{2}{3} [i_b \cos (\theta - 30°) - i_b \cos (\theta + 210°)]$$

For the first term of $_1i_b$

$$_1i_d = \frac{2}{3} \times 0.494[\sin(\theta-87°37')\cos(\theta-30°) - \sin(\theta-87°37')\cos(\theta+210°)]$$

$$= 2 \times \frac{0.494}{3} \times \frac{\sqrt{3}}{2} [\sin (2\theta - 87°37') - 1]$$

As was seen in the case of a line-to-ground circuit, only the part containing $(\sin 2\theta)$ goes into making up the series.

Where

$$D(2) = 1.342 - 1.170 \cos (2\omega t + 132°)$$

in a similar manner the sum of the first term's series for the field current is,

$$\text{sum} = -\frac{\frac{0.494}{3}\times\sqrt{3}\times 2.59\times 1.575[\sin(2\theta-87°37')-0.575\sin(-87°37')]}{D(2)}$$

$$= -\frac{1.17\sin(2\omega t+44°23')-0.681}{D(2)}$$

And likewise in a manner simi ar to the line-to-ground case, adding on the part found from the 3-phase solution, the total expression for field current is found.

$$I_{fa} = 1.0 + 2.88\epsilon^{-0.123\omega t} + 2.884\epsilon^{-0.101\omega t}\sin(0.991\omega t + 271°26') -$$

$$\frac{1.17\sin(2\omega t+44°23')+0.681}{1.342-1.170\cos(2\omega t+132°)} +$$

$$\frac{[3.37\sin(2\omega t+44°23')+1.96]\epsilon^{-0.123\omega t}}{1.342-1.170\cos(2\omega t+132°)} -$$

$$\frac{[1.68\sin(2.991\omega t+224°35')+2.87\sin(1.009\omega t+224°26')]\epsilon^{-0.101\omega t}}{1.342-1.170\cos(2\omega t+132°)} +$$

$$\frac{[2.657\sin(0.991\omega t+89°25')]\epsilon^{-0.101\omega t}}{1.342-1.170\cos(2\omega t+132°)}$$

An oscillogram of a line-to-line fault on this same machine is shown in figure 3. The calculated values of armature and field currents are shown in figures 4*a* and 4*b*, respectively.

## Appendix E

### Line-to-Ground Short Circuit With Reactance in Armature

It was shown in appendix *A* that if there is any external reactance in the armature circuit, it must be added to $x_d$, $x_2$, and $x_0$

For an external impedance of 0.96 units the values of $x_{qT}'$ become

$$x_{qT}' = 2.80 + 0.34 + 0.89 + 3(0.96) = 4.03 + 2.88 = 6.91$$
$$x_{dT}' = 0.21 + 0.34 + 0.89 + 3(0.96) = 1.44 + 2.88 = 4.32$$

The ratio $b$ now becomes

$$b = \frac{6.91-4.32}{6.91+4.32} = \frac{2.59}{11.23} = 0.231$$

The resistance of the added reactance was 0.061 units but 3 times this resistance must be added in the same manner as 3 times the reactance was used.

$$R = 0.22 + 3(0.061) = 0.22 + 0.18 = 0.40$$

The constants for use in the equations are then

$R_{fa} = 1.0$ $\quad x_{dT} = x_{qT} = 6.91$
$X_{afa} = 1.0$ $\quad X_{faa} = 81.7$
$R = 0.40$ $\quad X_{ffa} = 31.5$ $\quad \theta_0 = 5°$

The solution obtained is

$$i_a = 0.432\sin(\omega t - 81°41') + 0.261\epsilon^{-0.051\omega t}\sin(\omega t - 81°41') +$$
$$0.129\epsilon^{-0.075\omega t}\sin(1.99\omega t + 102°25') +$$
$$0.564\epsilon^{-0.075\omega t}\sin(0.001\omega t + 97°21')$$

$$I_{fa} = 1.0 + 0.600\epsilon^{-0.051\omega t} + 0.600\epsilon^{-0.075\omega t}\sin(0.999\omega t + 268°37')$$

Using the value of $b$ as found above to calculate the additional harmonics, the complete solution becomes

$$i_a = \frac{0.333\sin(\omega t+280°18')+0.201\epsilon^{-0.051\omega t}\sin(\omega t+280°18')}{1.053-0.462\cos(2\omega t+10°)} +$$

$$\frac{0.022\epsilon^{-0.075\omega t}\sin(1.999\omega t+180°)}{1.053-0.462\cos(2\omega t+10°)} +$$

$$\frac{0.525\epsilon^{-0.075\omega t}\sin(0.001\omega t+98°)}{1.053-0.462\cos(2\omega t+10°)}$$

$$I_{fa} = 1 + 0.60\epsilon^{-0.051\omega t} + 0.60\epsilon^{-0.075\omega t}\sin(0.999\omega t + 268°37') -$$

$$\frac{0.46\sin(2\omega t+283°19')+0.106}{1.053-0.462\cos(2\omega t+10°)} +$$

$$\frac{[0.277\sin(2\omega t+283°19')+0.064]\epsilon^{-0.051\omega t}}{1.053-0.462\cos(2\omega t+10°)} -$$

$$\frac{[0.137\sin(2.999\omega t+107°5')+0.60\sin(1.001\omega t+102°51')]\epsilon^{-0.075\omega t}}{1.053-0.462\cos(2\omega t+10°)} +$$

$$\frac{[0.170\sin(0.999\omega t+89°24')]\epsilon^{-0.075\omega t}}{1.053-0.462\cos(2\omega t+10°)}$$

Figure 5 is an oscillogram of a line-to-ground fault with an external impedance in the armature circuit. Figures 6*a* and 6*b* show the calculated curves of armature and field current.

## Appendix F

### Notation

In general the symbolic notation used in this paper is the same as was used in the previous paper by the authors.

In this paper there is added, however, a sequence and harmonic notation. It seemed advisable to maintain the sequence notation usually used. A subscript letter after a current designates the phase, a number after that designates the sequence. If there is no number after the letter it designates the total current in that phase.

The harmonic notation is quite similar to the sequence notation except that the subscript is placed before the current. The number designates the frequency of the harmonic and if no number is used, it designates the total current including all of the harmonics.

# Single-Phase Induction-Motor Performance

By A. F. PUCHSTEIN
MEMBER AIEE

T. C. LLOYD
ASSOCIATE AIEE

A COMMON procedure in the design of single-phase induction motors involves the determination of a stator winding to yield a desired maximum torque, followed by a check on motor performance. Yet in spite of the importance of the maximum torque value, little can be found in the technical literature concerning methods of predicting its magnitude, outside of those wherein the slip at which maximum torque occurs is substituted in the motor equations and the resulting maximum torque determined.[1] Inspection and trial from motor equations or the circle diagram are possible, but tedious, methods of approach.

A shorter and more direct method is given in this paper, offering the additional advantage of being largely in terms of the ratios of stator and rotor winding resistances to total leakage reactance. As such ratios are independent of the number of conductors used in the winding, analyses based on their use enable the designer to predict the winding necessary to yield a prescribed pull-out torque.

The equation for maximum torque will be derived here and its application and accuracy indicated.

With the winding fixed and the machine constants determined, it is frequently necessary to make a number of checks on the motor performance before it is constructed. Usually these checks involve only the calculation of no-load current and losses. Yet it is sometimes necessary to have performance curves (or several points thereon) while the machine is still in the design stage. Various analyses have been developed whereby the performance can be calculated from the machine constants. These analyses, whether based on the double-revolving-field theory, or the cross-field theory, take the form of circle or vector diagrams, equivalent networks, or analytical solutions. In any case they suffer the disadvantage of requiring tedious calculations, although improvements in simplifying the processes have been made by Branson, West,[6] Veinott[1] and others, with their tabulated procedures.

A process will be shown here which will enable the performance to be predicted readily, without complicated equations and with a precision greater than that of the resistance and reactance calculations. It is believed that a distinct need exists for this type of information.

It is possible to modify the cross-field equations for motor performance obtaining them in terms of ratios of machine constants. By assuming a series of values, the equations can be solved, the results plotted and hence made available for the analysis of any single-phase induction motor whose ratios of constants fall within the range prepared. Then for any speed, the primary current, power factor, watts input, output and efficiency, as well as less important values of counter electromotive force, rotor currents in each axis, and the rotor copper losses, can all be calculated by a comparatively simple process. Two methods of utilizing these curves will be shown, the first, being slightly more involved, requires one complex algebra calculation and is theoretically accurate except for the treatment of iron losses. (These cannot be covered with mathematical accuracy anyway.) The second method is shorter and easier to apply but with less theoretical accuracy. Calculations contrasting the 2 methods with test results and with standard analyses indicate that the shorter method is accurate enough for most routine work.

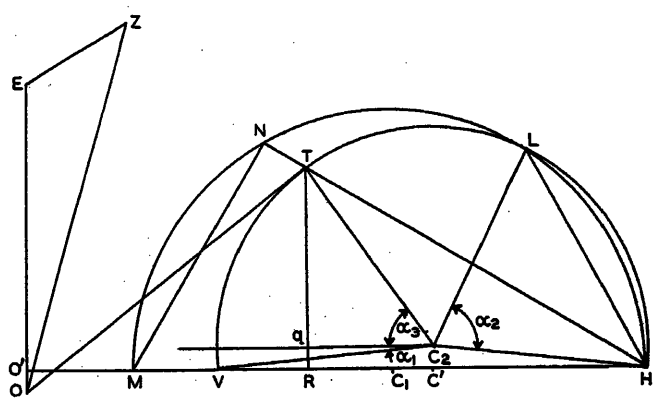

**Figure 1. Circle diagram of the single-phase induction motor, based on the cross-field theory**

Curve sheets will be shown here for 3 per cent slip only. Tabulated values suitable for preparing similar curves are given for other slips.

## Derivation of Maximum Torque Equation

The Branson[2] application of the La Tour type of circle diagram is represented in figure 1. On this diagram it can be shown that the maximum input to the rotor occurs when the point $T$ bisects the arc $VL$, the rotor input being

$$(OE) \times (TR)$$

$(OE)$ represents the voltage $E_c$, less than the applied voltage by the stator-winding resistance drop.

The maximum rotor input is not exactly the point at which the maximum torque occurs, but the difference is negligible in the single-phase induction motor and the equations will be derived on such an assumption.

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted December 9, 1936; released for publication July 29, 1937.

A. F. PUCHSTEIN is chief engineer and T. C. LLOYD is development engineer with Robbins & Myers, Inc., Springfield, Ohio.

1. For all numbered references, see list at end of paper.

To derive an expression for $TR$:

$$TR = C_2H \sin \alpha_3 + 0.5\ MV \frac{r_2}{X} \tag{1}$$

Let

$$\frac{r_2}{X} = p$$

The center $C_2$ is above the base by the distance $0.5\ MVr_2/X$

$$MV = O'M \frac{K_r}{2 - K_r} = \frac{E_c(1 - K_r)K_r}{X(2 - K_r)} \tag{2}$$

Then

$$0.5\ MV\frac{r_2}{X} = \frac{p}{2}\frac{E_c}{X}\frac{1 - K_r}{2 - K_r}K_r \tag{3}$$

$$C_2H = \sqrt{(C_2C')^2 + (C'\mathrm{H})^2} \tag{4}$$

$$VH = \frac{E_c}{X}\frac{K_r}{2 - K_r} \tag{5}$$

$$C_2H = \sqrt{\left(\frac{E_c}{2X}\frac{K_r}{2 - K_r}\right)^2 + \left(\frac{p}{2}\frac{E_c}{X}K_r\frac{1 - K_r}{2 - K_r}\right)^2} \tag{6}$$

$$\sin \alpha_3 = \frac{\cos\ \alpha_2}{2} = \sqrt{1 - \sin^2 \frac{\alpha_2}{2}} \tag{7}$$

$$\sin \frac{\alpha_2}{2} = \frac{p}{\sqrt{p^2 + 1}}\frac{2 - K_r}{\sqrt{1 + p^2(1 - K_r)^2}} \tag{8}$$

Then from equations 2, 6, 7, and 8:

$$TR = \frac{E_c}{X} \cdot \frac{K_r}{2(2 - K_r)} \times \left\{\sqrt{\left[1 + p^2(1 - K_r)^2\right]\left[1 - \frac{p^2(2 - K_r)^2}{(p^2 + 1)[1 + p^2(1 - K_r)^2]}\right]} + p(1 - K_r)\right\} \tag{9}$$

Define $tr$ such that $TR = (E_c/X)tr$. Values of $tr$ for various ratios of $r_2/X$ and values of $K_r$ are plotted in figure 2.

In order to apply the correction for the stator resistance drop it is necessary to determine the ratio of $E_c$ to the applied voltage $V$. To do this it is necessary to know the magnitude and position of the current $OT$. This depends obviously upon $O'R$ as well as $TR$ and an expression for $O'R$ will be obtained, applicable when the point $T$ bisects the arc $VL$. Under this condition:

$$O'R = \frac{E_c}{X} \cdot \left[1 - \frac{1}{2}\frac{K_r}{2 - K_r} - \frac{p}{2\sqrt{1 + p^2}}\right] \tag{10}$$

$O'O$ is the current component supplying the core losses; this can be neglected with little error, as it will make but slight modification in the magnitude of the current at the point of maximum torque, and still less modification in the ratio of voltages for which this value is to be used.

Define $o'r$ such that $O'R = (E_c/X)o'r$. Values are plotted in figure 2.

Let $r_1/X = p_1$. Then, accounting for the stator winding resistance drop:

$$V = E_c[1 + p_1(tr - jo'r)]$$

$$\left(\frac{E_c}{V}\right)^2 = \left(\frac{OE}{OZ}\right)^2 = \frac{1}{[(1 + p_1tr)^2 + (p_1o'r)^2]} \tag{11}$$

Let the expression in brackets be $Q'$. Then the final expression for maximum secondary input is

$$V^2\left(\frac{OE}{OZ}\right)^2\frac{tr}{X} = V^2\frac{tr}{Q'X} \tag{12}$$

As the last step it is necessary to fix the relationship between secondary input, secondary output, and torque.

$$\text{Secondary input} = \text{output} + F + Fe\ (C) + \text{Secondary } Cu\ (M) + \text{Secondary } Cu\ (C) \tag{13}$$

Where $(C)$ and $(M)$ represent cross and main axes, respectively.

Let

$$a = \frac{\text{Total secondary copper losses}}{\text{Output} + F + Fe\ (C)} \tag{14}$$

Then

$$\text{Output} = \frac{\text{Secondary input}}{(1 + a)} - [F + Fe\ (C)] \tag{15}$$

It has been shown by Veinott[3] that the ratio $a$ used above is equal to

$$\frac{1 - S^2}{S^2} + \frac{2(r_2/X_0)^2}{[(1 - S^2) - (r_2/X_0)^2]S^2}$$

This can also be written:

$$\frac{1 - S^2}{S^2} + \frac{2[p(1 - K_r)]^2}{[(1 - S^2) - p^2(1 - K_r)^2]S^2} = a$$

Where $S$ is the ratio of actual revolutions per minute to synchronous revolutions per minute. A value for $S$ at the point of maximum torque, as a function of $r_2/X$ is plotted in figure 3. This is slightly modified from Vei-

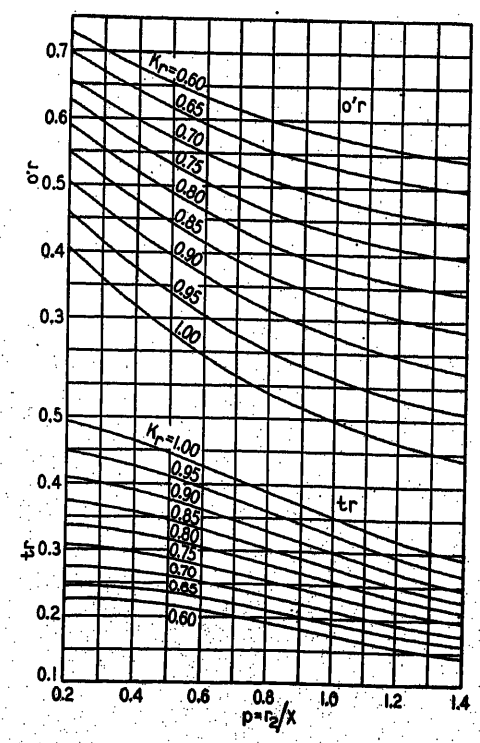

**Figure 2**

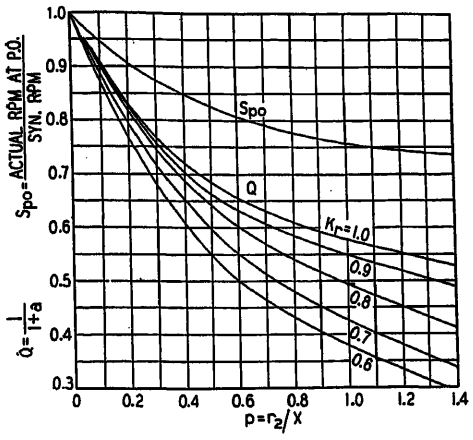

Figure 3

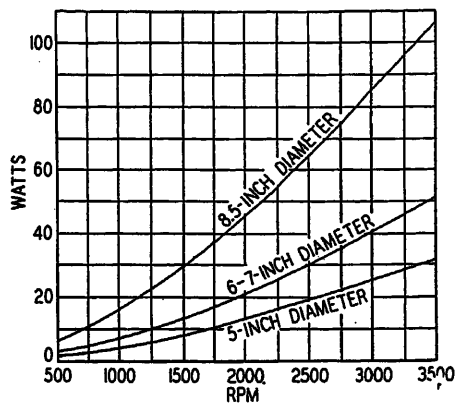

Figure 4. Friction and windage losses classified by outside diameter of stator. Sleeve bearings

nott's curve, which he obtained from the Branson circle diagram. Sumec[4] also gives a formula for this relationship but it applies to greatly restricted conditions.

Values of $1/(1+a)$ (denoted as $Q$) are shown in figure 3. As the final expression for maximum torque in ounce-feet:

$$\text{P. O. T.} = \frac{112.6}{\text{Syn. rpm}} \frac{1}{S_{po}} \left[ \frac{V^2}{X} tr \frac{Q}{Q'} - (F + Fe\,(C)) \right] \qquad (16)$$

The above equation is applicable when the windings are fixed and the constants are known. When the winding is to be determined in order to give a prescribed maximum torque, it should be such as to give the value of total leakage reactance calculated below. Then:

$$X = \frac{V^2\, tr\, Q/Q'}{\left[ \frac{\text{P. O. T.} \times \text{Syn. rpm} \times S_{po}}{112.6} + F + Fe\,(C) \right]} \qquad (17)$$

In using the above equation to design a single-phase motor of the required maximum torque, it is necessary to estimate the friction and windage losses as well as the iron loss of the cross axis. In making such estimates, data on similar machines are useful, but in the absence of such data table I is of value for iron-loss assumptions.

**Table I. Approximate Value of Cross-Axis Iron Losses**

| | | |
|---|---|---|
| 60 cycles: | Below 0.5 horsepower | $Fe\,(C) = 100 \times$ horsepower |
| | 0.5 to 1.5 horsepower | $Fe\,(C) = 50 \times$ horsepower |
| 25 cycles: | Below 0.5 horsepower | $Fe\,(C) = 75 \times$ horsepower |
| | 0.5 to 1.5 horsepower | $Fe\,(C) = 40 \times$ horsepower |

Probable friction and windage losses as a function of speed and outside stator diameter, are shown in figure 4.

It will be noted that $S_{po}$, $tr$, $Q$, and $Q'$ are functions of $r_1/X$, $r_2/X$, and $K_r$, each of which is independent of the actual number of conductors used in the stator winding as long as the saturation factor remains the same. A higher saturation factor reduces $K_r$.

Then since the total leakage reactance $X$ can be calculated from equation 17 in order for the motor to yield the designed pull-out torque, the number of series conductors necessary are:

$$C = \sqrt{\frac{X \cdot 10^8}{2\pi f P_L}} \qquad (18)$$

where $P_L$ = the equivalent permeance of the leakage flux paths (slot, zig-zag and end connection) corrected for winding pitch and distribution. Methods for determining it are well known, but a recent collection of data combining the work of various investigators has been prepared by the present writers,[5] along with processes for calculating $r_1/X$, $r_2/X$ and $K_r$ from machine dimensions.

The development given above involves no approximations aside from (1) those inherent in this type[2] of the circle diagram, (2) the neglect of iron-loss component in locating the position of the stator current, and (3) the slight error in the assumptions from which the speed

**Table II. Contrasted Test and Calculated Values**

Pull-out torque in ounce-feet

| Motor | P.O.T. Test | P.O.T. Calculated |
|---|---|---|
| 3/4-horsepower 4-pole 60-cycle | 107.00 | 104.0 |
| 1/4-horsepower 4-pole 50-cycle | 43.50 | 44.7 |
| 1/4-horsepower 4-pole 60-cycle | 37.75 | 36.8 |
| 1/4-horsepower 4-pole 60-cycle | 37.2 | 35.4 |
| 1/6-horsepower 2-pole 25-cycle | 30.0 | 32.0 |
| 1/10-horsepower 4-pole 40-cycle | 25.5 | 25.9 |
| 1/8-horsepower 2-pole 25-cycle | 23.0 | 23.0 |
| 1/6-horsepower 4-pole 60-cycle | 20.5 | 19.2 |

relationship was obtained.[3] That these errors are not serious can be seen from the contrasted results given in table II. Values were obtained from routine tests and were subject to uncorrected temperature effects and slight errors in constants.

As seen, the test and calculated results agree well within commercial requirements, particularly if $X$ can be calculated to sufficient precision.

An example of calculation is given in appendix I.

## Basis for Performance Calculations: Cross Field Theory

No attempt will be made to give the derivation of the cross-field theory on which the analysis is based, but since some differences exist between the work of different writers it will be necessary to identify the view-point taken.

The reader is referred to a paper by H. R. West,[6] in which he shows 3 fundamental equations for primary and

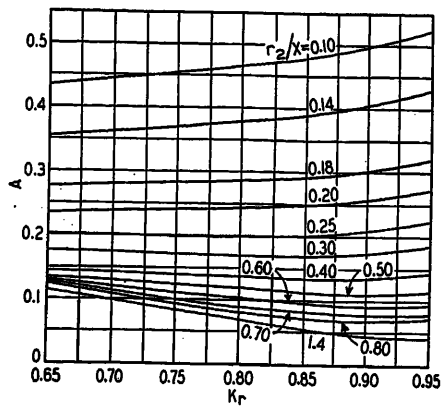

**Figure 5. Current constants for performance**

secondary voltage relationships in the single-phase motor. These are based on the assumptions:

1. Sine-wave distributions of magnetomotive force, and uniform air-gap permeances.

2. Angle of hysteretic lag between flux and magnetomotive force is neglected. (An approximate method of overcoming the small error caused by this assumption will be shown.)

3. The rotor conductors, in generating a speed electromotive force, are considered to cut not only the mutual flux but the rotor leakage flux as well. This assumption follows Arnold as against that of Steinmetz.[3] The evidence available indicates that the former basis is the more accurate, as signified by West.

4. The leakage reactance of stator and rotor will be assumed to be equal when in equivalent terms. The errors due to this are in general negligible.

## Equations

The determination of main and cross-axis rotor currents, as well as the stator current, is always complicated because the necessary simultaneous equations are three in number, and contain constants and variables as complex numbers. As a practical method of attack the local primary drop is neglected and a solution for the rotor values, which depend upon the counter electromotive force, is obtained. This also fixes the primary current, and the stator drop correction is applied later in a manner to be shown.

The 3 equations as given by West (several symbols changed) are:

$$V = I_1 r_1 + jI_1 x_1 + jX_m(I_1 - I_y) \tag{19}$$

$$0 = -jX_m(I_1 - I_y) - S(X_m + x_2)I_x + I_y(r_2 + jx_2) \tag{20}$$

$$0 = j(X_m + x_2)I_x - SX_m(I_1 - I_y) + Sx_2 I_y + r_2 I_x \tag{21}$$

It follows then that:

$I_1 - I_y = I_\phi$

$jI_\phi X_m$ = the counter electromotive force, $E$

Solving equations 20 and 21 for the 2 rotor currents:
Main axis,

$$I_y = E\frac{r_2 + jX_0(1 - S^2)}{r_2^2 - x_2(1 - S^2)X_0 + j(r_2 X_0 + r_2 x_2)} \tag{22}$$

Cross axis,

$$I_x = E\frac{-jr_2 S}{r_2^2 - x_2(1 - S^2)X_0 + j(r_2 X_0 + r_2 x_2)} \tag{23}$$

If the effect of the cross-axis core loss, which is considered as a rotor load (equal to slightly less than half of the total core loss) is taken into account, these equations would become (based on Arnold[8]):

$$I_y = E\frac{[(1 - S^2)(Z_0 + Z_2) + r_2 S^2]}{(Z_0 + Z_2)(Z_2 - jS^2 x_2) + jr_2 x_2 S^2} \tag{22a}$$

$$I_x = E\frac{-jr_2 S}{(Z_0 + Z_2)(Z_2 - jS^2 x_2) + jr_2 x_2 S^2} \tag{23a}$$

Where

$Z_2 = r_2 + jx_2$

$$Z_0 = \frac{1}{\frac{1}{r_f} + \frac{1}{jX_m}}$$

That is, the cross-axis core losses take place in an equivalent resistance, $r_f$; magnetizing reactance and core-loss resistance being represented by a series impedance $Z_0$. The use of these latter equations involving the additional variable $r_f$ would too greatly complicate the set of curves given here and will be neglected. Then $Z_0$ becomes equal to $-jX_m$.

Regardless of the magnitudes of the various constants in these equations, the values of $I_y$ and $I_x$ can always be obtained as functions of $E/X$ for all possible combinations of motor constants. Once such data are plotted they can then be used for practically all designs.

**Table III. Contrasted Calculated and Test Results**

Motor used as example in appendix

| Item | Method I | Method II | Test |
|---|---|---|---|
| Slip | 0.03 | 0.03 | |
| $I_1$ | 3.16 | 3.03 | 3.25 |
| Power factor | 0.595 | 0.619 | 0.585 |
| Input | 207.2 | 205.2 | 209.0 |
| $E$ | 90.5 | 91.0 | |
| $I_y$ | 2.04 | 2.045 | |
| $I_x$ | 1.145 | 1.15 | |
| Output | 0.158 horsepower | 0.159 | 0.1585 |
| Efficiency | 0.566 | 0.578 | 0.565 |
| Revolutions per minute | 1,164 | 1,164 | 1,150 |

## Determination of Curve Data

By substituting the values $r_2 = pX$ and $X_0 = X/(1 - K_r)$ in equations 22 and 23, they become:

$$I_y = \frac{E}{X}\left[\frac{p + j\frac{1 - S^2}{1 - K_r}}{p^2 - \frac{1 - S^2}{2(1 - K_r)} + j\left(\frac{p}{2} + \frac{p}{1 - K_r}\right)}\right] = \frac{E}{X}(A - jB) \tag{24}$$

$$I_x = \frac{E}{X}\left[\frac{-jpS}{p^2 - \frac{1 - S^2}{2(1 - K_r)} + j\left(\frac{p}{2} + \frac{p}{1 - K_r}\right)}\right] = \frac{E}{X}G \tag{25}$$

The values of the "current constants" $A$, $B$, and $G$, are functions of $r_2/X$, $K_r$, and speed. For any value of speed, curves can be drawn as shown in figures 5 and 6. These curves were prepared by assuming values of $p$ and $K_r$ for various slips and plotting the resultant current constants.

## Calculation of Performance, First Method

The fundamental equations neglect the effect of any iron loss in the cross axis. This will be considered here by adding an iron-loss current component to the in-phase part of the stator current.

**Table IV. Calculation Methods Contrasted**

1/4 horsepower, 4-pole, 60-cycle, 110-volts

| | Double Revolving Field | Cross Field Theory | | | |
|---|---|---|---|---|---|
| Item | Equivalent Circuit | Curves* of Method II | Modified[10] Arnold Method | Equivalent Circuit | Branson's Circle[2] Diagram |
| Speed | 1,700 | 1,700 | 1,700 | 1,700 | 1,700 |
| $I_1$ | 3.94 | 3.65 | 3.825 | 3.83 | 4.05 |
| Power factor | 0.734 | 0.762 | 0.737 | 0.722 | 0.745 |
| Input | 318.0 | 306.7 | 310.0 | 305.0 | 320 |
| Output | 197.0 | 203.3 | 199.0 | 203.2 | 198 |
| Efficiency | 0.620 | 0.66 | 0.642 | 0.665 | 0.630 |
| Losses | 121 | 103.4 | 111 | 101.8 | 122 |
| Synchronous watts | 208.4 | 215 | 211 | 215 | 210 |

* $A$, $B$, and $G$ were read for this speed from curves plotted against slip, rather than the set of curves given here, for which this slip is not included.

$$\text{In-phase current} = \frac{E}{X}A + \frac{Fe}{E}$$

$$= \frac{E}{X}(A') \qquad (26)$$

where

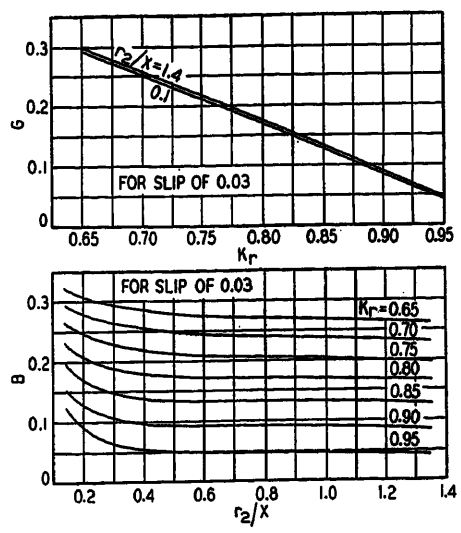
$$A' = A + \frac{FeX}{E^2}$$

Similarly the magnetizing current should be added to the out-of-phase component, then:

$$\text{Out-of-phase current} = \frac{E}{X}(B + 1 - K_r) = \frac{E}{X}U$$

Then the primary current is

$$\frac{E}{X}(A' - jU) = I_1 \qquad (27)$$



$$\text{Stator impedance} = r_1 + jx_1 = X(p_1 + j\,0.5)$$

$$\text{Applied voltage } V' = E[1 + (A' - jU)(p_1 + j\,0.5)]$$

As this voltage will likely be different from the applied, a ratio $V_{\text{rated}}$ to $V'$ is used to correct the assumed value of counter electromotive force.

With the counter electromotive force known, equations 24, 25, and 27 can be used to obtain the respective currents; input, output, efficiency, and power factor being figured in the usual manner as shown in appendix II. It will be seen that this process has been based simply upon the use of plotted solutions of rotor current.

**Figure 6. Current constants for performance**

## Second Method

In nearly all cases of normal design, it was found that little error is introduced in the vicinity of rated-load values, by assuming that the counter electromotive force differs from the applied voltage by the stator impedance drop considered algebraically. The in-phase component of stator current caused by considering the iron loss, will be neglected (as was done by West). Then:

$$I_1 Z_1 = E\sqrt{(A^2 + U^2)(p_1^2 + 0.25)} \qquad (28)$$

and

$$I_1 = \frac{V}{X}\frac{\sqrt{A^2 + U^2}}{[1 + \sqrt{(p_1^2 + 0.25)(A^2 + U^2)}]} \qquad (29)$$

Procedure: For the motor values of $r_2/X$ and $K_r$, at the slip for which performance is desired, $A$, $B$, and $G$ are calculated or read from the curves.

Calculate

$$U = B + 1 - K_r$$

$$C' = \sqrt{A^2 + U^2}$$

$$D = 1 + C'\sqrt{p_1^2 + 0.25}$$

Then

$$I_1 = \frac{V}{X}\frac{C'}{D}$$

$$\text{Power factor} = \frac{A}{C'} \text{ (See appendix III for correction based on iron loss)}$$

$$\text{Power input} = V \times I_1 \frac{A}{C'} \text{ (See appendix III for correction based on iron loss)}$$

$$\text{Counter electromotive force} = \frac{V}{D} = E$$

$$\text{Rotor input} = E^2\frac{A}{X}$$

$$I_y = \frac{E}{X}\sqrt{A^2 + B^2}$$

$$I_x = \frac{E}{X}G = I_1\frac{G}{C'}$$

Rotor losses $= r_2 (I_y^2 + I_x^2) + (F \& W) + Fe$

The iron loss $Fe$ can be treated differently and need not be included above.

Rotor output = Input − losses

By this process all significant performance items can be obtained at any speed for which curves are prepared. Simple arithmetical ratios are used, complex numbers being completely avoided.

Some comment should be made upon the treatment of core loss. Theoretically the cross-axis core loss (slightly less than half of the total) should appear as rotor load and be subtracted from the output. The subtraction of the total core loss (assumed constant at all loads), from the rotor output is not theoretically justified but produces fair results except in extreme cases. The reduction of core loss with load increase, due to a reduction in counter electromotive force, can be made in either method shown above, inasmuch as the counter electromotive force is known. Then since rotor currents and hence rotor input, were calculated with the assumption of no core loss, the addition of a reduced core loss to the stator input would appear to be a more consistent treatment than subtraction from the rotor output.

The neglect of this core loss results in calculated power factors that are inclined to be low, and more accurate results can be obtained by multiplying power factor, as calculated, by the ratio.

$$\frac{\text{Stator input with core loss}}{\text{Stator input without core loss}}$$

Illustrative examples and comparative results are given in appendix III.

## Conclusion

Calculations shown in tables III and IV are taken from design-sheet data in which later tests indicated a fair, but not exact, agreement between predicted motor constants and the values as measured. Under these conditions discrepancies between final test performance and predicted performance include the results of small design-sheet errors. Examples are available in which better agreement exists between predictions and tests but those included here were selected as about representative.

Designers are well aware that in dealing with small single-phase induction motors, predictions of performance cannot be made with the consistent accuracy possible, say, with large polyphase machines. This is true regardless of the theoretical accuracy of the method employed; the discrepancies arise largely from the nonconstant nature of the so-called constants. For this reason the accuracy of the calculation methods given here can best be investigated by comparison with other established analysis. Such data are given in table IV.

## Symbols and Factors

$V$ = applied voltage
$r_1$ = stator-winding resistance
$r_2$ = rotor resistance in stator terms
$x_1$ = stator-winding leakage reactance
$x_2$ = rotor leakage reactance in stator terms
$X_m$ = mutual or magnetizing reactance in stator terms
$X_0 = X_m + x_1$
= magnetizing reactance for air gap and primary leakage fluxes
$K_r = \dfrac{X_0 - X}{X_0}$
$X \cong x_1 + x_2$
$= x_1 + \sqrt{K_r}\, x_2$
$F$ = watts, friction and windage
$Fe$ = watts, core loss
$E_c = V - I_1 r_1$ (as vectors)
$E$ = counter electromotive force
$I_1$ = primary current
$I_y$ = rotor current of the main axis in stator terms
$I_x$ = cross-axis rotor current in stator terms
$S$ = per cent of synchronous speed

$S_{po}$ = per cent of synchronous speed at which maximum torque occurs

$p = r_2/X$

$p_1 = r_1/X$

$$tr = \frac{K_r}{2(2-K_r)} \times \left\{ \sqrt{\left[1 + p^2(1-K_r)^2\right]\left[1 - \frac{p^2(2-K_r)^2}{(p^2+1)[1+p^2(1-K_r)^2]}\right]} + p(1-K_r) \right\}$$

This is plotted in figure 2.

$$o'r = \left\{1 - 0.5 \cdot \frac{K_r}{2-K_r} - \frac{p}{2\sqrt{1+p^2}}\right\}$$

This is plotted in figure 2.

$$Q' = [(1 + p_1\, tr)^2 + (p_1\, o'r)^2]$$

$$Q = \frac{1}{1+a}$$

$$a = \frac{\text{Total secondary copper losses}}{\text{output} + F + Fe\,(C)}$$

This is plotted in figure 3.

$C$ = series conductors of the stator winding

$P_L$ = equivalent permeance of the leakage flux paths

$A$ = in-phase portion of the "current constant"

$$A - jB = \left\{ \frac{p + j\left(\frac{1-S^2}{1-K_r}\right)}{p^2 - \frac{1-S^2}{2(1-K_r)} + j\left(\frac{p}{2} + \frac{p}{1-K_r}\right)} \right\}$$

This is plotted in figures 5 and 6.

$$G = \left\{ \frac{-jpS}{p^2 - \frac{1-S^2}{2(1-K_r)} + j\left(\frac{p}{2} + \frac{p}{1-K_r}\right)} \right\}$$

This is plotted in figure 6.

$$A' = A + \frac{Fe\,X}{E^2}$$

$$U = (B + 1 - K_r)$$

$$C' = \sqrt{A^2 + U^2}$$

$$D = 1 + C'\sqrt{p_1^2 + 0.25}$$

## Appendix

*I. Example of Maximum Torque Calculations.* Machine data are taken from the example given by Veinott[1] for a single-phase induction motor, 110 volts, 4 poles, 60 cycles.

$r_1 = 3.8$ $\quad r_2 = 4.65$ $\quad X = 8.3$ $\quad K_r = K_p^2 = 0.929$

$F + Fe\,(C) = 19$ watts

$r_1/X = p_1 = 0.458$ $\quad r_2/X = p = 0.56$

From curves:

$tr = 0.392$, $o'r = 0.342$, $Q = 0.65$, $S_{po} = 0.817$, $(1 + p_1\, tr)^2 = 1.387$ $\quad (p_1\, or)^2 = 0.0246$ $\quad Q' = 1.387 + 0.0246$ or 1.4116

**Table VII. Approximate Values of G**

| Slip = | 0.02 | 0.04 | 0.05 |
|---|---|---|---|
| $K_r$ = 0.95 | 0.049 | 0.049 | 0.047 |
| 0.90 | 0.093 | 0.091 | 0.090 |
| 0.85 | 0.135 | 0.131 | 0.130 |
| 0.80 | 0.175 | 0.171 | 0.168 |
| 0.75 | 0.215 | 0.210 | 0.205 |
| 0.70 | 0.250 | 0.245 | 0.240 |

$$\text{P. O. T.} = \frac{112.6}{1800 \times 0.817}\left[\frac{110^2 \times 0.392 \times 0.65}{8.3 \times 1.411} - 19\right]$$

= 18.6 ounce-feet. This result is the same as that of Veinott.

*II. Performance Calculations, First Method.* Single-phase induction motor, 1/6-horsepower, 110 volts, 6 poles, 60 cycles.

$r_1 = 3.95$ ohms $\quad X = 9.72$ ohms $\quad r_1/X = p_1 = 0.406$

$r_2 = 3.07$ ohms $\quad K_r = 0.862$ $\quad r_2/X = p = 0.315$

Friction and windage ($F$ and $W$) = 9 watts; iron loss ($Fe$) = 29.4 watts; from curves, for a slip of 0.03, $A = 0.170$, $B = 0.138$, $G = 0.123$

$B + 1 - K_r = U = 0.276$

$\sqrt{A^2 + B^2} = 0.219$

Assume a counter electromotive force of 100 volts.

$\frac{Fe\,X}{E^2} = 0.026$ $\quad A' = 0.196$

$V' = 100[1 + (0.196 - j\,0.276)(0.406 + j\,0.5)] = 121.78 - j\,1.68 = 121.8$

$\text{Correction} = \frac{110}{121.8}$ or 0.905

$I_1 = \frac{90.5}{9.72}(0.196 - j\,0.276) = 1.82 - j\,2.58$ or 3.16

$I_y = \frac{90.5}{9.72}\,0.219 = 2.04$ $\quad I_y^2 r_2 = 12.72$ watts

$I_x = \frac{90.5}{9.72}\,0.123 = 1.145$ $\quad I_x^2 r_2 = 4.02$ watts

$\text{Rotor input} = EI_y \cos\theta_2 = 90.5 \times 2.04 \times \frac{0.17}{0.219}$ or 143.5 watts.

Rotor output = 143.5 − rotor losses = 143.5 − (12.72 + 4.02 + 9.0)
= 117.8 watts or 0.158 horsepower

$\text{Core loss} = \frac{\text{counter electromotive force}}{\text{applied voltage}}\,(Fe)$

$= \frac{90.5}{110} \times 29.4$ or 24.3 watts.

Stator input = Rotor input + Core loss + Stator copper loss
= 143.5 + 24.3 + 39.4 or 207.2 watts.

$\text{Power factor} = \frac{207.2}{3.16 \times 110}$ or 0.595

Alternate method, neglecting small angle between applied volts and counter electromotive force

$\text{Power factor} = \frac{1.82}{3.16}$ or 0.575

$\text{Efficiency} = \frac{117.8}{207.2}$ or 0.566

*III. Performance Calculations, Second Method.* Same motor used in II with a slip of 0.03.

$A = 0.17 \qquad B = 0.138 \qquad G = 0.123 \qquad U = 0.276$

$$C' = \sqrt{A^2 + U^2} = 0.324$$

$$D = 1 + C'\sqrt{p_1^2 + 0.25} = 1.209$$

$$I_1 = \frac{V}{X}\frac{C'}{D} = 3.03$$

$$\text{Counter electromotive force} = \frac{V}{D} = 91.0$$

$$\text{Rotor input} = E^2\frac{A}{X} = 144.7 \text{ watts}$$

$$I_y = \frac{E}{X}\sqrt{A^2 + B^2} = 2.045 \qquad I_y^2 r_2 = 12.85 \text{ watts}$$

$$I_x = \frac{E}{X}G = 1.15 \qquad I_x^2 r_2 = 4.05 \text{ watts}$$

$$\begin{aligned}\text{Rotor output} &= \text{Input} - \text{rotor losses} \\ &= 144.7 - (12.85 + 4.05 + 9.0) \\ &= 118.8 \text{ watts or } 0.159 \text{ horsepower}\end{aligned}$$

Core loss, corrected as before = 24.3 watts

$$\begin{aligned}\text{Stator input} &= \text{Rotor input} + \text{Core loss} + \text{Stator copper loss} \\ &= 205.2 \text{ watts}\end{aligned}$$

$$\text{Efficiency} = \frac{118.8}{205.2} \text{ or } 0.578$$

$$\text{Power factor} = \frac{205.2}{3.03 \times 110} \text{ or } 0.619$$

Alternate calculation method for input and power factor:

$$\text{Input, neglecting core loss} = VI_1\frac{A}{C'} \text{ or } 175 \text{ watts}$$

Corrected by adding core loss = 199.3 watts

$$\text{Power factor, core loss neglected} = \frac{A}{C'} = 0.526$$

$$\text{Power factor corrected for core loss} = \frac{A}{C'}\frac{\text{Input with core loss}}{\text{Input without core loss}}$$

$$= 0.526\,\frac{199.3}{175} \text{ or } 0.60$$

# The Engineer's English

IN AN ARTICLE entitled "The Importance of English to an Engineer," appearing in *The Electric Journal* for February 1937, pages 81–2, W. W. Palmer challenged engineers to assume as an obligation to themselves and to society, in which they are playing a rôle of increasing importance, the aim of becoming fluent speakers, more convincing writers, to the end of becoming better salesmen of the ideas constantly being created by their inventive minds.

Mr. Palmer believes that the engineer's inability to express himself forcefully is not an inherent characteristic, but a product of the environment and tradition in which he has received his professional training; and to strengthen that contention he traces the various stages in the evolution of an engineer, showing the factors at each stage contributing to the inarticulateness of the technical man. Quoting from the article, ". . . there is no objection to an engineer being given a cultural education, but the old idea that he must learn to write and speak a couple of dead languages and study the lives, characteristics, and vaporing of poets and writers of all ages has been overstressed."

Continuing, the author execrates the manner in which the engineering graduate attempts to obtain employment: "The employment manager, knowing engineers, expects their written applications to be evasive on their weak points and exaggerated on what they consider their strong ones. The general attempt is to prove that they can fill any position. . . . . No specific and sound reasons are given as to why the writer's services will pay dividends. The writer does not intentionally evade, but he is simply incapable of properly presenting his case in writing. . . . . Few engineers sell their services. They are hired. The distinction is reflected in their salaries."

After the young engineer has been hired "lack of practical experience necessitates that at first he work among those whose educational advantages have been inferior to his own. From them he frequently acquires the use of profanity for emphasis and superlatives for impressiveness. Enunciation and precision are forgotten. This loss is reflected in his work."

"Years later we find this engineer writing important purchase specifications that will be misinterpreted; dictating letters in which the ideas to be conveyed are smothered beneath an avalanche of words. To him punctuation is a stenographic function. At this age the engineer's work has become so specialized that few in, or outside of, his group of associates are capable of correcting or criticizing. . . . He speaks a highly technical language that normally isolates him from general conversations. He becomes a lone thinker but at the same time he must be able to interpret the results of his thoughts to less technical thinkers, such as his executives."

"We like to feel that engineers have been, and always will be, true pioneers in the advance of civilization. On the other hand, we know that those who lead best are often misunderstood, inadequately appreciated, and poorly compensated. The blame is our own when we do not make ourselves understood."

# D-C Machine Stray-Load-Loss Tests

By VICTOR SIEGFRIED
ASSOCIATE AIEE

## Synopsis

Two test methods for the determination of stray load losses in d-c machines are described. Application of the loading-back principle permits measurements to a high degree of accuracy. A technique is developed for stabilizing no-load losses so that consistency of results is improved. Results of tests of several machines are presented, together with an analysis of the relation of loss to operating conditions of the machine.

IN THE MEASUREMENT of efficiency of d-c machinery, stray load loss is generally receiving insufficient consideration. Its omission from conventional efficiency tests has resulted principally from the difficulty experienced in measuring it accurately. Variability in performance of the commutator apparently is the factor which has caused failure to obtain consistent results in previous attempts to measure stray load loss.[1-5] Consequently the accurate determination of d-c machine losses and efficiency has lagged behind that of other types of machinery.

Methods of controlling the performance were devised and applied to d-c machines in the course of work on stray load loss of induction machines,[6] in which it was found possible to repeat conditions and measurements almost at will. The present investigation was undertaken to extend this experience and information to the testing of other machines, and to demonstrate the applicability of the loading-back type of test to d-c machines.

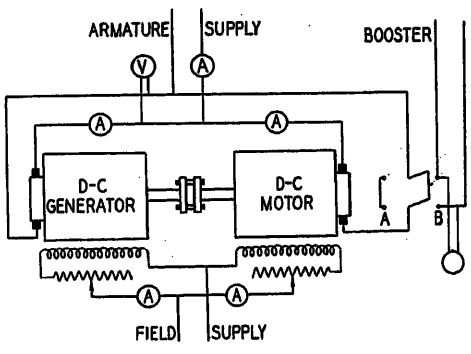

**Figure 1. Diagram of connections for load-back tests**

The load-back test is a familiar tool used extensively for loading machines and conducting heat runs. Two machines are direct-connected and operated from a common source with current circulating between them, one machine acting as a motor to drive the other as a generator. Slight adaptations which are necessary for applying it to the measurement of stray load loss are discussed. Two types of load-back test which are most practicable and easily performed commercially are described, together with the technique which should permit obtaining consistent results. The variation of stray load loss with some of the operating conditions is investigated, and curves are presented to show these effects graphically.

## Summary

This investigation of stray load loss in d-c machines outlines methods whereby that loss may be measured, and presents the results of application of some of those methods to several groups of machines as described in table I. Several definite conclusions may be drawn from this work:

1. Stray load loss is not a negligible factor in d-c machine performance and efficiency. It is in the order of magnitude of other losses and must receive due consideration.

2. Stray load loss can be measured, and should be measured in preference to the assignment of a value from an empirical formula.[4,5]

3. Stray load loss was found by test to range from 0.8 to 1.8 per cent of full-load input in several groups of machines.

4. Controlling factors of the amount of stray load loss are armature current, magnetic field strength, and machine speed.

5. The familiar load-back test can be adapted to the measurement of stray load losses in d-c machines. It can be made with the assurance of reasonably consistent results if proper technique be employed to eliminate variations in no-load losses during the test.

6. Two methods of loading-back appear to be the most practicable for commercial tests, from the standpoint of accuracy, convenience, and amount of equipment involved. The choice of test to be used will depend upon the equipment available to the tester.

7. The "electrical loss supply" method with a booster (Hutchinson method[7]) has the desirable feature of keeping armature currents nearly equal in both machines and of permitting loading of machines under the same conditions of excitation. It has the disadvantage of requiring an additional generator to serve as a booster. It involves input to the system from 2 electrical sources, thus doubling the chance for error in measurements.

8. The "electrical loss supply" (Kapp[7]) method has the simplest circuit available for the measurement of stray load loss. It can be performed with a minimum of equipment, although greater convenience may be achieved with 2 independent sources of voltage for armature and field circuits respectively.

9. Having only one source of supply for the losses, the Kapp method has the advantage of high accuracy and sensitivity.

10. Load-back methods usually require identical machines, but if one machine is available which has been calibrated previously for its stray load loss, any other machine of similar rating may be loaded-back upon it.

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted May 4, 1937; released for publication August 30, 1937.

VICTOR SIEGFRIED is assistant professor of electrical engineering at Worcester Polytechnic Institute, Worcester, Mass.

The author is indebted to Professor Theodore H. Morgan for his advice and encouragement and for the opportunity to do this work, and to the manufacturers who donated machines for the tests.

1. For all numbered references, see list at end of paper.

## Nature of Stray Load Loss

By definition, stray load loss is a residual loss that cannot be determined from "conventional performance" data taken at no load. It is the increase in loss that results from loading of the machine by increase in armature current. The flux distortion accompanying increases in armature current gives rise to this loss through far-reaching effects. The iron loss is changed; eddy currents occur in the conductors due to transverse fluxes and to tooth saturations; tooth-frequency losses are changed to some extent; and short-circuit loss in the coils undergoing commutation is changed. These effects are dependent in turn upon the amount of armature current; the frequency of flux pulsations and hence the speed of the machine; and upon the saturation of the iron at no load.

**Table I. Machines Tested for Stray Load Loss**

| Machines | Rating | Voltage | Current (Amperes) | Speed (RPM) | Stray Load Loss (Per Cent of Full-Load Input) |
|---|---|---|---|---|---|
| 1 and 2 | 15 hp | 230 | 55.6 | 1,750 | 1.2 |
| 3 and 4 | 10 hp | 110 | 79 | 1,700 | 1.6 |
| 5 and 6 | 10 hp | 220 | 38.2 | 1,750 | 0.95 |
| 7 | 10 hp | 230 | 38 | 1,750 | 0.85 |
| 8 and 9 | 7.5 kw | 160 | 47 | 1,800 | 1.8 |

Information as to the manner in which these factors influence the loss is helpful in devising test methods. It is desirable and usually necessary to include measurements of the loss at other than only normal operating speed, armature current, or excitation. This investigation therefore attempts to determine some of these relationships in order to bring out the significance of certain procedures required in some of the tests available.

## Load-Back Tests

The load-back test has long been used for loading machines in heat runs and to a certain extent for efficiency measurements. It was originated as early as 1886,[8] and several variations have been proposed since then. A brief discussion will serve to identify some of the methods and their salient features. More complete descriptions are to be found in the engineering literature.[7]

### Kapp Method

In their simplest form, load-back tests are made with rotors of 2 machines coupled or belted together. Both armatures are connected to a common source of power, the machines being loaded-back upon each other by means of current circulating between them. The loading is controlled by adjustment of the internal generated voltage of either or both machines, the one with the lower excitation becoming the motor. Assuming for purposes of this discussion that the field circuits are separately excited, the entire loss in this combination of machines is supplied electrically from the line, and includes the no-load losses of both machines plus the additional losses occasioned by the assumption of load. The machine acting as a motor thus supplies all of the losses through its circuit, and hence has the larger armature current. The difference between machine currents, however, decreases as the size of the units increases.

This method, attributed to Kapp and also called the "electrical loss supply" method uses the circuit shown in figure 1 when the switch in the motor circuit is in the *A* position. The total losses are determined from readings of the line ammeter, which indicates automatically the difference in machine currents. This test provides for measurements of high accuracy and considerable sensitivity to small changes in loss. Its principal disadvantage is that the 2 machines cannot be operated at the same magnetic saturation.

### Hutchinson Method

If a booster generator be placed in series with the armature of one machine, the loading-back of the system may be accomplished through adjustment of the booster voltage in such a way as to cause different voltages to exist at the terminals of the 2 machines. The connection for this is shown in figure 1 with the switch at *B*. Current thus will circulate without the necessity for adjustment of the internal generated voltage of either machine. The power input to the system from the booster will be approximately equal to the copper losses in the 2 machines. Mechanical losses will be supplied substantially as in the Kapp test, from the common voltage source. Thus the armature currents under load conditions will be nearly equal, and the field excitations will be exactly the same in both machines. Only one additional instrument is needed, a voltmeter indicating the booster voltage where it is impressed on the load-back system.

This type of test is known as the Hutchinson method. It operates the machines under quite desirable conditions, but does require an additional generator in the testing equipment. The total loss input from which stray load loss is calculated comes from 2 sources, however, which necessitates additional care in the reading of all instruments.

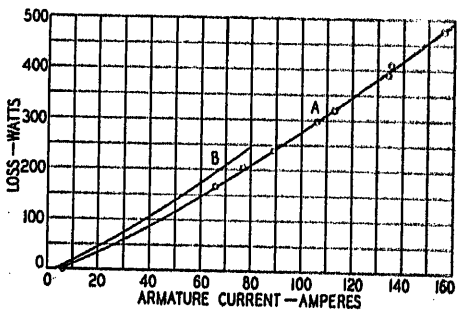

**Figure 2. Stray load loss of machines 1 and 2**

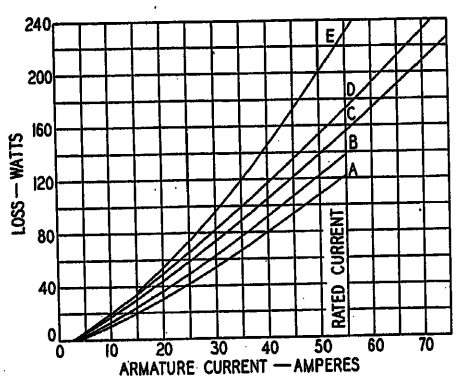
*A*—Loss as measured by load-back tests

*B*—Loss for one machine

Excitation normal

Speed—1,800 rpm

### Other Methods



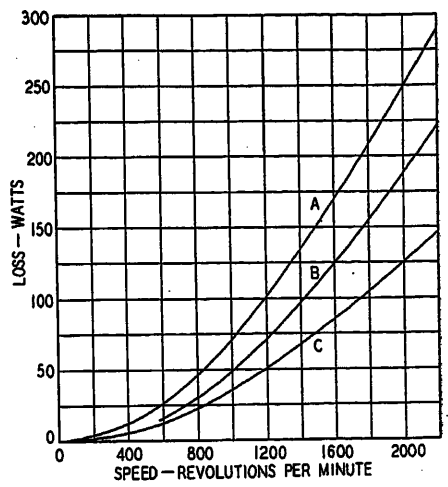
There are other types of load-back test which could be used, if the greater complication of circuits and possible loss of accuracy did not make them unsatisfactory for

commercial stray-load-loss measurements. The Blondel opposition method, in which an auxiliary motor connected to the set is used to supply the rotation losses and a booster to supply the electrical losses, does operate both machines under identical conditions. It is better suited to laboratory use than to commercial tests. Another method, called the "mechanical loss supply" method, uses the auxiliary motor coupled to the machines to supply all losses, the machines being operated independently of any common source. The adjustment of loading must be made entirely by manipulation of field current, thus making it undesirable as a test for stray load loss. The same objection applied to the Potier method, in which all the losses are supplied by a booster generator in series with both machines.

## Load-Back Test Procedure

In order to adapt the load-back test to the measurements of stray load loss, certain simplifications can be made in the usual test procedure employed. The requirements as to conditions to be maintained are different. Values of the loss are desired over the ordinary working range of armature current, speed, and excitation. It is therefore unnecessary to operate the machine with rated terminal voltage. Thus speed control may be had by variation of the armature voltage, and independently of field current adjustments. As loss in the field circuit is not included in the calculations for stray load loss, it is possible for it to be supplied from an independent source at constant voltage.

**Figure 3. Variation of stray load loss with excitation, machines 1 and 2**



Speed—1,800 rpm
Excitation:
*A*—129 per cent normal
*B*—114 per cent normal
*C*—Normal
*D*—86 per cent normal
*E*—28 per cent normal

The control of all losses during a load-back test is very important to the success of the test. Since the stray load loss results from the difference between total measured loss and the known losses, variation of any of these during a run may cause considerable error in the final result.

The most important item requiring control is the brush-friction loss. This loss ordinarily is quite erratic, and causes the no-load loss of which it is a part to be unstable. In these tests it is not necessary that no-load losses duplicate those for ordinary working conditions, but merely that they be held constant during measurements of other quantities. Control of this brush-friction loss may be had by stabilizing surface conditions of the commutator. This is done through a judicious application of paraffin to the commutator to form a thin lubricating film. Paraffin is applied in quantities only sufficient to reduce the friction loss and consequently the no-load loss to a minimum, as indicated by input to the machines for a particular speed and excitation. For short periods of time, the no-load loss will then remain practically constant, but will gradually increase as the film of paraffin wears off. Frequent checks of the no-load loss are quite essential to consistent results in all tests. Where curves of no-load losses with various field currents and speed will be necessary as in tests conducted according to the Kapp method, they will be useful only so long as the original conditions are repeated.

**Figure 4. Variation of stray load loss with speed, machines 1 and 2**

Excitation—Normal
Armature current:
*A*—70 amperes
*B*—55 amperes (rated)
*C*—40 amperes

The use of paraffin on the commutator is practically indispensable for stray load loss testing. It is doubtful whether this treatment should be recommended for general practice, however. As to the effect on brush-contact resistance, paraffining does not make it abnormally large. Apparently carbon particles become imbedded in the thin film and assist in maintaining good commutation.

Accurate determination of copper loss in the machines is also very important to the stray-load-loss test. Actual values of terminal-to-terminal drop must be measured instead of being calculated on the basis of assumed constant values of brush-contact drop. Care must be taken to include the drops in all parts of the machine circuits back to the junction where applied voltage is measured.

Proper specification of the magnetic saturation also is necessary, particularly where machines have compound field windings. Total ampere-turns determine the field strength; so it is better for purposes of this test to omit the series windings and retain only the shunt and commutating windings. More stable operation of machines is obtained as a result of this procedure. Brushes must be set carefully in the neutral position to eliminate undue loss in the commutated coils.

## Test of Machines

Measurements were made for the stray load loss of several sets of machines as described in table I. All machines are stock models of their type. Machines 3, 4, and 7 are of the same type as 5 and 6 except older and of different voltage ratings. Number 7 was loaded back on number 5. All machines were mounted on a solid base, carefully aligned and direct-connected through flexible couplings.

Electrical connections were made as shown in figure 1. A variable voltage supply was provided for the armatures, and a fixed voltage supply for the shunt fields. The booster, used in all tests except on machines 8 and 9, was a variable voltage machine of suitable capacity. Instruments were calibrated against primary standards. Speeds were measured by stroboscope where feasible, otherwise by tachometer, so that it was convenient to consider 1,800 rpm as the normal speed of all machines.

As a preliminary to the testing of each pair of machines, the brushes were set in the neutral position as found by running the machines successively under full load in opposite directions at the same speed. The brushes were worn in and the commutator was lubricated with paraffin until a stable value of no-load loss was reached. Curves of no-load loss were then taken for various speeds and excitations.

The sequence of operations in the Hutchinson test was first to warm the machines by running them under load. Then both were motored and a setting made so that currents were equal in both machines with excitation adjusted to a specified value. The value of the no-load loss was read, the switch in figure 1 thrown to the $B$ position, and the booster voltage increased in gradual steps to increase the loading, speed being maintained at a desired value by adjustment of the supply voltage. A final reading was then taken of the no-load loss and the machines were shut down quickly to obtain the terminal-to-terminal drop. On some sets of machines, other data were taken for loading the machines by the Kapp method, with the motor switch always in the $A$ position.

## Results of Tests

The data obtained in these tests were reduced to stray load loss by subtracting all of the known losses from the power input of the line, and of the booster when used. Curves shown in figures 2–4 are for the test of machines 1 and 2 by the booster (Hutchinson) method and are typical of results of tests on all machines. Figure 2 shows the loss under normal conditions of speed and excitation. Curve $A$ shows the experimental points, which give the loss for both machines acting together, plotted as a function of the arithmetical sum of armature currents. The curve $B$, for one machine by itself, is obtained by a graphical separation method.[9] Briefly, the first approximation of curve $B$ is found by plotting one-half of the ordinate of $A$ against half of its abscissa. Using the actual ratio of machine currents, this approximation is used to reconstruct a curve similar to $A$. One-fourth of the difference between the reconstruction and the experimental curve is used as a correction by which to find the true curve of $B$. Actually, in all of the tests performed the armature currents were sufficiently close in value, and such was the nature of the variation of the loss that very little correction was necessary.

The change of stray load loss with armature current, other conditions being constant, follows a smooth progression, with the loss increasing at a greater rate for larger currents. This is what might be expected, but it is interesting to note that it does not increase with the square of the current, as might first be supposed.

### Variation With Excitation

In figure 3 are shown curves for the loss of one machine alone with various field currents. These curves are similar to curve $B$ of figure 2, and are those derived from experimental points by graphical separation. From them, it is apparent that stray load loss increases as the excitation or magnetic saturation is reduced. This effect was observed to differing degrees in all machines tested. The explanation is probably that flux distortion has farther-reaching effects in producing stray load loss as the initial saturation of the iron is reduced. For small variations in excitation around normal conditions, the changes in loss seem to be nearly proportional. Curves $A$–$D$ show results typical of all machines.

This relationship makes it advisable to manipulate field currents, when required in the conduct of the stray-load-loss test by the Kapp method, in such a way that as the excitation of one machine is reduced to make it assume load as a motor, that of the other is increased in like proportion. In this way, the error introduced by changing the saturation as machines are loaded is minimized.

Attempts were made in tests of machines 1 and 2 to measure the loss for extremely low excitations, in the order of 25 per cent of normal field current. Under such conditions, however, one factor which affects the measurement becomes more apparent, and machines are operating so low on the saturation curve that an exact specification of the degree of excitation is not possible. The loss itself can be measured with the same accuracy as at normal conditions, but the initial total magnetization conditions are dependent not alone upon field ampere-turns but also upon the residual magnetism or hysteresis of the iron as a result of changing armature flux. Thus, for the same values of shunt field current, different curves will be obtained depending upon whether armature currents are being increased or decreased. This effect is present at all saturations to some extent, but becomes of smaller importance as the excitation approaches normal. It does contribute to the difficulty of manipulation in the tests, and may account for inconsistencies in results which have not been explainable heretofore. Curve $E$ in figure 3 shows the loss for approximately 30 per cent of normal excitation.

### Variation With Speed

The variation of stray load loss with speed is shown in figure 4 for several values of machine current, excitation being held constant for all cases. The loss is seen to in-

crease rapidly with speed. This is to be expected from the fact that the frequency at which the stray load losses occur is proportional to speed, and that the loss should therefore be a function of speed to some power between 1 and 2. For the curves shown in figure 4, the exponent is approximately 1.9. Other machines showed exponents from 1.2 to 1.6.

### Summary of Results

To sum up the results of the tests, values are given in table I of the stray load loss for each machine under normal conditions of load, excitation, and speed, expressed in per cent of input at full load. These figures show that stray load loss differs with the type of machine.

For some of the machines, tests for stray load losses were conducted by both the Kapp and Hutchinson methods. Good agreement was shown in the results, and final figures are given as an average value of the 2 tests. The methods are fundamentally the same, although by means of the booster it is possible to keep field currents constant at all times. In the Kapp test, manipulation of the field current is necessary to make the machines take load, with the result that the 2 machines will be operating under somewhat different saturation conditions. The error caused by this effect can be minimized by following the procedure suggested above. This offers no serious handicap to the measurement of stray load loss by this method and results will be well within any tolerance for accuracy in the final value of stray load loss.

Emphasis should be made here that it is not always necessary to have 2 identical machines for a load-back test if one machine has previously been subjected to a test for its stray load losses. The requirement of 2 identical machines is only necessary for the purpose of making proper division of the stray load loss between them.

# Central-Station Voltages for Lighting

OF THE POPULATION in the United States receiving central-station service, 98 per cent is now supplied at a nominal standard voltage of 115 or 120, according to an article by G. S. Merrill (A'08, M'12) head of the section of lighting economics of the incandescent lamp department, General Electric Company, Cleveland, Ohio, appearing in the August 1937 issue of the Edison Electric Institute *Bulletin*, pages 327–8. The trend has been slowly toward the adoption of the higher voltages. In 1923, 36.3 per cent of the population using central-station service obtained power at 110 volts, 40.9 per cent used 115 volts, and 19.4 per cent used 120 volts. In 1937 only 1.8 per cent of this population is supplied by 110-volt circuits, but 52.1 per cent of the users obtain power at 115 volts, and 46.0 per cent at 120 volts. From 1923 until 1933 the use of 115-volt service increased, but since 1933 its use has declined and 120-volt service has gained in favor at the expense of both of the other standard voltages. This trend is attributed to the increasing use of light, heat, and power on residential circuits and the use of 3-phase 4-wire 120/208-volt networks in commercial areas.

In the interest of good lighting service, public utility companies and lamp manufacturers in general are trying to encourage the use of lamps of which the labeled voltage corresponds to the average voltage at which they are operated. Although the amount spent by customers for electric energy and for lamps decreases if the lamps are operated at lower voltage, the light output diminishes more rapidly than the operating expense, and the customer pays more per unit of light.

In areas where part or all of the business section is supplied at 120 volts and the residential section at 115, the problem of keeping properly rated lamps in use throughout the community is very difficult, and the re-establishment of a single standard voltage for the whole community is presumed to be best accomplished by increasing the voltage on the existing 115-volt circuits to 120. Poor voltage regulation throughout an area also contributes to undervoltage operation of lamps, because lamps properly rated for operation along the high-voltage branches of the network must be provided, and experience has indicated that these high-voltage lamps find their way into many low-voltage sockets. The same difficulty is experienced along the boundary line between systems operating at different voltages.

The author suggests that the establishment of a single standard utilization voltage of 120 throughout the United States not only would remove a great obstacle to the operation of lamps at correct voltage, but also would contribute to improvements in the design, production, distribution, and use of appliances on central-station circuits. The article contains a comprehensive statistical survey of the utilization voltages employed in various states in convenient tabular form, and one figure delineating the upward trend of these voltages during the last 14 years.

# Discussions

## Of AIEE Papers—as Recommended for Publication by Technical Committees

ON THIS and the following 29 pages appear discussions submitted for publication, and approved by the technical committees, on papers presented at the sessions on communication and research, insulation co-ordination, general power applications, power generation and electrical machinery, power transmission, and vibration and balance at the 1937 AIEE summer convention, Milwaukee, Wis., June 21–25. Authors' closures, where they have been submitted, will be found at the end of the discussion on their respective papers. Other discussion of summer convention papers will be published as it is made available.

Members anywhere are encouraged to submit written discussion of any paper published in ELECTRICAL ENGINEERING, which discussion will be reviewed by the proper committee and considered for possible publication in a subsequent issue. Discussions of papers scheduled for presentation at any AIEE meeting or convention will be closed 2 weeks after presentation. Discussions should be (1) concise; (2) restricted to the subject of the paper or papers under consideration; and (3) typewritten and submitted in triplicate to AIEE headquarters 33 West 39th Street, New York, N. Y.

### Application of Spill Gaps and Selection of Insulation Levels

**Discussion of a paper by H. L. Melvin and R. E. Pierce published in the June 1937 issue, pages 689–94, and presented for oral discussion at the insulation co-ordination session of the summer convention, Milwaukee, Wis., June 25, 1937.**

**J. H. Foote and J. R. North** (Commonwealth & Southern Corporation, Jackson, Mich.): This paper gives an excellent presentation of the application of gaps as protective devices co-ordinated with insulation levels.

The authors point out that the protected level varies with the time of incidence of the surge, the protected level or surge voltage allowed on apparatus being higher with decrease in time, i.e., with increased steepness of wave front, higher voltages are impressed. With this in mind, the statement of page 689 that, "A spill gap provides a definite voltage discharge level . . ." may be misleading. Should not the word "curve" or "characteristic" be substituted for the word "level" which ordinarily brings to mind one numerical value remaining uniform under varying conditions.

Figure 1 is clear and should be widely studied by the users of gapped equipment. Much misunderstanding might thereby be eliminated relative to the protection afforded by gaps.

We cannot agree with item 1 under conclusions, "Spill gaps . . . afford dependable protection to equipment and insulation against failure from lightning" unless qualified. Gaps are particularly adapted for the protection of insulation in air, such as bushings and insulators, rather than for solid or laminated forms of insulation. The authors point out the necessity of extremely close gap spacing when used for the protection of solid insulation against fast waves.

Data as to allowable spacings from the operating standpoint are interesting and valuable. Evaluation of service interruptions occasioned by the operation of gaps must be made by each operator to suit existing conditions. In view of the wide range of gap settings used at the same operating voltage in different locations, we would like to ask the authors to give correlating data regarding apparatus insulation strengths and neutral grounding conditions in order that these gap settings may be further studied. It would be very helpful if this explanatory data could include the following information for each of the locations cited:

Original insulation tests specified for apparatus protected.

System neutral effectively grounded or ungrounded.

Ratio of zero sequence impedance to positive sequence impedance under maximum fault conditions.

**M. H. Lovelady** (Central Power and Light Company, San Antonio, Texas): Melvin and Pierce are to be commended for the abundance of information contained in their paper "Application of Spill Gaps and Selection of Insulation Levels."

The table I in the paper tabulates the operating record of spill gaps in Texas. Although not stated, these apparently are mostly straight grounded gaps without fuses or expulsion tubes. The table shows a remarkably small percentage of gap operations and it would be of interest to know whether means were used definitely to determine whether or not the gaps operated.

A south Texas company has perhaps more repeater type fused gaps in operation than any of those companies to which the authors had access to operating records and a condensed report covering the operating record of these gaps is of interest.

A total of 185 repeater-type fused gaps have been installed to date and 200 more will be installed this year, however only 103 single-phase installations were in operation during the entire lightning season of 1936 and the tabulation is confined to these 103 installations.

The authors conclusions with respect to minimum permissible gap settings are of interest and bear out operating experience of the south Texas company. Excessive operations due to switching surges have not been experienced with gap settings of a lower ratio than those mentioned in the paper. The settings at all installations have a ratio of normal line to neutral voltage approximately as follows; for 69-kv systems 1.35, for 38-kv systems 1.87, for 22-kv systems 2.2, and for 12-kv systems 2.85. All of the installations are on solidly grounded-neutral systems.

More information regarding the frequency of operation of close-set gaps would be of interest. The table in this discussion shows the number of operations that took place between inspections. All installations were inspected after each lightning disturbance.

Thirty of the installations are at attended stations and it is of interest to note that operators have on several occasions reported that the gaps spilled over without system follow up current, indicating that the surge was dissipated during the instant of very low or zero system voltage.

| Line Voltage (Kilovolts) | Gap Setting (Inches) | Number of Installations | Operations Between Inspections — No. of Tubes 1 | 2 | 3 | 4 | Total Operations |
|---|---|---|---|---|---|---|---|
| 66 | 6 | 60 | 80 | 23 | 8 | 8 | 182 |
| 38 | 4 | 16 | 30 | 15 | 2 | 2 | 89 |
| 22 | 2 | 9 | 10 | 4 | 2 | 0 | 33 |
| 12 | 1.25 | 18 | 17 | 7 | 2 | 0 | 37 |
| Total | | 103 | 146 | 49 | 14 | 10 | 341 |

All of the fused gaps except 9, are installed on transformers directly at the bushing and in series with the transformer fuse. The other 9 are installed on the line side of the oil circuit breakers at the bushing, at a station where 3 69-kv lines enter the station. The station being located at a point where lightning is particularly severe. This station also has fused gaps located at the transformer bushings. The station is protected by overhead ground wires over the the station and extending one mile out on each of the 69-kv circuits.

It is interesting to note that on 2 occasions the gaps at the transformers operated when none of the line gaps operated and that there were 10 operations of the line gaps when the transformer gaps did not operate. On no occasion did both sets of gaps operate simultaneously and on no occasion did more than one gap operate on the same phase. Of the 10 line gap operations, 8 were on the same line, the remaining 2 operations taking place one on each line.

Only 2 of the 341 operations were accompanied by blowing of transformer fuses and those were probably due to faulty fuses as a number of operations have taken place at the same locations without fuse failures.

During the entire period there were no tube failures on the fuse gaps and no tube flashovers. There were several failures of devices to trip the next tube into operating position. These failures however were due to mechanical difficulties and the trouble has now been remedied.

Nine of the operations were caused by birds shorting out the gaps, a condition not considered serious as the operations caused no system disturbance and the loss of one tube out of 4 is not serious.

Only 2 of the operations occured during periods when there was no visible lightning and these are the only 2 operations that may be attributed to switching surges.

It is of interest to note from the tabulation that of the 10 reports of all 4 fuses operating between inspections, 9 of these occurred at end of the line stations. It is also interesting to note that average operations per unit per year for the system is 3.4, while average operations per unit per year for end of the line installations is 6.5.

Based upon the above record, the company now plans to change all of the end of the line installations to 8 fuse repeaters instead of 4.

Although the repeater-type fuse gaps have only been in operation on the Texas system for a little more than a year, single-shop fuse gaps have been used for several years. The transformer failure record at points where the single-shop fuse gaps had been installed lead to the installation of the repeater type. A comparison of transformer failure records at some of these points is of interest.

At one 38-kv station 3 transformers failed in 1930 and one more in 1931. Fused gaps were installed in 1932 and there have been no more failures.

At a 69-kv station, 2 transformers failed in 1931 and 2 more in 1932. Fused gaps were installed after the 1932 failure and there have been no more failures.

At another 69-kv station, 2 transformers failed in 1932, 2 in 1935, and 2 more in the early part of 1936. After the 1936 failure, fused gaps were installed and there have been no more failures.

**H. L. Rorden** (Ohio Brass Company, Barberton, Ohio): It is unfortunate that the volt-time characteristics of insulation failures are not susceptible to mathematical analysis. The problem of insulation co-ordination depends upon volt-time characteristics, which must be determined empirically. Because of this and the vast amount of data that has been accumulated from a great number of sources, it is difficult to draw reasonable conclusions. Differences of opinion also complicate the problem, so that the absolute performance of dielectrics under high-voltage surges is still not completely understood. Since volt-time performance plays such a prominent part in the general scheme of co-ordination, it seems timely to point out some characteristics which may not be generally understood and which may lead to erroneous conclusions if overlooked.

It should be of interest to all working in this field to know that the volt-time characteristics of insulation failures in general, are not as definite or precise as we may like to have them. As an illustration, it is frequently possible to obtain time lags at minimum impulse flashovers which differ by 100 per cent or more in time without a measurable difference in voltage. In flashover tests of a simple rod gap for instance, successive flashovers may range from about 8 microseconds to more than 20 microseconds with identically the same voltage applied. It is apparent that the phenomenon that produces such flashovers is very unstable and cannot be measured as an exact time. It would seem more logical that these data be plotted as a band. This band becomes narrow rapidly with increasing overvoltages, but is still measurable in the very short time range. In this short time range the curve may be very steep with respect to voltage, so that in spite of the narrow band a considerable range of voltage may obtain at exactly the same time to flashover. The band, therefore, is broad as a function of time at minimum flashovers and is broad as a function of voltage at the high overvoltages. In some instances it is found that a variation of 100 per cent in voltage may obtain at identically the same time to flashover. This range is not common, but in some tests it does obtain. It is apparent that to assume an average and plot a line to represent such volt-time characteristics, may be misleading and result in the adoption of margins which may be insufficient.

Another point of interest is in connection with so-called "flat" volt-time characteristics such as are illustrated in figure 1 of the transformer subcommittee report, figure 3 of the arrester levels paper by Messrs. Foote and North, and figure 1 of the spill gap paper by Messrs. Melvin and Pierce. Flashovers which are not dependent upon the formation of corona to complete the breakdown, are usually said to have a flat volt-time characteristic. An example of this is the sphere gap. In nonuniform dielectric fields such as in the rod gap where long times to flashover may obtain, the curve is said to be sloping. A little further clarification on these phenomena is in order. It would seem probable that the conception of a flat curve originated from the fact that analytically no flashover may be considered as a flashover at infinity. Therefore, once a minimum voltage was reached, the curve was continued without change in voltage to infinity. This is a misnomer, since it is impossible to obtain long time lags in sphere-gap flashovers. The flashover of spheres, being almost independent of corona, will occur very quickly or not at all. Thus the volt-time curve of a sphere-gap tested with the $1^1/_2 \times 40$ wave ceases to exist as soon as it becomes flat. Ordinarily it is not possible to obtain flashovers of a sphere-gap with this test wave in more than 3 microseconds. Therefore, the entire curve is that part which curves upward in times less than 3 microseconds. This point is of interest because it has been assumed in some instances that lower flashovers of gaps, irrespective of time, indicates better protection. It is apparent that if a gap or insulation having a "flat" characteristic is to be protected by another gap, it would be useless to provide protection that might flashover in 10 or 15 microseconds when a failure would occur in less than 3 microseconds or not at all. Thus the minimum flashover alone not only may offer no protection, but may be a definite hazard to the system, since it may result in an outage which would offer no protection in any event.

If the curves in the 3 papers mentioned are intended to illustrate general characteristics of surge tests irrespective of wave shape, then it might be said that the flat part of the curves exist as illustrated. The flat portion may be true for slow waves where flashover occurs on the wave front or at the crest. In that event, the flat part of the curves exist and the short time to flashover does not. Therefore, while the curves may illustrate a general principle, they must be used with care, since the complete curves as illustrated do not represent all possible wave shapes and must be limited when one wave only is considered. A complete family of curves would be necessary to represent relative volt-time curves for all waves.

It is significant that the authors of all 3 papers (excepting the committee reports) in this group, have expressed some unfavorable comment on bushing gaps. Laboratory tests indicate that bushing gaps have several undesirable features, which makes them a hazard rather than a help. The one point in favor of bushing gaps is, that it is possible with these gaps in general to obtain the same flashover for both polarities at minimum voltages. Power arcs frequently whip in any direction and the use of bushing gaps encourages an arc to form near the surface of porcelain where it can do considerable damage. The impulse characteristics of bushing gaps are very similar to rod gaps and, therefore, their usefulness for surge voltages is limited to minimum flashovers with slow waves. They are useless for fast waves, as previously mentioned in the discussion of "flat" curves. They are also useless at the high overvoltages where they are most needed, unless an unusually low gap spacing is adopted. If a parallel rod gap is desirable to protect the bushing, a spacing considerably less than the usually recommended gap spacings for bushings must be adopted if overvoltage protection of the bushing is expected. This low gap spacing is necessary because an overvoltage arc tends to follow a surface, where at minimum voltage an arc may strike clear. This phenomenon is observed also in strings of suspension insulators. For example, in an insulator string equipped with arcing horns, the horns may be so adjusted that the arc will strike clear between the horns at minimum flashover, but unless an unusually low spacing between the arcing electrodes is adopted the arc may cascade the insulators on high overvoltages exactly as though the horns were not present. Bushing gaps and rod gaps are parallel cases to the insulator string.

These gaps adjusted to the so-called test gap spacing, may flashover at minimum impulses, and at the high overvoltages, the arc may follow the surface of a parallel bushing exactly as though the gap were not present.

I should like to ask the authors of the 3 papers, if their experience indicates whether most insulation failures are associated with a single severe surge such as direct strokes or if there are a fair percentage of failures that occur with strokes of lesser magnitude and

current, such as traveling waves. Recent publications have shown that a large percentage of direct strokes are above 10,000 amperes, and up to 50,000 amperes. It would seem probable that if many failures are due to surges of low current such as arresters are capable of dissipating, that there must be some breakdowns which occur during surges of low magnitude on systems not equipped with arresters. That is, if progressive deterioration weakens insulation, so that failure becomes imminent, such failures would not necessarily be assoicated with direct strokes. However, if most failures are associated with direct strokes, it would seem that more attention should be given to the higher current and energy surges than to those of lesser magnitude.

**K. B. McEachron** (General Electric Company, Pittsfield, Mass.): The proper solution of the problem of insulation co-ordination depends upon a knowledge of the flashover or failure characteristics of the apparatus to be protected, as compared with the protective level allowed by the protective devices used. If all apparatus had the same shape volt-time curves of failure or performance, the problem would be relatively simple. Thus, if the volt-time flashover characteristics of the line insulator, bus and switch support, bushing, and the puncture of solid insulation as used in the transformer, were all similar in shape, and if the rod gap or lightning arrester were entirely independent of the effects of wave front and current magnitude, it would be possible to maintain any desired levels without knowledge of what sort of impulses must be considered when lightning strikes the line or station.

Actually, however, although the volt-time curves for the lightning arrester and transformer insulation are similar in shape, the bushing, line and bus insulators, and the rod gap, all have volt-time curves which increase very rapidly as the time to flashover becomes short. This characteristic does no harm, and in fact, is an advantage in a device being protected, but is not a desirable characteristic for a protective device. This is especially true when the frequency of occurrence of any particular wave of lightning front is not known. The variation in the rod-gap spark potential from 60 cycles wet to flashover on a 1,000 kv per microsecond front will be of the order of 6 to 1, while the same ratio for the lightning arrester will not in general be more than 2 to 1, the arrester being unaffected by weather conditions.

These considerations lead to the conclusion that, if close and dependable protection is to be expected, one should make use of the lightning arrester installed close to the transformer, with adequate direct stroke protection over the station and for a short distance out, so that waves of known magnitude and steepness can arrive only through the surge impedance of the line, giving rise to voltages across the arrester which can be predicted reasonably well in advance. This allows one to operate with a known margin between the arrester potential and the tested strength of the transformer.

The ideal arrester protection, which has been long recognized as such, would be to have the arrester potential unaffected by either the rate of voltage rise or the amount of current in the discharge. It is true that considerable progress has been made in this direction in the last few years, which provides more definite protective levels than possible heretofore, and yet for the best results and to maintain dependable margins, a knowledge of the maximum magnitudes of the incoming waves is essential, both as to rate of rise and magnitude of current.

These considerations indicate that the greatest lack of knowledge concerning lightning is in relation to the wave shapes and magnitudes which may result from direct strokes at the point where the stroke occurs. This is especially important in connection with distribution systems where direct stroke protection cannot be readily installed at transformers. Knowledge of such wave shapes is very difficult to secure at reasonable expense, and although some data are available much still remains to be done.

Fortunately, waves which travel over conductors, even relatively short distances, are subject to calculation, and are so modified that an exact knowledge of the original lightning stroke is not necessary. This method is conservative, but until more is known of the wave shapes of lightning and the frequency of occurrence of those wave shapes, it appears to be the safest policy to pursue.

Messrs. Sporn and Gross are to be complimented, particularly on the co-ordination chart, which I am sure will be very useful.

With reference to the Melvin-Pierce paper, what was the ampere rating of the fuses used on the 110-kv system discussed on page 691? With the type of repeator fuse used, how quickly does another fuse become available, and is protection lost in the interval? Multiple strokes involve time intervals as short as 0.0005 seconds and successive discharges may be as far apart in time as 0.5 seconds, which makes the answers to these questions of interest.

**J. T. Lusignan, Jr.** (Ohio Brass Company, Mansfield, Ohio): All 3 papers on insulation co-ordination or selection of insulation levels bring out quite well the factors involved and the advantages to be gained. Messrs. Sporn and Gross very aptly summarize the advantages when they term them "economy." In other words it is merely a case of saving equipment cost and watching the weakest link of the chain. That is, all equipment should be reasonably high enough so as to have small chance of failing, but none should be abnormally higher than others as this usually involves high costs with no particular gain in the net performance of the system.

All of the papers have to do with choosing protective levels and arranging the equipment above them. The question that probably arises in the minds of most readers is how the individual equipment pieces should be arranged relative to one another. Messrs. Foote and North seem to feel that the only care necessary is that all equipment be above the protective level, making no recommendations as to which should be highest or lowest. Messrs. Sporn and Gross seem to favor having the bus insulation the highest in the station.

Whatever procedure is used, care must be taken not to choose insulation levels on too close hair lines. In this regard I would like to emphasize a few points as to the porcelain members involved, that is the bushings and bus insulators. Besides the atmospheric factors which cause the flashover voltages of such insulation to vary, each of these devices has individual characteristics which affect flashover.

Bushings seem to be the most variable in this respect, probably because they have the more involved electrostatic field. This field is that of a rod and torus, with a mass of solid and/or liquid insulation as a principal dielectric between them. It is this mass of insulation which is supposed to support all applied potentials, any relief from high overvoltages being gained by flashover of the air along the outer porcelain shell. The inside insulation has an appreciable effect upon the outside flux of the air, and therefore the flashover characteristics of the bushing. Since some bushings nowadays are made entirely of porcelain or paper, some of porcelain and oil and some of paper and oil, it can be appreciated that each will have the outside air paths affected differently. Also the temperature and condition of the inside insulation has some affect upon the outside electrostatic field. All of these factors combine to make very difficult the problem of standardizing bushing flashover values within narrow bands. There is also the question of using the flashover values secured in a laboratory on a smooth testing tank, with those which will occur when the bushings are mounted on breaker or transformer tanks having protruding metal parts in different arrangements around the base of the bushings.

The question of standardizing bus insulator flashover values is a little less complicated, since the dimensions, materials, and shapes of many of these insulators are rather well standardized today. However, tolerances must be allowed on each side of the flashover values, established under standard conditions in laboratories, since these insulators are not always mounted alike in stations. In other words, some are base-mounted and some cap-mounted, while others are arranged in double as well as single stacks, and with widely different hardware fittings at the line ends.

In those cases where suspension insulators are used in stations, it must be remembered that the established suspension flashover values are based on simple hanging strings in laboratories, and not the horizontal tension strings, with and without jumpers, as is frequently used in some bus structures.

In all of the above papers the need is recognized for putting the "protective level" above the expected switching surge level. The question that I would like to raise is as to what should constitute the switching surge level. Messrs. Melvin and Pierce introduce new data which I feel should change the idea of many of us as to the proper switching surge level. In their conclusions they state:

"The minimum permissible spill-gap settings, for transmission voltages, without adverse effects on service, are less than those previously considered possible.

*a.* The lower limit generally applicable is the equivalent of approximately 3.0 times the normal phase-to-netural voltage, in terms of 60-cycle flashover.

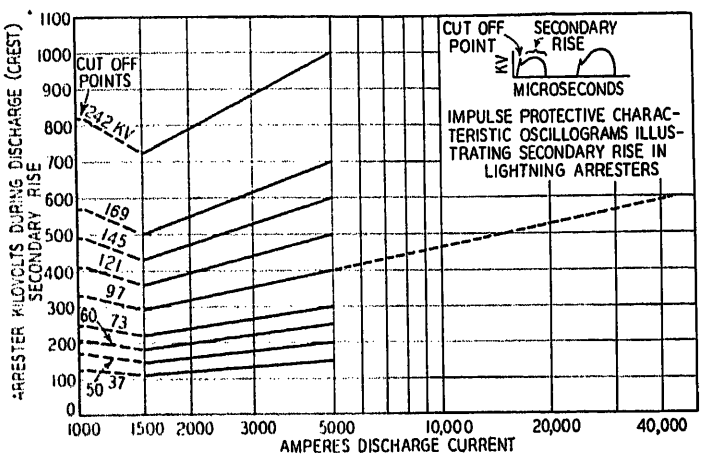

**Figure 1. Performance of station-type arresters**

Data from table I of paper by Foote and North

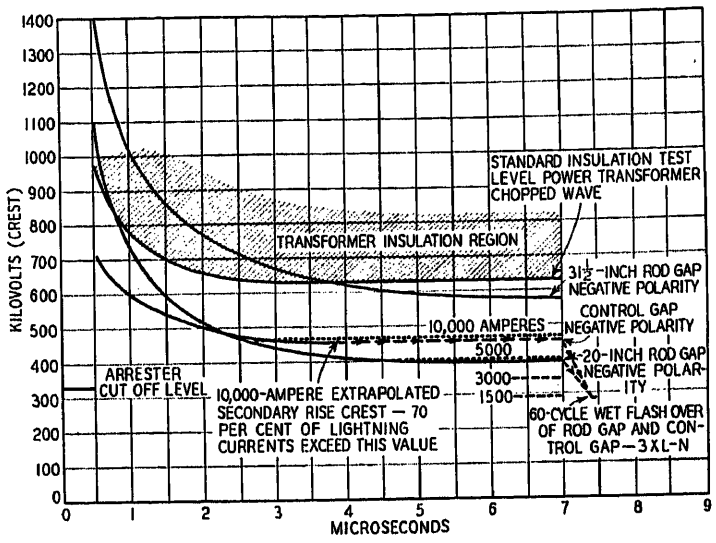

**Figure 2. Typical insulation co-ordination showing relative effects of arrester secondary rise and back-up protection of rod gaps and control gap**

*b.* When extremely low protective levels are necessary or desirable and preferably where fused gaps may be applied, the minimum permissible limit may be approximately 2.0 times normal."

Up to now I believe that most of us have felt that a switching surge had the same flashover characteristics as the power frequency wave. Recent work in our laboratory has led us to believe that a switching surge, with its short duration and rapid attenuation, compared to a long 60-cycle wave, might have flashover characteristics higher than the latter and closer to those of impulse surges than originally supposed.

Accordingly, our engineers feel that it is wiser to design a protective device to handle expected lightning surges, overlooking pure 60-cycle overvoltages, on the assumption that the latter is the result of generator overspeeding but not switching. Appreciable data have been gathered showing the crest values of switching surges. We believe that it would be most helpful if more were gathered telling of the wave shapes of switching surges. We feel that this might reveal wave shapes which will permit devices being set appreciably lower than is felt to be safe on the present power frequency basis.

**P. M. Ross** (Ohio Brass Company, Barberton, Ohio): The operating experience of Messrs. Melvin and Pierce is of valuable assistance in arriving at protective gap levels which are sufficiently low to protect expensive insulation, yet of such magnitude that they can be "lived with" on the system under operating conditions.

The authors mention various switching surge tests conducted to determine the minimum spill-gap settings which are permissible from an outage standpoint. I should like to ask the authors if they can give any information relative to the switching surge wave shapes.

Emphasis has been placed on establishing basic protection levels by means of spill gaps. Such gaps are not subject to deterioration, and remain unchanged by time. There still remains the important problem of determining the time deterioration of major insulation so that a change in basic insulation levels may be adopted to compensate for such reduced levels. I would like to inquire if the experience of the authors of all 3 papers indicates a relative destruction effect of switching surges, induced surges, and direct strokes.

Table I of Messrs. Foote and North's paper illustrates arrester characteristics up to 5,000 amperes. Thus it is shown that for the usual surge or traveling waves arresters are capable of maintaining the surge potential to a safe value.

The authors state in a footnote under table I that station-type arresters can withstand 10,000-ampere crest surge currents. In recent publications statistical data indicate that approximately 70 per cent of stroke crest currents will be in the neighborhood of 26,000 amperes ("The Lightning-Stroke Mechanism of Discharge," McEachron and McMorris, October 1936, *General Electric Review*). The data as presented by the authors in table I have been plotted on a semilogarithmic basis, figure 1. Since the data plotted in this manner are found to lie on a straight line, extrapolation into the regions in which the greater percentage of direct strokes actually obtain seems reasonable. It is thereby found that the secondary rise crest kilovolts across the arrester at 10,000 amperes has risen to 460 kv and to approximately 600 kv at 50,000 amperes (if the arrester will thermally withstand these currents).

It is interesting to consider these figures when they are plotted with typical transformer insulation in view of the authors' statement that "Arresters generally have the following characteristics which are of value in this connection: . . . . (*c*) The performance characteristics are such as to approximate the volt-time characteristics of transformer insulation." In figure 2 is plotted a typical transformer insulation band with a 20-inch negative-impulse rod-gap characteristic (95 per cent lightning strokes on transmission lines are negative polarity), negative-impulse characteristics of a 115-kv control gap set with wet switching surge flashover of 3 times line to neutral voltage and a 97-kv arrester as recommended by the authors for an effectively grounded neutral 3-phase system. The arrester gap breakdown or cut-off point is shown at 330-kv at the ordinate.

The secondary rise crest kilovolts are plotted horizontally. They have been terminated at the 20-inch rod gap, the 60-cycle flashover of which is also 3 times line to neutral voltage. It is to be noted that if surge currents exceed approximately 5,000 amperes the 20-inch back-up gap having a negative minimum flashover of 395 kv will flashover due to the secondary rise across the arrester. Carrying this analysis still farther it is to be seen that the extrapolated value for 10,000 amperes falls at approximately 5 times line to neutral voltage. Currents as high as 50,000 amperes would cause a secondary rise voltage approaching the breakdown of new transformer insulation. I would like to ask the authors if they have any additional data to extend the secondary rise kilovolts crest into the region from 5,000 amperes to 50,000 amperes, also if they have available the total time to crest of the secondary rises for the various discharge currents? Such an analysis as shown in figure 2 indicates that the cut-off point is of minor importance when surge currents of 3,000 amperes and up are encountered as insulation failures are caused by crest voltages, the values of which are determined or permitted by the secondary rise crest of the arrester.

## Application of Arresters and the Selection of Insulation Levels

**Discussion of a paper by J. H. Foote and J. R. North published in the June 1937 issue, pages 677–82, and presented for oral discussion at the insulation co-ordination session of the summer convention, Milwaukee, Wis., June 25, 1937.**

**H. L. Rorden:** See discussion, page 1291.

**P. M. Ross:** See discussion, this page.

**J. T. Lusignan, Jr.:** See discussion, page 1292.

**Herman Halperin** (Commonwealth Edison Company, Chicago, Ill.): The authors state on page 680 that "The arrester voltage

rating must be at least 10 per cent above the calculated maximum sound phase voltage to ground." As we have not followed this practice in Chicago, I should like to discuss it.

The manufacturers state that for modern arresters the 60-cycle breakdown is at least 150 per cent of the arrester rating. This factor alone usually provides a safe margin to justify the use of an arrester rated equal or less than the maximum phase-to-ground voltage during abnormal conditions.

We have been using 3-kv arresters on the 4,000-volt distribution system, which is grounded at the substations through 3/4-ohm reactors. During unusually heavy fault currents, the fuse that normally short-circuits the reactor blows. In general, the ratio $Z_0/Z_1$ is over 2 when the fuse has blown, and is less than 2 when it has not blown. For faults near the substations our information shows definitely that the maximum line to neutral voltage may reach 3,500 to 3,800 volts, and this condition applies when the fuse across the reactor blows. The fuse blows in about 15 cases a year, or about once every 3 years for each substation. For most faults, the maximum voltage is 3,000 volts or less.

Arresters rated at 3 kv have been used for 25 years on this system with satisfactory results. The rate of arrester failures due to all causes is about 0.3 per cent per year and the rate for the modern type of arrester but a small fraction of this percentage. These failures include, of course, those due to corrosion of the gaps and other deterioration.

For the year 1936, 69 arresters failed in service incidental to lightning. The average distance to these arresters from the substation bus was 7,500 feet. There were also 40 failures of arresters due to unknown causes, and for these cases the average distance from the arresters to the substations was 6,300 feet. The average distance for all arresters on the system from the substation busses was 6,000 feet. The voltages during faults are highest on the line wires nearest substations, and yet this characteristic did not cause a large proportion of the arresters near substations to fail.

Table III of the paper shows a margin of arrester performance in the basic insulation level which includes a circuit gradient of one kv per foot. This value may not be sufficiently high to insure an adequate safety factor under severe conditions. Hodnette and Ludwig reported in their June 1937 paper voltage drops in arrester leads as high as 10 kv per foot in laboratory tests. Lightning investigations on the Chicago distribution system as reported by Halperin and Grosser in the January 1936 issue of ELECTRICAL ENGINEERING indicated values of circuit gradient as high as 1.0 to 1.7 kv per foot. In our measurements no cases of transformer failure and only one fuse blowing occurred, although a large number of measurements were made. It appears quite possible that, with lightning conditions severe enough to cause actual equipment damage, higher values of circuit gradient might have been encountered. At least until more definite data are available, particularly for transmission systems, values higher than one kv per foot should in some cases be used in designing and in analyzing equipment performance.

The use of higher gradients reduces or eliminates the selectivity margins given in the paper. Some compensation, however, exists in the 5 per cent or greater differential between the basic impulse level and the transformer bushing flashover. Perhaps the selectivity margin could properly be determined on the basis of actual flashover voltage of the equipment to be protected rather than on the basic impulse insulation level.

These remarks emphasize the authors' recommendation to place arresters as close as possible to transformers or other equipment to be protected.

**E. Piepho** (Detroit Edison Company, Detroit, Mich.): Foote and North have condensed the great body of available material relating to lightning protection of electrical apparatus, and presented it in a form immediately usable to the operating engineer. Data which they give have passed through the controversial stage and are now widely accepted. Interpretation and use of this material, however, may warrant some comment.

To the section on marginal requirements, the authors might have added a statement concerning the effect of deteriorated lightning arresters, or arresters of earlier manufacture than the more improved types whose performance is shown in table I. Such arresters would give higher voltage drops during discharge than the values shown in the paper. The surge impedance of ground connections is also of great importance since the voltage drop across this impedance adds to the voltage across the arrester during discharge, giving proportionally higher impressed voltages on the protected equipment. For example, on distribution systems ground-connection impedance has so much effect that considerable improvement in protection of transformers has been realized by interconnection at the transformer of the secondary neutral wire and the arrester ground lead.

The selectivity margins shown in table III appear to be comfortable for all voltage classes, yet the operating engineer using these data should bear in mind that these margins can easily be wiped out by any one or more of the marginal requirements having greater weight than assigned by the authors. This has the effect of making each arrester installation almost an individual matter. It also suggests that operating companies using a great number of lightning arresters will find it profitable to undertake a program of testing a certain percentage of new, and all reclaimed, arresters before placing them in service. Furthermore, now that basic insulation levels are being established, operating companies can proceed to test the various kinds of old equipment in service to determine their fitness to operate in their voltage class.

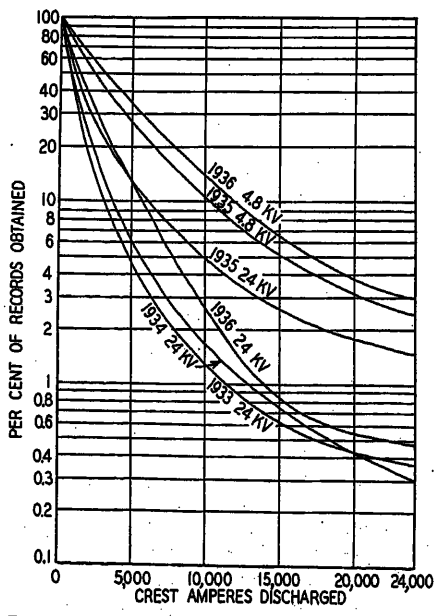

**Figure 1. Magnitude of lightning current through arresters on 4,800- and 24,000-volt lines**

It is regrettable that the authors were unable to present data on lightning arrester performance beyond 5,000 amperes. The majority of lightning surges passed by arresters appear to be less than 5,000 amperes, nevertheless surges of greater magnitude are not uncommon. Records of surge currents through arresters have been obtained on the Detroit Edison system for several years, using surge recorders in the ground connections of various 24,000-volt arresters, and surge-crest ammeters in the ground leads of arresters on 4,800-volt distribution transformers. H. W. Collins reported the first year results of this investigation on 24,000-volt lines in the May 12, 1934, issue of *Electrical World*. This work has been continued and considerable additional data obtained. The accompanying curves show the per cent discharges at different current values obtained from these records. About 9 per cent of the surges recorded on 24,000-volt lines were over 5,000 amperes, and about 30 per cent were over 5,000 amperes on the 4,800-volt lines. The greater percentage of high current surges on the distribution lines in probably due to greater exposure, since all the 4,800-volt line recorders are located on farm lines, whereas many of the 24,000-volt recorders are in the urban area. These records have also demonstrated that lightning arresters of present manufacture can pass surge currents in excess of 20,000 amperes without damage. Consequently, it seems the time has come for manufacturers to extend the data on voltage across arresters during discharge considerably beyond the present 5,000-ampere limit.

This paper should focus attention of all operating men on co-ordination of equipment insulation which is important because better protection can thereby be secured at less cost. It should also enable manufacturers to standardize somewhat on lightning-arrester characteristics, which should lead to lower costs and consequent broader application of arresters.

**Hollis K. Sels** (Public Service Electric & Gas Company, Newark, N. J.): Messrs. Foote and North, in their paper on "Application of Arresters and the Selection of Insulation Levels" and Messrs. Sporn and Gross in their paper on "Insulation Coordination" bring out valuable comparisons between the protection afforded by lightning arresters and the basic insulation levels of other equipment. While a great deal of information has been gathered on the characteristics of insulated equipment and protective devices, a great deal of informa-

tion is still needed on the impulse strength of equipment in service and on new equipment being manufactured by those who are not equipped with complete testing facilities or, if equipped, may not have complete information on equipment being built.

The opinion expressed in both these papers seems to be to rate the bus insulation strongest, with bushings, transformer insulation, and lightning arresters following with suitable margin requirements provided in each step. There are 2 major factors which appear to us to need further consideration before they can be standardized on as a general policy. First, while it is theoretically possible to maintain a marginal requirement between steps of only 10 per cent, we believe that in practice it will be impossible to maintain less than 20 per cent between barrier-type insulation level inside transformers and circuit breakers and the protection level because of the deterioration which is bound to take place in insulation and the variation in protective ability of equipment. The company with which I am associated has purchased plenty of equipment which, at the time of purchase was properly co-ordinated, but now, because of its depreciation, is almost as uncoordinated as if no co-ordination had been made originally. Messrs. Melvin and Pierce have made some allowances for deterioration in their application of spillway gaps. Second, every station design naturally falls into at least 4 levels, that is, line entrance insulation, the disconnecting switch and bus insulation, which are usually the same, the circuit breaker and transformer bushings, which are usually interchangeable but may be gapped differently, and the internal transformer and breaker insulation levels.

Considering the relative cost to repair, and the fact that most busses are sectionalized if not properly protected, it would appear that bus and disconnect supports should not necessarily be the strongest insulation in the station. In our own designs we have tried to adopt the following order of strength:

1. Transformer and circuit-breaker internal insulation.
2. Transformer and circuit-breaker bushings and bus insulation.
3. Co-ordination gap and line insulation.
4. Lightning arresters.

We feel that a minimum margin of 10 per cent between each of these groups, allowing 30 per cent between the transformers and the arrester and 10 per cent between porcelain insulation and the arrester, should give a reasonable degree of protection, both in service and dollars.

We note that Messrs. Foote and North, in setting up their marginal requirements to take care of the distance and potential gradient between the equipment and protective device, have based their calculations on an allowance of a potential gradient of only one kv per foot, which is equivalent to an incoming wave having a 500-kv-per-microsecond front. In our calculations we have used corresponding values of 1.7 kv per foot, which is equivalent to 1,000 kv per microsecond wave front.

While the values assigned in some of our basic assumptions may be debatable, I am presenting this discussion to show that there is considerable need for a further discussion and standardization on the various factors involved. We cannot simply say that here is a basic insulation level which is adequately protected by the protective characteristics of lightning arresters which you can buy today.

**L. G. Smith** (Consolidated Gas, Electric Light & Power Company of Baltimore, Md.): This paper is an excellent step in the placing of the co-ordination of arresters and station insulation on an arithmetical basis. Until it is possible to accomplish this we are only guessing when lightning arresters are applied. Unfortunately even now we cannot place insulation co-ordination and arrester application on a basis of ready calculation since the data concerning actual lightning discharges are quite meager. However, we do know that

1. Some wave fronts are very steep and apparently the closer the stroke to the substation the steeper the wave front.
2. Stroke currents vary from small values to very high ones and these current values can be expressed on a probability basis.

The data presented by the method followed by the authors are predicated upon wave fronts sufficiently low to permit the arrester gaps to break down before the solid insulation fails and upon surge currents of 5,000 amperes or less. With the present information this is the nearest approach that can be made to an arithmetical solution. However, whether or not this solution represents the majority of the cases is questionable. With lines of the completely shielded or "lightning-proof" type connected to a station, the margin of safety given by the authors can probably be applied with some assurance of being adequate.

However, in the case of stations connected to unshielded lines other factors must be considered. Direct strokes near the station may result in very steep wave fronts being imposed upon the station insulation. As a matter of fact there are no published data giving volt-time characteristics of lightning arrester gaps. If such curves approach those of sphere gaps better assurance of co-ordination is obtained. From published data the probability is that 85 per cent of the strokes will be greater than 5,000 amperes. On unshielded lines the limit of the surge currents carried to the stations will be the insulation level of the lines themselves. However, there will be strokes sufficiently close to the station so that lightning arresters will function before the line insulation has time to flashover, thus probably requiring the arresters to discharge more than 5,000 amperes. Records of lightning arrester and equipment failures justify this point.

In cases where the stroke occurs sufficiently far from the station to permit the line insulation to flashover before imposing a high-voltage surge on the substation the 5,000 amperes assumed by the authors should be ample for practically all operating voltages. However, in order adequately to handle steep-wave-front surges or surges originating close to the station, the ideal arrester is one which has a gap with a volt-time characteristic co-ordinated with the transformer insulation and has an impedance drop for currents up to the point where the arrester element flashes over lower than the impulse strength of the equipment protected.

Therefore, it is believed that, until further data are available, the safest practice in application of lightning arresters is the use of arresters with the lowest possible rating consistent with the dynamic potentials that exist on a given system.

**F. J. Vogel** (Westinghouse Electric & Manufacturing Company, Sharon, Pa.): The report on "Basic Impulse Insulation Levels" gives a tabulation of voltage classes and impulse insulation levels in terms of crest kilovolts. This basic impulse insulation level is presumed to be the minimum insulation level of any apparatus in a station. It is supposed that transformers should have at least this impulse strength or higher and that protective devices would limit the voltages to a lower value to provide a factor of safety in service.

I note that this is the beginning of a program to standardize the level of all the individual parts of a station. I believe this will lead to satisfactory results if it is recognized that considerable latitude must still be given to the designers of equipment. For example, the level of protective equipment should be the determining value for transformers and other equipment, and there exists at the present time no standardization of these devices. Therefore, the basic impulse insulation level given is purely arbitrary since the foundation, which is the voltage level which can be maintained by protective equipment, is lacking.

There is also a trend toward the use of unit equipment, that is to say transformers with either deion gaps or arresters built into the equipment. Since such devices are self-protecting and are a unit, there is little or no point in setting arbitrarily the impulse levels of any of the parts of such devices. The designer must know the performance of each part and provide sufficient factor of safety so that it is a serviceable piece of equipment. Such equipment might or might not adhere to present standards in so far as the performance of the individual parts is concerned.

These points are also brought out in the paper by Messrs. Foote and North. They point out that it is essential, before designing any structure, to determine the stresses which will be placed upon the structure. In this paper the insulation stresses on transformers and equipment are assumed to be limited by the performance of arresters only, and the limits in the application of arresters are important in considering the insulation co-ordination problem from this angle. The authors have made a very thorough study of the problem, and have arrived at sound conclusions.

Arresters are often applied where, due to overhead ground wires and favorable conditions, it is considered that there is little chance of direct strokes. On the other hand, there are few, if any, locations where it can be stated that there is absolutely no possibility of direct strokes, and many where it is not considered economically possible to guard against direct strokes. Therefore, the performance of arresters when subjected to extremely steep wave fronts and heavy surge currents are the important limits.

In design work, where the stresses are known, it is common to apply a "factor of safety." In the paper, this has been done by the use of a "tolerance factor," and a "selectivity margin." The "gradient factor" is really a factor not dependent on the arrester, but on the application. Let us briefly consider what these factors involve. The "tolerance factor" tells us that the arrester is a manufactured product, and as such is subject to variations when new, and

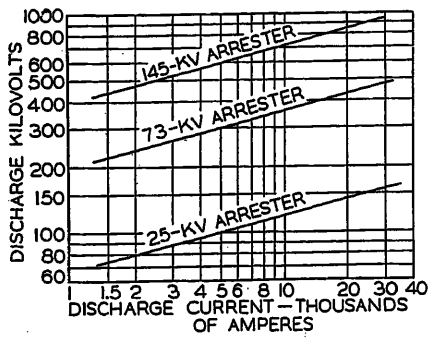

**Figure 2. Discharge kilovolt-ampere curve for lightning arresters from table I of paper by Foote and North**

in service. The tolerance and selectivity factors also tell us that there are unknown factors, such as steepness of the front of the surge. The breakdown voltage of any gap is subject to increase when the wave front is steep enough. The question then is, what steepness may be expected, and in turn what will be the voltage and what effect will this voltage have on the insulation? The answer to these questions is not entirely available, and differs for low- and high-voltage classes. It is possibly safe to say that protection, regardless of wave-front steepness, can be guaranteed for the low-voltage classes, but not necessarily so for the high-voltage classes. Further data and discussion of this subject will undoubtedly follow in the next few months.

The very existence of a distance or gradient factor indicates the necessity of placing the arrester immediately adjacent to the transformer in so far as the transformer only is concerned. The use of a value of one kv per foot may be a fair assumption, but it may be exceeded. In the laboratory, while making steep-wave-front tests on actual apparatus, values 2 or 3 times this high have been seen. There is no guarantee that natural lightning might not occasionally furnish similar results. The practice of locating the protective device, whether gap or arrester immediately adjacent to the transformer appears very desirable from the standpoint of transformer protection.

The question of "surge current" is an important one. Again, surge currents have been assumed at the very nominal value of 5,000 amperes, but there are definite possibilities of currents as high as 10,000 or 15,000 amperes in many cases, to say nothing of the rare cases when there may be from 60,000 to 200,000 amperes. The factors of "thermal ability" to discharge heavy currents, as well as the resultant discharge voltage have not been completely disposed of, as little data are published. A possible extrapolation of the author's data from table I is shown on figure 2 of this discussion for 3 voltage classes. If this extrapolation be correct, the arrester might conceivably cease to protect transformers beyond the following limits: The full wave transformer strengths are 645 kv, 345 kv, and 153 kv for the 138-, 69-, and 25-kv classes, respectively. These voltages will be exceeded when arrester currents in excess of 7,000, 9,000, and 25,000 amperes are encountered. The lack of standardization of arresters is shown by the fact that there are arresters available which will protect these same transformers with discharge currents up to 40,000 amperes or more.

It is interesting to note that the use of the deion gap has been omitted for the low-voltage distribution transformers, in which case there is little or no increase in voltage due to discharge current and no "thermal limitations." This application in certain transformers has had a nearly 100 per cent service record.

The above discussion leads to the same general conclusions as drawn by the authors, and places additional emphasis on the desirability of recommending protective gaps in the station, located as described by the authors, since they provide a limited amount of free insurance against failure of the arrester, and might prevent the failure of a transformer when the surge current is beyond the discharge capacity of the arrester, resulting in too high a discharge voltage.

# Insulation Co-ordination

**Discussion of a paper by Philip Sporn and I. W. Gross published in the June 1937 issue, pages 715–20, and presented for oral discussion at the insulation co-ordination session of the summer convention, Milwaukee, Wis., June 25, 1937.**

**K. B. McEachron:** See discussion, page 1292.

**J. T. Lusignan, Jr.:** See discussion, page 1292.

**P. M. Ross:** See discussion, page 1293.

**J. H. Foote** (Commonwealth & Southern Corporation, Jackson, Mich.): The authors in this paper have presented a most excellent recapitulation of the important considerations involved in insulation co-ordination. They have pointed out that co-ordination has 2 main objectives, (1) protection of service and equipment, (2) economy, and to these we heartily subscribe.

Your attention is particularly called to their "insulation co-ordination chart." This presents, in graph form, for ready use, a vast amount of data pertaining to the insulation strength of apparatus, performance of protective devices, etc. At first, it may appear complicated, but a little study will clearly demonstrate its value in solving insulation co-ordination problems.

**L. G. Smith** (Consolidated Gas, Electric Light & Power Company of Baltimore, Md.): The authors' classification of the 3 types of overvoltage is quite complete. The first 2 types readily lend themselves either to calculation or to estimation, based upon operating data. However, the third classification, that is overvoltage due to lightning, is still a somewhat indefinite factor and at the same time is the one which is most likely to cause damage to equipment. The practice of the authors' company to install transformers with reduced insulation is a very intriguing one in view of the economic savings resulting. The natural question is whether or not the present-day transformer insulation is too safe from an economic point of view.

In setting a level for transformer insulation, if sufficient information were available, it should be possible to place it on an economic basis, that is, obtaining a balance between capital cost and cost of transformer failures and depreciation. However, to do this it would be necessary to have:

1. Complete information as to probability of strokes of various magnitudes and wave front that could enter stations, in which transformer equipment is installed.
2. Complete volt-time curves of lightning-arrester gaps would be necessary.
3. Volt-ampere characteristics of arresters would be required up to very high surge currents.
4. Volt-time curves of transformer insulation.
5. The effect of repeated voltage strains on transformer insulation, upon the volt-time breakdown characteristics, and upon the characteristics of transformer insulation would be necessary, in order to determine the deteriorating effects of repeated surges.

The lower the margin of safety between the transformer insulation and the voltages to which the lightning arresters will limit the incoming surges, the broader must be the knowledge of the probable types of surges that will be encountered. If the margins are too low, steep wave front surges may damage the transformer insulation before the arrester gap can discharge. Likewise, with low margins, the higher values of surge currents may cause impedance drop in arresters sufficiently high to cause transformer failure.

In reference to the practice cited by the authors of installing the arresters, as close as possible, if not mounted directly on the transformers protected: This is unquestionably an ideal location from the standpoint of lightning protection to the transformers. It is the practice which our company is following. However, it must be remembered that when arresters are installed at the transformers in a large outdoor substation, there may be oil circuit breakers or air-break switches, installed at locations remote from the arresters which might need some supplementary protection. Likewise, air-break switches in incoming lines may be open. As this would constitute a point of reflection, frequent flashovers may occur when such switches are open. With the object of preventing such troubles it has been the practice of our company in 13.2-kv substations to install station-type arresters as close as possible to the transformers, and to install line-type arresters at the terminals of the incoming or outgoing lines. For the protection of such air-break switches, lightning arresters may not be necessary, in that an expulsion protective

gap may be used, due to the fact that the volt-time curves of the expulsion protective gap and the post insulator both have about the same shape.

**V. M. Montsinger** (General Electric Company, Pittsfield, Mass.): In connection with the general problem of insulation co-ordination I wish to point out that so far as I am aware the insulation co-ordination movement was started in the transformer subcommittee in 1927, although nothing was published until the 1930 summer convention at Toronto.

This activity was initiated as the result of the failure in August 1926 of some 220-kv transformers having reduced insulation levels (that is, transformers given an induced voltage test of 2.73 times line to neutral voltage) operating on a highly insulated line and without any form of lightning protection. This was the first 220-kv circuit built in the East where lightning was severe and the failure of the transformers brought home the fact that consideration must be given not only to protection against lightning but to the possibility of designs more highly resistant to lightning impulses.

Under item 7 of the minutes of the May 27, 1927, meeting of the AIEE transformer subcommittee, there appears the following heading: "Relation Between Impulse Strength of Transformer Windings, High Voltage Bushings and Line Insulators Near the Transformer Bank." Under this item appears in part the following:

"The question of whether it was best to use the bushing or some external arcing device as a protection to the transformer was discussed and it was the consensus of opinion that it would be poor engineering to use the bushing as a protective device for the windings. It was agreed, therefore, that the committee draw up recommendations on the length of insulators or number of discs which should be used next to the transformer banks of different standard voltages. . ."

The question of co-ordination of transformers was discussed at each subsequent meeting and at the May 9, 1928, meeting the following table for co-ordination was recommended:

| System Voltage (Kilovolts) | Maximum Value of Line Insulation Adjacent to Station in Terms of 60-Cycle Root-Mean-Square Dry Flashover Kilovolts |
|---|---|
| 66 | 250 |
| 88 | 360 |
| 110 | 400 |
| 132 | 450 |
| 154 | 550 |
| 187 | 650 |
| 220 | 750 |

The 60-cycle flashover given in the above table corresponds to the number of line insulators given in the second column of table I of the report of the transformer subcommittee on "Insulation Strength of Transformers" being presented at this session.

The method of establishing protective levels by means of insulator disks was, of course, quite crude and was soon superseded by the use of the more flexible rod gap or "co-ordination gap." As soon as it was realized that the co-ordination gap did not necessarily co-ordinate, the spacings were increased 10 per cent and its name was changed to "test gap."

This early consideration of transformer insulation co-ordination by the transformer subcommittee stirred up interest in the general problem of co-ordination and, as pointed out in the article on "Basic Impulse Insulation Levels," other committees became interested and this finally led to the formation of the EEI-NEMA joint committee to act upon the broad subject of co-ordination.

It is interesting to note that the test gap spacings given in the EEI-NEMA report and from which the basic impulse kilovolt levels were obtained are the same as those recommended by the transformer subcommittee in 1933. This shows that even though the method of selecting the insulation level was quite crude we arrived at the level eventually selected by the EEI-NEMA committee on a more rational basis; namely, the protective level that is available.

The fact recognized in 1927, as mentioned before, that it would be poor engineering to depend on the transformer bushing as a protective device has been fully justified by later developments. In fact, the latest proposal of expressing the insulation level by kilovolts instead of by test gap eliminates the bushing entirely as the yard stick for even impulse testing of transformers, much less using the bushing as a protective device.

While the industry has been feeling its way for the past 10 years on the problem of co-ordination, making use of the best information available, I think we have finally reached the stage where a logical and practical basis has been reached both for impulse testing of transformers and for protecting transformers in service. This, of course, does not mean that further progress will not be made as many groups are still working along these lines.

## Insulation Strength of Transformers

**Discussion of a paper by the transformer subcommittee of the AIEE committee on electrical machinery published in the June 1937 issue, pages 749–54, and presented for oral discussion at the insulation co-ordination session of the summer convention, Milwaukee, Wis., June 25, 1937.**

**H. L. Rorden:** See discussion, page 1291.

**V. M. Montsinger** (General Electric Company, Pittsfield, Mass.): I wish to comment on 2 points which apparently are not clear in connection with this report. One of the points is the "minimum time to flashover" given in column 8, table II.

The reason why a minimum time to flashover is specified is to prevent the use of a short rod-gap spacing for the chopped wave tests resulting in flashover in, say, 0.5 or 1.0 microsecond, where the impulse strength of insulation is considerably in excess of the strength for longer periods of time to flashover. This increase in strength of insulation is shown in a general way in the volt-time curve for transformer insulation given in figure 1.

The volt-time curve of insulation based on single shots has been fairly well established* and the values are as follows:

| Time to Breakdown (Microseconds) | Single-Shot Impulse Strength in Per Cent of Full-Wave Strength |
|---|---|
| 3 and longer | 100 |
| 2 | 105 |
| 1.5 | 112 |
| 1.0 | 125 |
| 0.5 | 150 |
| 0.25 | 190 |

The shape of the volt-time curve of insulation based on repeated shots (i.e., 100 shots or more at various time intervals) has not yet been definitely established. Some data are available and tests are now in progress. It is planned to give the results of the tests in a future paper.

The question of how the chopped wave test (110 per cent of the basic level) and the full wave test (95 per cent of the basic level) were arrived at has been asked since this report was published, indicating that their derivation is not clear. As pointed out in the report, the standard bushing level for distribution transformers is 5 per cent above the test gap level which has been in use for some time. Also, the level of power-transformer bushings above 69 kv is approximately 5 per cent above the test gap level. The present impulse test code specifies that in test (*b*) the bushing be flashed over at 5 per cent overvoltage. The maximum impulse voltage applied is, therefore, 10 per cent above the minimum full-wave flashover of the test gap.

Since the basic insulation level given in the EEI-NEMA report corresponds to the minimum full-wave flashover of the test gaps, the chopped-wave test should be 110 per cent of the basic insulation level.

The present test code specifies that the full wave must be not less than 90 per cent of the standard minimum flashover voltage of the standard bushings. Since the basic insulation level or test-gap level is 5 per cent over the standard-bushing level, the new full-wave test should be 95 per cent of the basic level.

To agree with the recommendations made by the subcommittee since this report was written, the 100 kv and 115 kv given in columns 3 and 4 of table II should be changed to 95 kv and 110 kv, respectively. The 110 kv given in column 3 of table III should be changed to 105 kv. The reason for this change is that the EEI-NEMA report has a footnote to table I, page 711 of the June issue of ELECTRICAL ENGINEERING, to the effect that consideration should be given to increasing by approximately 10 per cent, the basic level of 100 kv.

The 100-, 115-, and 110-kv values given in tables II and III, respectively (mentioned above) were based on a basic

*Figure 1, page 480, April 1937 issue of ELECTRICAL ENGINEERING, discussion of paper entitled "Dielectric Strength of Transformer Insulation," by P. L. Bellaschi and W. L. Teague.

impulse level of 105 kv instead of 100 kv in anticipating that the basic level would be increased later. It appears rather doubtful now that the 100-kv basic level will be changed.

In connection with the question of gapping bushings on which the report requests comments, now that the impulse test level will soon be expressed in kilovolts and the bushing will no longer be used as a voltmeter during the impulse test, there is no need for gaps on bushings.

However, as a protection to the bushing in those cases where other protective equipment is not provided, a gap may be used in the station to prevent flashover of the bushing and damage to the porcelain by follow current.

Since the volt-time curves of gaps and bushings are similar in shape the spacing of the gap should be at least 10 to 15 per cent below the ungapped-bushing positive-wave flashover, but not low enough to cause undue outages by flashover of the gap. The gap will provide protection to the bushing over quite a wide range of impulse waves. It should be understood, however, that a gap of this spacing will serve only as a protection to the bushing and cannot be depended upon to protect the winding from steep waves because the volt-time curve of insulation is relatively flat.

**J. R. North** (Commonwealth & Southern Corporation, Jackson, Mich.): This report presents a most excellent summary, both historical and factual, of the insulation strength of transformers and will be highly appreciated by the industry. It will serve not only as a valuable reference report, but will also eliminate confusion in the minds of those who have not been able to follow closely the developments which have taken place during recent years.

Discussion is invited regarding gaps on bushings. In our opinion, based upon experience and analytical studies, the manufacturers' practice of furnishing short rod gaps mounted directly on bushings is very undesirable and should be discontinued for the following reasons:

(*a*) These gaps tend to lead the arc directly along the porcelain and thus they represent a distinct hazard because of the possibility of damage to the porcelain and serious interruption in case of arc-over.

(*b*) These gaps give a false sense of security against lightning surges since the protection is limited to the gap flashover voltage and the volt-time characteristic of the gap may be widely different from that of the insulation to be protected.

(*c*) It is not always realized that care must be taken to insure that the low gap setting required to give some degree of protection does not cause unnecessary service interruptions during switching surges.

We agree, of course, with the thought that suitable lightning protective devices should be installed at stations to protect apparatus from lightning surges. However, these devices should be installed in such a manner as to give proper protection without jeopardizing service or equipment.

An interesting definition of a "directly grounded circuit" appears in the note at the bottom of page 749. We would like to inquire as to the derivation of this statement and how it relates to the values of sequence impedances and sound phase voltages to ground.

Referring to table II, it is believed that the test levels for distribution transformers should correctly be limited to ratings of 69 kv and below.

## Basic Impulse Insulation Levels

**Discussion of a paper by the EEI-NEMA Joint Committee on System Insulation Co-ordination, published in the June 1937 issue, pages 711–12, and presented for oral discussion at the insulation co-ordination session of the summer convention, Milwaukee, Wis., June 25, 1937.**

**V. M. Montsinger:** See discussion, page 1297.

**F. J. Vogel:** See discussion, page 1295.

**J. H. Foote** (Commonwealth & Southern Corporation, Jackson, Mich.): This report presents the basic insulation levels expressed in terms of voltage which were agreed upon as the result of a thorough study by the joint EEI-NEMA committee of apparatus performance records, operating conditions, and the characteristics of available lightning protective devices. The next step in the work of the committee is, as stated in the report, "specification of insulation strengths of all classes of equipment in the established insulation levels." It will be noted that a change is necessary in the wording of the scope of the committee, item 2, on page 711.

In presenting table I, "Basic Impulse Insulation Levels," an important note has been omitted. The basic levels are intended to be reference levels. A statement should therefore be included with the table to the effect that apparatus to be suitable for operation in the voltage classifications must have insulation which has an impulse strength at least equal to and presumably greater than the levels as expressed in kilovolts. Insulation strengths in excess of the levels are satisfactory.

In our opinion, the basic insulation level of 100 kv for the 15-kv classification should be raised approximately 10 per cent to a value of 110 kv to line up with the other levels and to properly fit with available lightning protective devices. The basic level of the 34.5-kv classification should also be raised from 190 to 200 kv, to be consistent with the immediately adjacent levels.

The first column of table I is entitled "Maximum Rated Voltage Classification." These named voltage classes are intended chiefly as indexes and the column should better be labeled "Present Standard Voltage Class" or some similar title.

The voltage classifications are those at present generally associated with these values. Basic insulation levels a step higher or lower than shown as associated with the voltage classifications may often be used. For example, where lightning arresters of less than full voltage rating can be utilized on systems having the neutral effectively grounded, insulation levels one step below the basic levels can generally be protected.

## Tests on Oil-Impregnated Paper—II

**Discussion and author's closure of a paper by Hubert H. Race published in the July 1937 issue, pages 845–9, and presented for oral discussion at the communication and research session of the summer convention, Milwaukee, Wis., June 25, 1937.**

**Herman Halperin** (Commonwealth Edison Company, Chicago, Ill.): It was of considerable interest to learn that high power-factor oil does not seem to mean correspondingly high power factor for the impregnated-paper insulation. We have found some increases in the power factor of core oil in the oil-filled cables in service in Chicago. The typical value of power factor of the core oil in new cable was about 2 per cent at 100 degrees centigrade. Since the lines have been in service, it has been found that typical values are about 0.8 and 5 per cent at 60 and 100 degrees centigrade, respectively. In some cases the power factors are higher; for example 15 per cent at 100 degrees centigrade. So far these power factors do not seem to be increasing after the changes occurring in the first few years of service, and there have been no indications of changes in the insulation from what tests have been made on short lines or from temperature measurements on other cable on longer lines.

It is hoped that the author is correct in his deduction that oxidized oil does not appreciably affect the life of samples which are gas-free. In tests on experimental oil-filled 132-kv cables, we have found in one case that changes did not occur until after 3 years of deterioration. Conclusions from this experience as well as from the observations of others, especially the English cable makers on their tests of one year and more, are that unusual phenomena may take a matter of several months or more to develop and give evidence of their presence by means of power-factor tests.

However, the quality of insulation should not be judged on the basis of life on voltage only. Doctor Race found that there is no apparent correlation between life and increase in power factor due to oxidation. In the practical operation of oil-filled cable, such excessive increases in dielectric losses and resultant decreases in carrying capacity can terminate the useful life of the cable without failures occurring.

The conclusion of the author about the longer life of gas-free oil-impregnated paper at one atmosphere as compared to similar cable with gas at pressures up to 200 pounds per square inch is of vital interest in connection with the discussions and tests during the past several years on the various gas-pressure types of cable to operate at 180 or 200 pounds per square inch. The implication of the author's conclusion is that oil-filled cables installed in the regular manner are preferable to these other types of cables

In interpreting these results, it should be kept in mind, however, that the miniature samples do not represent truly pressure-type cables. In the Hochstadter-Bowden-Vogel pressure cable and the Henley gas-cushion cable, and in some other types, the insulation is impregnated with a heavy, degasified compound, and the insulation is not in direct

contact with the gas. In Doctor Race's samples the oil is thin and gas-saturated and is in contact with the gas space. Most of the samples tested under gas pressure were surrounded by a gas space while the degasified samples were surrounded by a large oil volume. It appears that the difference in heat conductivity of the surrounding media might have influenced the test results. It should also be kept in mind that gaseous ionization is depending on both pressure and stress. While 200 pounds per square inch might not be sufficient at the stresses used in the accelerated life tests to prevent ionization, it might be quite sufficient at the lower stresses occurring in normal cable operation.

**G. M. L. Sommerman** (American Steel & Wire Company, Worcester, Mass.): In connection with the results for specimen 225, for which the saturant was a used oil from an oil-filled cable in service, Doctor Race states that high power factor of oil does not mean correspondingly high power factor of oil-impregnated paper. From figure 2 it is seen that the oil power factor when first measured at 100 degrees centigrade was 0.15, but after heating to 115 degrees centigrade the power factor at 100 degrees centigrade was 0.12. This suggests that part of the high measured power factor of the used oil was due to the presence of moisture or other impurities which could be volatilized, and that the power factor of the oil was much less than that indicated, probably less than 0.05 at 100 degrees centigrade, after the vacuum treatment in the impregnation process. The writer reported (ELECTRICAL ENGINEERING, 1937, page 572) a relationship between power factor of oil and power factor of impregnated paper, but it is necessary to consider the power factors of the vacuum-treated oils in order to obtain this correlation.

The conclusion that high power factor of oil-impregnated paper does not necessarily mean short life as long as temperature equilibrium is maintained confirms a similar conclusion reached by Professor Whitehead (AIEE TRANSACTIONS, 1933, page 1011). Also, in a previous discussion (ELECTRICAL ENGINEERING, 1936, page 1141), the writer pointed out that dielectric loss has no bearing on cable insulation life, unless the insulation loss is comparable with the maximum allowable conductor loss.

The comparison between the life of gas-free, oil-filled cables and the life of compressed gas-filled impregnated cables is dependent on the test conditions, because the life of gas-filled cables is very markedly dependent on the electric stress for stresses in excess of that necessary to initiate gaseous ionization. For the test specimens used by Doctor Race and a test voltage of 22 kv, the stress on a gas film at the conductor surface would be about 1,100 volts per mil if the conductor were smooth; it is actually even greater due to the fact that the conductors are threaded. The breakdown strength of thin films of carbon dioxide or nitrogen under 200 pounds per square inch pressure is about 800 volts per mil. It is therefore indicated that considerable gaseous ionization occurred in testing the specimens which were drained and saturated with compressed gas. If these specimens were prepared with smooth conductors and tested at a voltage of 13 kv (average stress of 200 volts per mil), they probably would last indefinitely.

**Hubert H. Race:** The first sentence of the second paragraph of Mr. Halperin's discussion is a misstatement of the conclusions drawn from the data presented. While the oil used to impregnate specimen number 202 had high power factor we have no evidence that it was oxidized, and precautions were taken using an evacuated reservoir so that the oil was not in contact with air at any time. Its high power factor was probably caused by asphaltic varnish dissolved from the tape used in making the joint from which it was drawn. The interesting points learned from this specimen are that the power factor of the impregnated paper was much lower than that of the oil alone (see figure 2), and that its stability was good and its life relatively long (150 days at 22 kv and 123 days at 30 kv. See figure 1).

On the other hand, specimens numbers 201 and 202, which were gas free but were impregnated with preoxidized oil, showed less stable life histories and very much shorter life than any other specimens in this group (see figure 1). Also, table VIII shows that upon post-mortem examination, the oil-impregnated paper from specimen number 202, containing preoxidized oil, was much more nonuniform and had from 2 to 10 times the dielectric loss of specimen number 225, containing used oil. It seems to me that these data contradict Mr. Halperin's statement.

I agree with the first and last sentences of the third paragraph of Mr. Halperin's comments—that, from the point of view of the operator, high power factor with its attendant power losses and decrease in current carrying capacity is important. However, for our miniature tests the second sentence of this paragraph is misleading in that as far as is experimentally possible all specimens in the third group were oxygen free, being completely sealed after drying and evacuation to 0.1 micron pressure. Therefore, deterioration during life was not comparable to conditions which might exist in a cable in service if air is accidentally entrapped during installation.

Regarding the last paragraphs of both Mr. Halperin's and Mr. Sommerman's comments, I doubt whether small differences in thermal conductivity had any appreciable effect on life since we have found little difference between tests on gas-free specimens at 60 degrees centigrade and 100 degrees centigrade. Gaseous ionization is certainly a function of both pressure and stresses and it is probable that for any pressure there is a gradient below which little ionization will occur. To say the least, it seems to me that our tests show that the gas-free, oil-filled systems have a higher factor of safety than any gas saturated system up to 200 pounds per square inch pressure, which is the limit of our experimental experience.

Regarding the first paragraph of Mr. Sommerman's comments, I agree that the difference between heating and cooling points in figure 2 was probably caused by the removal of moisture. The point illustrated by this specimen is that the power factor of impregnated paper may be much lower than that of the oil with which it is impregnated. This depends upon the physical properties of the paper and upon the nature of the material in solution or in suspension in the oil causing its high conductivity. In this case I believe the solute was asphaltic varnish, as already mentioned.

# The Dielectric Strength of Noninflammable Synthetic Insulating Oils

**Discussion and author's closure of a paper by F. M. Clark published in the June 1937 issue, pages 671–6, and presented for oral discussion at the communication and research session of the summer convention, Milwaukee, Wis., June 25, 1937.**

**E. J. Rutan** (Consolidated Edison Company of New York, Inc., New York, N. Y.): It may be desirable to present data from an investigation being carried on as part of committee work in the ASTM on the breakdown voltage test method for synthetic insulating liquids. The present procedure requires 5 breakdowns on each cup filling. For synthetic liquids this may lead to reporting reduced values as seen from the accompanying figure.

The author does not state the details of his test procedure. It might be well if he did so as regards the number of shots and number of fillings in arriving at values of dielectric strength.

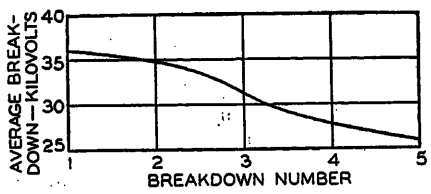

**Figure 1. Dielectric-strength tests on 80 fillings of new and used Pyranol, 1934–35**

Relative breakdown voltage of each of 5 succeeding breakdowns on the same filling of the test cup

**Herman Halperin** (Commonwealth Edison Company, Chicago, Ill.): While this paper presents very interesting information, it leaves unanswered important questions regarding power factor, thermal properties, and chemical characteristics. It is true that these properties are not within the scope of the paper, but in connection with oil-impregnated paper insulation these properties may be of greater practical importance in some instances than dielectric strength.

It is stated that the Pyranol compounds are mixtures prepared to give the desired physical characteristics for various purposes. No data are presented to show that the results of the one mixture covered in the paper are representative for the various Pyranol compounds, or to show the effect of composition on dielectric strength.

Since the dielectric strength of mineral oil is largely dependent on treatment, the differences in dielectric strength shown between Pyranol and transformer oil might for some types of oil with proper treatment be

reduced to practically zero. The author's information, however, does indicate that the Pyranol will retain its dielectric strength better than mineral oil.

The oxidation stability of Pyranol is emphasized, however, on the basis of figure 2. It is known that, for at least mineral oils, dielectric strength is not a reliable criterion of oxidation, and more information on this matter for Pyranol would be of interest. For impregnated-paper insulation, it has been found that the short-time breakdown tests are not a reliable criterion of the performance of the insulation in service. Long-time data would be of interest and value.

**V. M. Montsinger** (General Electric Company, Pittsfield, Mass.): I wish to discuss this paper from the standpoint of using noninflammable synthetic liquid in power transformers.

While up to the present time this synthetic liquid has been used mostly in distribution transformers, 500 kva and less, there is an increasing demand and application in power transformers. Up to the present time the General Electric Company has built a total of approximately 60,000 kva of power transformers using the noninflammable synthetic liquid. Approximately 80,000 kva more are under construction.

One particularly suitable case is where transformers are used in electric cars and locomotives where light weight and small dimensions are essential and noninflammability is important. In the past, locomotive transformers of the air-blast type have been used but they were not entirely successful, as it is difficult to keep dirt and moisture out of the coils. Space limitations prevent using factors of safety high enough to take care of these impurities that get into air-cooled coils, and as a result these transformers have not been immune from failure. Since, for a given spacing, a synthetic liquid (or oil) gives from 3 to 4 times the dielectric strength of air it can readily be appreciated what a noninflammable liquid means in the way of improvement in the design of locomotive transformers. It not only enables one to build a transformer with greatly increased dielectric strength, but makes it possible to maintain this high strength during its entire life. Several such transformers are already in service and the indications are that their use will rapidly increase.

There are also some other cases where a synthetic noninflammable liquid can be used to advantage in power transformers, namely, where the use of an inflammable oil is impractical or forbidden and the voltage is too high for transformers of the air-blast type. In such cases on account of the high cost of the liquid, great pains are taken in the design to reduce the amount of liquid required to a minimum. This minimum liquid space is obtained by the use of a design of tank which reduces the amount of liquid to a minimum. The additional cost of the tank is more than offset by the saving in the amount of the noninflammable liquid.

There are, of course, means of using nonabsorbent high-dielectric-strength materials to displace some of the expensive liquid, provided sufficient clearance is left to allow the necessary flow of oil to carry the heat from the core and coils to the cooling tank surface. Laboratory investigations have shown that the amount of liquid necessary to dissipate the heat is very much less than the amount ordinarily required to fill the transformer.

The broad use of this noninflammable liquid in power transformers for general purposes depends largely upon 2 important factors.

1. Lower cost resulting from improved technique and skill in manufacture of the liquid and from its use in larger quantities.
2. Means for making further reductions in the amount of liquid required in a given transformer.

Both of these developments are being pushed aggressively.

There is no question but that the time is coming when all power transformers will be built with a noninflammable synthetic liquid.

**L. J. N. Mothersill** (Philco Products, Ltd., Toronto, Ont., Canada): Mr. Clark publishes a comparison of 40 capacitor sections with mineral oil and with chlorinated hydrocarbon impregnant subjected to a stress of 733 volts per mil. What percentage of the conservative working stress is this value in the application of these liquids to (*a*) transformers, (*b*) cable, (*c*) capacitors? In computing probable life of capacitors from accelerated life test at higher than rated voltage it is customary to employ an inverse power relation which has been stated at anywhere from the inverse of the fourth to eighth power of the applied voltage. What exponent is suitable with these liquids and does the author favor direct current or alternating current for such life testing? I would be interested in the drying and impregnation times of the samples.

In a paper published by Jackson, *Proceedings* of the Royal Society, volume 153, the temperature power-factor characteristic of chlorinated diphenyls is reviewed and the power factor shows a decided hump near the solidifying point of the compound and also a decrease in the dielectric constant. Is this general with this type of liquid dielectric? This would appear to affect operation of capacitors in cold climates considerably. It would be of interest in the corona test procedure to know if the foils protrude from the ends of the section (i.e., if they are staggered to give the so-called noninductive winding)? Is the capacitor tissue employed of standard or of special quality and what is the relative value of super calendered and more porous papers? The writer has had some experience with the application of solid chlorinated compounds as capacitor impregnants and would be interested in comparison of the newer liquid impregnants with, say, chlorinated naphthalene. In matching paper and impregnant dielectric constants is it advisable to utilize a paper with high constant but also with accompanying high power factor? These points of discussion apply to cable and to capacitors as well as to transformers in a lesser extent but in the capacitor the stress effect is more easily segregated from temperature effects and that is the reason for approaching the discussion from this angle.

In connection with the chemical stability, the writer has noticed that chlorinated naphthalene gives rise to serious erythema on skin exposed to vapor or solutions of the wax. Is this experienced with the Pyranol type of compound?

**E. W. Greenfield** (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): The dielectric properties of these chlorinated derivatives of cyclic organic hydrocarbons as reported by Mr. Clark are exceedingly interesting. Three characteristics are outstanding, namely, high initial dielectric strength, high chemical stability (as based on dielectric strength measurements), and high dielectric constant.

Although we have occasionally noted dielectric strength of clean dry mineral transformer oil as high as 40 kv (ASTM), there appears to be little doubt from the figures reported by Mr. Clark that the synthetic dielectric liquid possesses a consistently greater electrical strength. It is suggested that the basis of this difference lies in the relatively greater specific gravity and thermal conductivity of the synthetic liquid rather than in a greater ionization potential of the molecule. The conventional dielectric strength tests on oils involve both electric and thermal effects so that impulse dielectric strength testing would be highly desirable in determining the cause of the observed phenomena.

Of the 2 synthetic dielectric liquids studied, Mr. Clark describes a "viscous" type which is indicated as being commercially available for use as a cable saturant. It is assumed from the nature of the data that this synthetic cable saturant is offered as a possible substitute for unsynthesized oils in high-voltage impregnated-paper cables and as such may present certain advantages. Several remarks concerning this use of the new liquids are pertinent.

Table I giving certain physical properties of the viscous synthetic liquid shows a viscosity at 210 degrees Fahrenheit of only 48 seconds (S.U.). This would indicate that the liquid is much less viscous than those saturants normally associated with solid type cable which have viscosities in the neighborhood of 100 to 150 seconds (S.U.) at the same temperature. From the same table I, the pour point of the synthetic liquid is given as +10 degrees centigrade (50 degrees Fahrenheit) which would immediately exclude its use from the field of oil-filled cables, the saturant of which must be limpid at all service temperatures. However, the situation is not as incompatible as at first apparent. From the standpoint of the solid-type cable and its own particular problems, the flow characteristics of the synthetic liquid may be such as to provide a low impregnating viscosity and a high viscosity over the operating temperature of the cable. These features might be desirable, particularly in the so-called "nonmigrating compound" cable applications. However, there is no indication from table I what the flow characteristics are and it is to be hoped that Mr. Clark, in his closure, will present a viscosity-temperature curve of the synthetic liquid under discussion. Data on surface tension and wetting characteristics would also be valuable.

Oxidation stability of cable saturants is normally evaluated on the basis of accelerated aging in the presence of air at high temperature. Of all the dielectric properties studied, dielectric strength is the

least sensitive to the chemical changes taking place during aging whereas power factor is perhaps the most sensitive. This is also apparent from figure 1 for transformer-type oils at least over a period of the first 20 days. It is to be regretted that power factor measurements were not made during this same period since any difference in induction phenomena would have been easily apparent.

By increasing the dielectric constant of the saturant, the synthetic-liquid-impregnated papers present a more equitable distribution of stress. The increase in dielectric strength of the laboratory samples when impregnated with the synthetic liquid is probably a result of this more uniform stress distribution in combination with the higher dielectric strength of the saturant. However, it must be pointed out that, in the absence of any description of the test cell or test conditions, no comparisons can be drawn from these results with actual thick-wall cable conditions. In long-life tests of cable samples, dielectric energy loss and gaseous ionization are most important factors. In cases where gaseous ionization may be present, the increased dielectric constant of the saturant may place a heavier stress burden on the vacuous or gas phases, thus lowering the initiating ionizing potential of the entire cable. This, in combination with a high over-all dielectric constant (and generally accompanying high power factor), may place the synthetic liquid saturated cable in a disadvantageous position. Although high dielectric strength of the impregnated paper material as such is desirable, it by no means can serve as a criterion for the quality and stability of the power cable.

**F. M. Clark:** In considering the characteristics and industrial application of new types of dielectric compounds, the attempt is frequently made to evaluate the new materials from the standpoint of the experience accumulated in applying the older type of compounds which are to be replaced. This frequently leads to confusion and error since many of the ideas developed from experience with the older compounds apply only to such compounds but are often accepted as generalizations of fundamental value. Such an evaluation is to be particularly avoided when the chemical type of compound is so radically changed as in the subject matter of the present paper, wherein the oxidizable hydrocarbon molecules of mineral oil are considered in comparison with the nonoxidizable molecules of chlorinated aromatic hydrocarbons. It is particularly unfortunate that space would not allow me to discuss the dielectric loss characteristics of the compounds presented in this paper. To discuss adequately the dielectric properties of these compounds other than the dielectric strength is also impossible in my closure. I prefer rather to present the data concerning the dielectric loss and dielectric constant characteristics of these materials in a separate paper at some future date.

Mr. Rutan asks whether the dielectric strength data represent single-shot values or the average of a series of tests. All dielectric strength data presented in the paper are the average of a series of 5 tests for each filling of the dielectric-strength test cup. In each case, 3 distinct samples of the dielectric liquid were tested and the total of 15 dielectric test "shots" was averaged. The testing procedure is in accordance with the usual commercial and ASTM practice. In testing the dielectric strength of any liquid carbonization results with each arc-over, the amount of carbonization depending upon the period during which the electric arc is allowed to play. In the test setup used in the present paper, the arc duration is reduced sufficiently in time such that the tendency of a single sample to drop in dielectric strength from the first to the fifth "shot" has been eliminated. With longer time of arc duration, the tendency described by Mr. Rutan is recognized to exist. This drop, however, involves atmospheric conditions of humidity and is most pronounced with increasing water content in the air in contact with the liquid under test.

I appreciate the comments of Mr. V. M. Montsinger. His enthusiasm concerning the commercial possibilities in these liquids strengthens my own. Materials such as described, characterized by a high and permanent dielectric strength, nonoxidizable and of high dielectric constant, possess highly desirable dielectric characteristics.

The 733 volts per mil used in the long-time tests referred to by Mr. Mothersill represent approximately twice the normal working stress of capacitors and a considerably higher ratio to the average working stress of oil-filled cables. In the case of transformers, the usual working stress is considerably lower because of design differences. It is probably possible to predict more reliably the relationship between commercial life and higher-than-rated-voltage short-time life test results under laboratory conditions, using the chlorinated-hydrocarbon-impregnated insulation, than with mineral-oil-treated insulation. This follows because of the chemical stability of the chlorinated hydrocarbon as compared to the susceptibility of mineral oil to change. However, the value of such a relationship, especially for mineral-oil-treated insulation, may well be doubted. Sufficient data are not available in the case of the chlorinated-hydrocarbon-treated insulation to warrant a statement at this time. Furthermore, it is to be observed as stated in the publication that the dielectric failures with the chlorinated-hydrocarbon-treated insulation are so infrequent that no attempt is warranted to establish an empirical relationship between the 733 volts per mil and commercial ratings. The dielectric assemblies referred to were dried at 100–105 degrees centigrade under a pressure of less than 300 microns over a period of 48 hours, after which they were impregnated with the insulating liquid over a period of 24 hours, during which the whole assembly was kept under heat and vacuum after which the assemblies were cooled to room temperature under vacuum while immersed in the treating liquid.

Mr. Mothersill refers to a publication by Jackson in which it is described that the power factor had "a decided hump near the solidifying point." This change is not peculiar for the chlorinated hydrocarbons but occurs with all liquids undergoing a change in state. The actual temperature at which it occurs with mineral oil depends upon the physical characteristics of the oil. We have never found that the changes as described by Jackson are at all effective in determining the dielectric strength and permanency of the chlorinated-hydrocarbon-treated insulation.

All tests for corona formation were made with electrode arrangements in which the edges of the electrodes were practically superimposed. The dielectrics in all cases were of standard commercial quality with no special preparation. It is impossible to compare the dielectric characteristics of chlorinated naphthalene with those of the newer liquid impregnants as requested by Mr. Mothersill. The chlorinated naphthalenes of best dielectric characteristics are high-melting solids limited in their voltage application because of crystalline tendencies. The liquids have the advantage of being able to be operated at higher voltage stresses because of the absence of void formation, the usual accompanying feature of crystalline formation in solids.

Mr. Mothersill requests information concerning the relative toxicity of chlorinated naphthalenes and the chlorinated hydrocarbons described in the paper under discussion. Conclusions concerning this point must be postponed until investigations now in progress have been completed. In the work with which I am familiar, no serious erythema has been encountered.

The present paper describes the dielectric characteristics of blends of chlorinated hydrocarbons and single component mixtures. It has been found that blends in general show the same dielectric-strength characteristics as exhibited by the individual components.

In the dielectric-strength data of the paper, no special treatment has been given either the mineral oil or the chlorinated hydrocarbon aside from the usual commercial preparation. Mr. Halperin's speculation that the differences in dielectric strength between the chlorinated hydrocarbons and the transformer oil mixtures "might be reduced to zero with proper treatment" does not appear to be substantiated in fact.

Figure 2 referred to by Mr. Halperin was in no sense given as an indication that dielectric strength was a criterion of oxidation. Figure 2 was given to demonstrate the ability of the chlorinated hydrocarbon to retain its dielectric strength even under the most severe water-contaminating conditions. It is recognized that low dielectric-strength values are the inevitable result of water contamination in mineral oil.

In answer to many of the comments of Mr. E. W. Greenfield, I refer him to an article entitled "Nonflammable Dielectric Organic Compounds," published in *Industrial and Engineering Chemistry* for June 1937, pages 698–702. The accumulated evidence tends to indicate that the dangers arising from the ionization of trapped gas pockets are materially reduced by the use of chlorinated-hydrocarbon liquids. Whether or not a gas pocket will form in insulation depends upon many factors involving the physical characteristics of the impregnating liquid and the solubility of gases therein. The characteristics of the chlorinated hydrocarbon liquids described in the present paper on the basis of experience seem particularly well adapted to eliminate or reduce the ionization dangers which have been the subject of so much investigation and concern in oil-treated dielectrics.

# Properties of Saturants for Paper-Insulated Cables

**Discussion and author's closure of a paper by G. M. L. Sommerman published in the May 1937 issue, pages 566–76, and presented for oral discussion at the communication and research session of the summer convention, Milwaukee, Wis., June 25, 1937.**

**Herman Halperin** (Commonwealth Edison Company, Chicago, Ill.): This paper gives some excellent information on the properties of cable saturants with and without resin added. The data show that the addition of suitable resin to some oils improves the aging properties considerably without deleterious effects on other properties. I was particularly interested in noting that the resultant impregnated-paper insulation had low dielectric losses.

The author's work has in general been carried up to the temperature of 85 degrees centigrade. We have established emergency ratings for cables operating at 4 kv to 33 kv in Chicago based on maximum allowable temperatures ranging from 90 degrees to 105 degrees centigrade, depending on the cable. Although such operation is not expected to occur in more than one day every year or every few years for a given line, yet it seems that the author's work would have been of a little more interest if his temperatures had been carried above 85 degrees centigrade.

Mr. Sommerman found that the stability of naphthenic oils might be improved if better methods of refining them were used. Interest in insulating oils on the part of oil refiners has increased recently and data of this kind should expedite the procurement of better oils. It is indicated that naphthenic oils are more stable to gaseous ionization than paraffinic oils but are less stable to oxidation. In cable insulation of the ordinary or solid type, some void spaces are certain to occur incidental to manufacture and to installation and operation, and stability to gaseous ionization in high-voltage cable is of great importance. The initial losses in cables now being manufactured are low and slight increases due to oxidation, although not desirable, are less important than increases in losses due to ionization because the small amount of available oxygen can be consumed, but the changes due to ionization may be cumulative. At present, it appears, therefore, that long life and best over-all economy will be gained by emphasis on immunity to effects of ionization at the expense, if necessary, of some loss in oxidation stability.

**Wm. A. Del Mar** (Habirshaw Cable & Wire Corporation, Yonkers, N. Y.): Two types of saturants are now in use in American paper-insulated cables one a naphthenic base oil of tacky consistency and the other a paraffin base oil mixed with rosin.

Cable users naturally wish to know which is the better saturant and why some manufacturers use the pure mineral oil, while others use the rosin blend.

I do not think that the time has come to make a final decision between the 2 types as there is not enough difference to permit a completely logical choice to be made. The prospects of improvement are brighter while the 2 types are both available, as this condition leaves open 2 avenues of development, rather than one.

The case, as I see it, may be summarized as follows:

ARGUMENTS FOR NAPHTHENE-BASE OIL

1. It does not leave deposits in the tanks and pipes and thus saves expensive and time-consuming cleanings, which are necessary with rosin blends. However important this may be to the manufacturer, it does not affect the cable user.

2. It gives somewhat lower initial dielectric loss at high temperatures, i.e., above 60 degrees centigrade.

ARGUMENTS FOR PARAFFIN-BASE OIL BLEND

1. Ability to maintain a constant initial quality by blending oils from several sources of supply. This is not practicable with the tacky naphthene-base oil.

2. Less susceptibility to oxidation, as shown by Doctor Sommerman.

3. Less migration of saturant, due to greater viscosity.

4. Somewhat greater stability when subjected to electrical discharge in vacuo.

Our research laboratory has made a series of load-cycle life tests to compare cables made with the 2 types of saturants and found little difference, such difference as

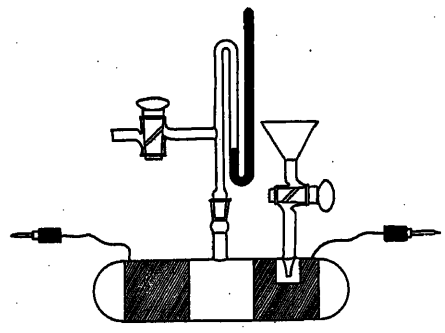

**Figure 1. Oil stability tester**

there was being consistently in favor of the rosin type. This finding is substantiated by data given by Halperin and Betzer, ELECTRICAL ENGINEERING, October 1936.

The laboratory also made tests of electrical stability in the presence of electrical discharges in vacuo, taking as starting point the work of Z. W. Nederbragt, referred to as number 10 in Doctor Sommerman's bibliography.

This test is based on the well-known fact that insulating oils may give off gas, chiefly hydrogen, under the influence of electric discharge. To determine how various compounds compare with each other in this respect, we have arranged a test set wherein a sample of a given oil is degassed to a constant pressure (1.0 millimeter mercury absolute) in a discharge tube, and then subjected to a glow discharge. The amount of gassing is then measured by the pressure rise in the tube, as indicated by a mercury manometer. The sample is tested for power factor and resistivity before and after exposure to the electrical discharge.

Figure 1 shows the oil stability tester or discharge tube. It is similar to Nederbragt's discharge tube but has added the funnel, stop-cock, and nozzle, shown to the right. These make possible a closer control in the preparation of the oil sample to be tested, it having been found that the rate of gas evolution is greatly affected by the degree of degassification of the oil, as well as by the initial vacuum. The electrodes consist of tin foil wrapped around the outside of tube at each end. Quoting Nederbragt:

"On its way from one tin-foil coating to the other, the current passes through the glass as a displacement current, then as an electron, and ion current through the gas space, and finally again through the glass. A small portion of the current passes through the glass where this is covered with oil and therefore also passes through the oil as a displacement current."

The electrical circuit is shown in figure 2.

A current of slightly under a milliampere is passed through the apparatus with a voltage of about 15,000. We used 60-cycle voltage as being nearer to practical conditions than Nederbragt's 7,500 cycles. The oil becomes agitated and foams, evolving gas and depositing a filmy residue of cable wax.

Typical results are shown by figure 3 in which curve *A* represents a paraffin base oil with 15 per cent rosin. Curve *C* represents the same oil without rosin. Naphthene base oil, as used in solid type cables, gave curves that coincided substantially with curve *C* except that there was less downward tendency at the right-hand side. In other words, the 2 pure oils were substantially equal. The addition of rosin improved the paraffin oil.

Oil-filled-cable oil shows less than half the gas evolution of oil *A*. The oil now used by all the oil-filled-cable makers is the same and has proved to be the best, from the standpoint of gas evolution, of any oil so far tested. There are, however, prospects of improvement.

The different types of failure which occur on load-cycle life test have been puzzling, as have the irregularity of results on apparently identical cables. It is hoped that these oil tests will throw some light on this problem. The apparent irregularities may turn out to be the results of a race between gas evolution and rising power factor. The stability of power factor and resistivity promises to be as significant as gas evolution but we are not yet prepared to make any report on it.

This work is in active progress and it is impossible to predict what will come out of it. We hope, however, to be able to publish more details in the course of a few months.

**L. J. Berberich** (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): In the last 10 years there has been

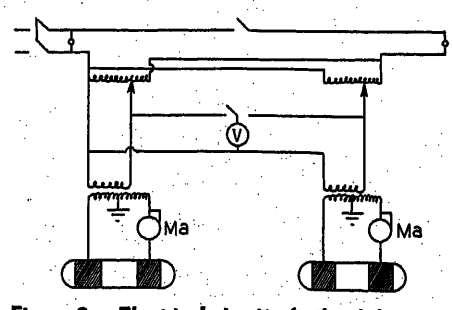

**Figure 2. Electrical circuit of oil stability test set**

considerable controversy over the use of rosin in cable saturants. The proponents and opponents of rosin are about equally divided. The reason for this division of opinion is perhaps twofold: (1) Whatever investigations of the effects of rosin that have been made were sketchy and did not cover the action of various types of rosins in various types of oils, and (2) the effects of rosin in terms of cable life have not been conclusively shown. Thus, it is encouraging to see Doctor Sommerman's paper,

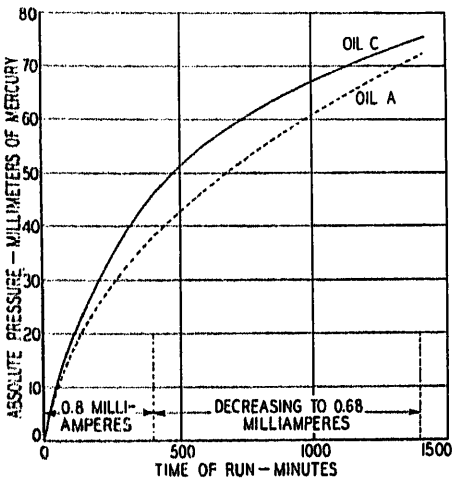

**Figure 3. Oil stability tests**

Temperature 35 degrees centigrade
Initial pressure = 1.0 millimeter of air

which reports for the first time the results of a careful, wide-range investigation covering various types of oils and rosins. Although the results indicate that a purified rosin compounded with the proper type of oil should result in better cable performance, yet definite proof of this is still lacking.

The addition of rosin to cable oils in the past by some manufacturers was encouraged perhaps because it was found that rosin increased the viscosity of the saturant and thus reduced migration, and that it showed some oxidation inhibition. This was done, however, at the expense of increasing the saturant power factor. More recently, however, purified forms of rosin have become available and, as Doctor Sommerman shows, these can be added to mineral oils with little or no increase in saturant power factor

Rosin is believed to be active as an oxidation inhibitor because it itself is easily oxidized, that is, it consumes the oxygen dissolved in the saturant through the phenomenon of antoxidation. Apparently, however, its oxidation products have less effect on the cable power factor than those of mineral oil. The results of Piper, Thomas, and Smith[1] may provide an explanation for this. These investigators have shown that only low molecular weight oxidation products increase the power factor of impregnated paper to a significant extent, apparently because such products are selectively sorbed by the paper. Mineral oil appears to form more low molecular weight oxidation products than rosin does. Rosin itself is a mono-carboxylic acid and because of the peculiar nature of the compound and its high molecular weight, it does not contribute to the saturant power factor when freed of impurities.

Doctor Sommerman also shows that rosin decreases the wax formation for all types of oils studied when they were subjected to gaseous ionization. The writer has found in studying the gas evolution from oils in a low-pressure gaseous discharge that rosin actually increased the gas evolution from low-viscosity-index oils, while for oils of higher viscosity index, the gas evolution was decreased. It was also found that oils of low viscosity index formed considerable quantities of wax and very small amounts of gas and the reverse was true of oils of high viscosity index. This is corroborated by the work of Linder[2] who showed that for pure organic compounds the wax formed decreased as the hydrogen to carbon ratio of the compound increased. In other words, he found that the aromatic type of compound tended to polymerize to a waxy solid with little gas evolution while the paraffins formed little wax and considerable amounts of gas. This does not agree with figure 13 of Doctor Sommerman's paper. Thus it is suggested that in evaluating stability to gaseous ionization, both gas evolution and wax formation should be determined. In the writer's opinion, gas evolution is perhaps more dangerous than wax formation. The wax formed is a fair insulator and results in no serious harm, but the gas may spread throughout the cable and initiate more gaseous ionization which may become cumulative.

In analyzing the oils studied, Doctor Sommerman has listed 3 basic constituents; namely, "paraffinic," "naphthenic," and "residual." Although used in petroleum technology, the term "paraffinic" as related to molecular structure is a misnomer. All oils in the lubricating oil range which have been freed of wax contain no straight chain paraffins. Paraffins having molecular weights equivalent to those of cable oils or even transformer oils, would be solid at room temperature. Petroleum chemists now have evidence that the major portion of the heavier petroleum fractions are polycyclic naphthenes or cycoparaffins with varying lengths and numbers of paraffin side chains. In oils of high viscosity index, the side chains are numerous and long enough to dominate and in the low-viscosity-index oils, the naphthenic nucleus dominates since the side chains are probably small. Oils of very low viscosity index (below 0) contain considerable percentages of aromatic or benzenoid type of hydrocarbons again modified by side chains. This accounts for the steep slope of the viscosity-temperature curve of such oils. The problem of determining the structure of petroleum is exceedingly difficult because the various constituents lie so close to each other in physical and chemical properties that even the most refined methods of separation have failed to result in the isolation of individual compounds.

The data given by Doctor Sommerman should be of assistance to both the refiner and to the cable manufacturer.

**G. M. L. Sommerman:** Mr. Halperin raises the question of the relative importance of oxidation stability and stability to gaseous ionization for cable saturants. The importance attached to oxidation stability varies greatly among different cable engineers and it has also fluctuated up and down, during the past 10 years. Only 2 or 3 years ago, the importance attached to oxidation stability was very high as evidenced by the number of researches started, and patents applied for on this subject. Just recently it has dropped to a rather low value. The true value is probably somewhere in between, especially when the cable manufacturing requirements are included in the consideration. Some oils possessing excellent stability to gaseous ionization are so poor in oxidation stability that it is impracticable for a cable manufacturer to use them as straight oils. The addition of 15 per cent improved resin to these oils increases the oxidation stability to a value exceeding that of the oils most stable to oxidation; at the same time the stability to gaseous ionization is increased to a value exceeding that of the oils most stable to gaseous ionization.

It may be noted that the increased oxidation stability imparted by resin additions which was observed in the tests of saturants alone is also evident in aging tests of impregnated paper.

Mr. Halperin states that for reasons involving emergency loadings on cables he is interested in power factor values at temperatures as high as 90 to 105 degrees centigrade (these temperatures are 20 degrees centigrade higher than maximum cable operating temperatures). Data at these higher temperatures were obtained on a number of samples, and these indicate that the power factor-temperature curves in figures 4, 5, and 6 may be extrapolated reliably to 105 degrees centigrade. If a measuring temperature somewhat above 85 degrees centigrade had been employed in the aging tests reported in figures 8 to 11, all the power factors would have been larger in nearly the same proportion, and the same comparisons and conclusions would have been obtained.

The writer is glad to note Mr. Del Mar's confirmatory evidence that the addition of rosin to a paraffin base oil reduces the gas evolution in gaseous ionization tests. The publication of his results on power factor stability in such tests will be awaited with interest.

Relative to the importance of wax formation of saturants exposed to gaseous ionization, mentioned by Doctor Berberich, it may be said that excessive wax formation must be avoided because the wax would interfere with the free radial movement of the saturant in the cable caused by load cycles. This radial movement is necessary for proper operation of cables.

Concerning the form of the wax formation versus viscosity index curve of oils (figure 13), it was recognized in the paper that the wax test results were not conclusive for the 2 oils of lowest viscosity index, and that the wax formation for these oils might actually be higher than that for oils of intermediate viscosity index. For oils in the lower viscosity index range, the behavior would be in accordance with Berberich's suggestion. For oils in the higher viscosity index range, however, the writer

observed that the wax formation as well as the gas evolution increased with increasing viscosity index. For these oils, the percentage of aromatic constituents is small in all cases, and the observed behavior may be due to a dependence on the degree of predominance of open chain groups or ring groups in the oil molecules, as suggested in the paper at the beginning of page 575.

## Oxidation in Insulating Oil

**Discussion and authors' closure of a paper by J. B. Whitehead and F. E. Mauritz published in the April 1937 issue, pages 465–74, and presented for oral discussion at the communication and research session of the summer convention, Milwaukee, Wis., June 25, 1937.**

**E. J. Rutan** (Consolidated Edison Company of New York, Inc., New York, N. Y.): In this paper the authors have attacked a problem which it seems has waited too long for definite data. Particularly interesting are the frequent straight-line relationships which their results develop. Examination of the data on acidity and saponification and its relation to power factor does disclose that the results depend on but a limited range. This is noticeable on figure 11 where one point seems to be used to determine a flattening of the curve. In figures 8 and 10 data are given for acidity number at 0.8 and 1.1 which when computed gives 2 additional points for figure 11 showing the curve to be flat when extended to higher acidity numbers.

In view of the fact that the authors state a change in the ratio of the type of acids is shown by figure 11 it is unfortunate that they did not measure power factor on samples having 0.8 and 1.1 acid number. This would have extended the curves in figures 12 and 13 and made the results more conclusive.

The writer would also like to inquire regarding the reliability of the electrometric acidity determinations. The authors discuss the method in considerable detail giving data on sensitivity and blank determinations but they do not state the limit of accuracy based on several checks of the same oxidation condition. This point is raised because in the ASTM a section has been working for several years on electrometric acidity methods but has been unable to recommend any method as yet as reliable although many methods have been investigated. It would be desirable to discuss this method because this paper will no doubt be referred to by many and the acidity method may be accepted without the necessary investigations.

To this writer the authors' conclusion number 5 does not seem reasonable. Usual experience with dielectric strength measurements on insulating oil in accordance with ASTM methods shows variations between samples of 3 kv which might be 10 per cent of the average. It does not seem reasonable therefore, to attempt to draw a curve through points of less than 1 per cent difference. In my opinion the authors should have plotted the measured values of breakdown voltage giving due consideration to the accuracy of the method. Thus their conclusion would have been that there is no noticeable effect of oxidation on breakdown voltage over the range investigated. It would also have been desirable if data for figure 16 had been carried to the higher acidity numbers. Comparison might be made between figure 16 and the mineral transformer oil results in figure 1 of the paper by F. M. Clark on "The Dielectric Strength of Noninflammable Synthetic Insulating Oils" (ELECTRICAL ENGINEERING, June 1937), which seem also to contradict the authors' conclusion number 5.

**Herman Halperin** (Commonwealth Edison Company, Chicago, Ill.): This paper is another stimulating addition to our knowledge of insulation as developed by Whitehead and his assistants.

It is remarkable and interesting to find that in most cases the authors show practically straight-line relations between the electrical and chemical properties. Several other investigators have failed to get such good agreement. It was especially remarkable that the power factor is proportional as well to the acid number as to the saponification number. It would be of interest to learn whether or not this proportionality still holds if the oil is allowed to form soaps. Our data and the data of some others indicate that the various oxidation products are quite different in their effect on the power factor.

Conclusion 2 is based on an inhibition period during which no carbon dioxide is formed and on figure 11. This inhibition period is in accord with some test results of R. W. Dornte (*Industrial and Engineering Chemistry*, volume 28, page 26, January 1936). Probably the high ratio of saponification number to acid number shown in figure 11 at low acid numbers is due to lack of sensitivity of the test for low acid numbers. This is suggested by the data shown in figure 10 indicating zero acid number initially. A slight change in the position of the line in figure 10 could flatten the curve of figure 11 toward a horizontal line.

**W. M. Goodhue** (Harvard University, Cambridge, Mass.): The paper raised a question in my mind concerning the comparison of oils from different sources. In the paper, a correlation between chemical and electrical properties is given for one oil and, as suggested by the authors, a similar correlation would probably be found if another oil were substituted. But this is not the same as saying that 2 oils from different sources can be directly compared electrically *if the independent variable is not time* but a chemical variable such as oxygen absorbed. The difficulty is that oil is not a chemical individual or even a single series of chemical compounds. The correlation between specific chemical and electrical properties would certainly depend on the proportion of compounds present among the different chemical series, and on the proportion of compounds present within a given series, as well as catalytic impurities. Therefore we have the likelihood of 2 dissimilar oils behaving with stability in reverse order compared to their electrical characteristics if a chemical independent variable such as oxygen absorption is used instead of time.

For example, in equation form, if

$$\text{oxygen absorption} = \alpha_1 t \text{ for oil number 1}$$
$$= \alpha_2 t \text{ for oil number 2}$$

where

$$t = \text{time}$$
$$\text{power factor} = \beta_1 t \text{ for oil number 1}$$
$$= \beta_2 t \text{ for oil number 2}$$

Then, on combining equations,

$$\text{power factor} = \frac{\beta_1}{\alpha_1} \times \text{oxygen absorption, for oil number 1}$$
$$= \frac{\beta_2}{\alpha_2} \times \text{oxygen absorption, for oil number 2}$$

Now with 2 dissimilar oils there is no assurance that $\beta_1/\alpha_1$ and $\beta_2/\alpha_2$ are in the same order as $\beta_1$ and $\beta_2$; therefore the change of variable in the power factor from time to oxygen absorption is unsafe, for the purpose of comparing the 2 oils concerning stability, that is in this case the increase of power factor with time.

Therefore I wish to insist that the chemical variables be used only for studying the performance of a single oil throughout its history. When comparing 2 oils, the fundamental variable of time must be used. The excellent curves employing time obtained by the authors themselves show that accuracy can be obtained in an oxidizing apparatus of specified surface areas and other dimensions. This is less empirical than employing a chemical variable instead of time, since with a chemical variable dissimilar oils are not even comparable.

The authors' contributions, however, are valuable, namely (1) a reliable test method for studying electrical properties versus time, under *standardized conditions* of exposure to oxidization and (2) methods of studying the chemical variables. Contribution 1 is suitable for comparing 2 dissimilar oils and contribution 2 is suitable for studying the improvement in manufacture of a single oil. Therefore what has been said in this discussion does not detract in any way from the value of the authors' work and, furthermore, may supplement it when applied to the question of standard testing methods for oils of unspecified origin.

**F. M. Clark** (General Electric Company, Pittsfield, Mass.): The paper by Whitehead and Mauritz describes a series of oxidation test results obtained with what is described as a "highly refined insulating oil as used in oil-filled cables." Data such as these suffer from the difficulty of interpretation and practical application. However, the continued accumulation of such data may eventually lead to the recognition of worthwhile relationships between the chemistry and the dielectric properties of mineral oils.

There is, however, an underlying thought in the paper which from my own experience demands further consideration because of the attempts which may be made to extend the idea beyond that specifically stated by the authors. This is the thought which is summarized in conclusion number 7.

Experiments in my own laboratory extending over a period of years tend to show that, when on oil of the type used in cables

and transformers is oxidized in the manner similar to that described by the authors, substantially the same results are obtained with regard to the linear relationships described. However, there are distinct exceptions to the linear relationship which appear unexpectedly as different oils are investigated or as the oxidation conditions are changed. Furthermore, even when the linear relations obtained by the authors are observed in a variety of oils, they are not of the same character. Although a linear relation between power factor and acid number or saponification may be obtained for 2 oils, the slope angle of the linear relation is rarely the same, indicating a different chemical value for the same power factor. It is because of such variations, which trace back to chemical differences in the oils tested, that but slow progress has been made in attempts to correlate chemical and electrical oil characteristics.

The usual method of estimating the suitability of consecutive shipments of impregnating oil from a definite source of supply is to study the physical and chemical properties of the oil, including an oxidation test and the effect of oxidation on the electrical properties of the oil. In such work, data such as that presented by the authors have been recognized as being of value in the detection of variations from the normal. Too often, however, such laboratory control-of-oil-shipment tests have assumed an importance out of all proportion to their original significance. Instead of being considered as tests to determine continuity of properties from one shipment to the next, they have come to be considered as of fundamental importance. This has led to widespread discussion of oxidation tests of all sorts. While it is true that no oil with abnormally low oxidation resistance would be looked upon favorably by a cable engineer, still the mere fact that an oil may have excellent resistance to oxidation, as measured by tests similar to those of the present paper, is no indication of its suitability for impregnation use. Many interested in the problem believe that just as the lubricating properties of an oil are to be evaluated best by actual test in contact with the bearing metal, so the suitability of an impregnating oil is to be determined best by examination under voltage and in a paper-impregnated assembly. I therefore caution against attempts to extend the conclusions of the authors, especially conclusion number 7, to the extent that such studies are to be interpreted as providing a basis for the determination of the *suitability* of the oil for impregnation use.

Among the oxidation products of mineral oil are acids of low volatility and water. In addition, at the higher test temperatures, oil distillation will occur. I ask whether the authors prevented the removal of such materials by distillation during the oxidation run. One of the major objections to oxidation runs of the present type is the volatilization and loss of those materials of greatest importance in the oxidation studies.

I also request data concerning the iodine value of the oil tested.

The dielectric strength data appear to lose significance because of the dehydration treatment and the removal of oxidation-formed moisture and possibly the more volatile oxidation products before the dielectric test was made.

**J. B. Whitehead and F. E. Mauritz:** The linear relationships which Mr. Clark has found are interesting; there should be some significance to the slope of the power factor versus acid number characteristic. It may be possible to determine the relative proportions of organic acids to other compounds which are capable of dissociating.

We doubt that the withdrawal of the volatile products of oxidation has an important influence on the inherent power factor. Evacuation also removes absorbed oxygen and thus stops the oxidation process. Recently we have found evidence that the oxidation process itself is attended by ionization or dissociation, and that the lowering of power factor on evacuation is due to the cessation of the oxidation process rather than to the removal of oxidation products.

No iodine determinations were made on the oils studied.

In reply to Mr. W. M. Goodhue, obviously it remains to be shown how other oils behave as related to time, and also as to the correlations here studied, and whether there are other correlations with chemical structure. We do emphasize however the striking linear relations we have shown.

In reply to Mr. Herman Halperin, other workers who have thus far reported linear relationships are Clark in this discussion and Sommerman at the National Research Council meeting this past November. Sommerman's paper appears in ELECTRICAL ENGINEERING for May 1937.

It would be interesting to determine the effect of metallic soaps. However, under experimental conditions, it would be difficult to determine the relative contributions of the metal acting as a catalyst or inhibitor for further deterioration and that caused by the metallic salt or soap formed.

The ratios in figure 11 were not determined from data taken from figure 10, as Halperin may believe, but from the individual readings of acid number and saponification number on the oil at a given state of deterioration. This method is, of course, much more accurate.

In reply to E. J. Rutan, the reproducibility of acidity results taken on different oil samples depends almost entirely on the cleanliness of sampling and, more particularly, on the preparation of the titration cell. With due care different samples of the same oil would have a maximum deviation from the average of 0.009 in acid number. This value should be considered as a residual due to impurities introduced and not as directly proportional to the acidity of the oil being measured. It is also imperative to use clear, nonturbid titer and to check its acidity before each oil determination. Great care and labor are necessary in preparing the titration cell, especially for low values of acidity. The agar-agar bridge should be changed after every determination, and for simplicity and speed in routine laboratory measurements we would ask Mr. Rutan to consider also the titration cell developed at Massachusetts Institute of Technology, which involves a glass electrode and which seems much easier to clean.

The oil samples used in the breakdown tests were degassed and dehydrated. Each point on the curves is the average of 15 breakdowns, 5 each on 3 identical samples. While the spread of values was of the same order as the observed average, we feel the latter to be a reliable figure. Slight increases of dielectric strength with increasing acidity in the low range have been reported by others.

# Vibration-Measuring Instruments

C. D. Greentree

# Dynamic Balancing of Small Gyroscope Rotors

O. E. Esval and C. A. Frische

**Discussion of papers published in the June 1937 issue, pages 706–10 and 729–34, and presented for oral discussion at the vibration and balance session of the summer convention, Milwaukee, Wis., June 25, 1937.**

**P. L. Alger** (General Electric Company, Schenectady, N. Y.): These papers give evidence of the rapid progress being made in measuring and describing the various sorts of vibration which give rise to noise and other undesirable effects of machine operation. The need for absolutely smooth operation of motors driving grinding machines and other machine tools, as well as the need for quieter operation of all types of machines, make it important that adequate measuring devices be more generally used, and that methods of describing these measurements be agreed upon by industry as a whole. Difficulties frequently arise now because of customers specifying that motors be furnished with a definitely limited amount of vibration, without saying whether the vibration of the shaft or the bearings is to be measured, and whether the motor is to be mounted on a rigid base, on rubber pads, or in some other way. A revision of the test code for polyphase induction machines has recently been approved, I believe, which includes a provision for measuring the unbalance of small motors in terms of the amplitude of motion of the bearings, when the motor is freely supported on elastic pads. I believe this is a very sensible provision, that will do much toward clarifying understanding on the refinements of design and manufacture necessary to meet industry's requirements.

The next step is to bring into use more adequate instruments for measuring the motion, so that the results obtained by different observers at different times will be in agreement. This evidently requires better instruments than have heretofore been used, and so I believe Mr. Greentree's paper, outlining the requirements for suitable instruments, is an important contribution. As he points out, it may be desirable to measure the velocity of the motion or its acceleration rather than to either measure amplitude directly or to attempt to obtain the amplitude from calculations based on the measured velocity or acceleration of the vibration. If, as is usually the case, the vibration is not sinusoidal in character, there will be no simple relationship between the acceleration, the velocity, and the amplitude of the motion as measured;

and, if, as Mr. Greentree suggests, the measurement of the velocity of the vibration is the most convenient and accurate means of testing, then we ought to be thinking about specifications and industry standards in terms of vibration velocity, rather than amplitude.

The AIEE subcommittee on sound has completed a draft of a test code for apparatus noise measurement, which when published will make available general recommendations on means of measuring noise or any piece of apparatus, based upon the American Standards recently published by the ASA. With the 2 fields of vibration and noise measurement both clarified by these proposed test methods, there appears to be left one further task in this vibration measurement field to be undertaken. That is the question of evaluating the performance of various types of elastic mountings intended to isolate the vibration of a machine from its foundation.

There are a great many varieties of elastic supports now in use and proposed for motors and other machines. Many different types of such supports are, of course, desirable for different applications, so that no general agreement on what type is best can or should be reached. However, it does seem desirable to develop acceptable means of comparing the performance of different types of support by some method, for example, of measuring the vibration transmitted to a foundation with and without the use of an elastic base. Probably it is too early to take the question up in any formal way, but I shall appreciate hearing from any one interested as to the desirability of such measurements of elastic base performance being included in any of the Institute test codes.

## Vibration Isolation of Machinery

**Discussion of a paper by L. H. Hansel published in the June 1937 issue, pages 735–8, and presented for oral discussion at the vibration and balance session of the summer convention, Milwaukee, Wis., June 25, 1937.**

**Frederick C. Lindvall** (California Institute of Technology, Pasadena): Relating to the paper, "Vibration Isolation of Machinery," by Mr. Hansel, one or 2 points have suggested themselves to me as being worthy of inclusion in this general discussion of vibrations.

In the first place, electrical engineers should find the general problem of vibration isolation to be one which is of considerable interest inasmuch as through the electromechanical analogy the problem becomes a simple one of electrical-circuit elements and sinusoidal a-c quantities which lend themselves at once to the symbolic or complex method of solution.

A second point which should be emphasized is the convenient form in which the natural frequency of an elastic system as discussed may be expressed:

$$f = \frac{1}{2\pi}\sqrt{\frac{g}{\delta_{st}}} \text{ *cycles per second}$$

$g$ = gravity acceleration
$\delta_{st}$ = static deflection in units of $g$

Thus it is apparent that if the static deflection of the system is known the natural frequency is also known; from the static deflection, in turn, the spring constant of the elastic support may be deduced when the desirable static deflection has been determined.

A general calculation chart or nomogram which I have found very convenient in vibration studies is one expressing transmissibility of an isolation system directly in terms of the parameters static deflection and frequency of vibration. The mathematical expression on which the chart is based is given by a form similar to equation 1 of Mr. Hansel's paper.

The chart is constructed on log-log paper by laying out the transmissibility curve in terms of the ratio of applied frequency to natural frequency of the system; then through the middle of the chart a horizontal line is drawn which serves as a reference line *A-A*, for entering this transmissibility curve. The horizontal lines *B-B* and *C-C* are suitably scaled in terms of frequency and static deflection, respectively, their positions relative to each other being indicated by the obvious tie that a straight line connecting any particular static deflection on *C-C* with the corresponding resonant frequency on *B-B* should pass through the point *O* on the reference line *A-A*. Then for any desired transmissibility the corresponding abscissa is noted on *A-A* at some point, say *P*. Through *P* and the frequency to be isolated to the extent of the selected transmissibility, a straight edge is laid giving at once the necessary static deflection of the elastic support. This static deflection and the weight at the supports give at once the spring constant. It is, of course, obvious that straight lines through the point *O* relate at once the static deflection with the corresponding resonant frequency. This chart may have a family of resonance curves corresponding to different degrees of damping in the elastic system, the most convenient parameter to be used being the ratio of selected damping to critical damping of the system.

And now a word of caution, or perhaps it should be called "sales resistance," which Mr. Hansel has suggested but which I believe should receive further emphasis. There is no magic in vibration pads or isolation materials. This belief in magic seems, in the minds of many engineers, to be intimately associated with certain materials—one in particular being rubber. In the first place, the term "rubber" is indefinite since we all know the tremendous range of rubber compounds in both elasticity and internal damping, and any rubber or similar material which is to be used as an elastic support should be regarded simply for what it is; namely, a spring which may have either a high or low degree of internal damping. This spring, in turn, is useful as an isolation device to the extent indicated by the transmissibility of the system.

One further point: The engineer employing vibration isolation material should have the 2 basic problems, transmission of vibration and transmission of noise, in mind, because an elastic support of metallic nature which may give an adequately low factor of transmissibility will be capable of transmitting noise to an extent that may be objectionable; whereas some other material, such as felt, or rubber, with the same static deflection will achieve the same desirable transmissibility and minimize noise transmission through elimination of direct metallic connection.

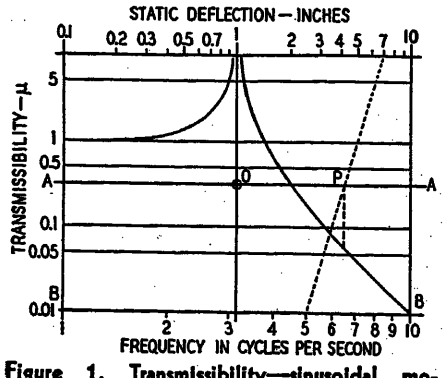

**Figure 1. Transmissibility—sinusoidal motion, no damping, one degree of freedom**

* Note: $f = \frac{3.12}{\sqrt{\delta_{st}}}$ cycles/per second

$\delta_{st}$ = static deflection in inches

**P. L. Alger:** See discussion, page 1305.

## A-C Motor Protection

**Discussion and author's closure of a paper by C. W. Kuhn published in the May 1937 issue, pages 589–93, and presented for oral discussion at the general power applications session of the summer convention, Milwaukee, Wis., June 22, 1937.**

**E. Herzog** (U.S. Army Air Corps, Wright Field, Dayton, Ohio): The author claims adequate protection by means of thermal overload relays even in case of longer starting periods. As pointed out in the previous discussion present long-time thermal-overload relays do not offer enough protection in starting high-inertia load. In the starting of blowers where air loading increases rapidly as the blower comes up to speed, the condition becomes most serious. The writer has been able to obtain satisfactory protection only in one way, i.e., by separate protection during the starting and the running periods even with across-line-starting motors. This naturally increases the cost greatly.

**C. W. Kuhn:** It has not been possible to obtain motor protection with general-purpose thermal-overload relays when starting high-inertia load. Such overload relays must be designed to protect many different classes and designs of a-c motors. Their tripping time must, therefore, be sufficiently short to protect those motors having limited capacity for starting conditions.

The use of special "slow tripping" thermal overloads permits starting high-inertia

loads without unnecessary tripping of the overload. Consequently, smaller overload heaters can be used than would be possible with the faster-tripping standard-type thermal overload. These slow-tripping overloads of lower current rating can be made such as to completely protect motors with high-inertia starting load.

## Coincidental Electric Drives

**Discussion and author's closure of a paper by L. E. Miller published in the May 1937 issue, pages 578–82, and presented for oral discussion at the general power applications session of the summer convention, Milwaukee, Wis., June 22, 1937.**

**L. M. Nowacki** (General Electric Company, Schenectady, N. Y.): Mr. Miller described a very interesting application of a coincidental electric drive, namely, the winding of strip material on a reel. A requisite of the drive is the maintenance of approximately constant tension. The d-c motor is most adaptable for the application. Nevertheless, the question arises, can the same result be obtained with an a-c motor?

Exact coincidence can be obtained with 2 wound-rotor motors used as power Selsyn units or Synchrolocks. The reel drive requires a continually decreasing speed of rotation and an increasing torque. The change in the Selsyn motor speed may then be accomplished by a differential Selsyn unit placed in the rotor circuit between the transmitter and receiver Selsyn, or it may be accomplished by the use of a variable speed transmission interposed between the main drive and the Selsyn generator. As in the case Mr. Miller described, a regulator would be required with the function to control the speed of the differential Selsyn unit or the pulley ratio of the mechanical transmission. If the regulator is to operate on a constant-current principle, it will be necessary to vary the input voltage to the Selsyn units in order to maintain constant rotor current with increasing torque.

The application of an a-c motor to the coincidental reel drive does not appear impossible. A suitable regulator, if developed may provide an a-c drive as flexible as the d-c drive described by Mr. Miller.

**E. Herzog** (U.S. Army Air Corps, Wright Field, Dayton, Ohio): The double-winding motor controlling the field rheostat appears to be the heart of the entire control scheme proposed. A torque motor with spring restraint and a single winding should be able to accomplish the same purpose. The author states that the double winding was used to give the characteristics of an infinitely long spring. A more detailed explanation of this point would be welcome to the writer.

**L. E. Miller:** Mr. Nowacki has suggested a very intriguing problem in the use of a-c with Selsyns or Synchrolocks driving a reel on which material is being wound. There is considerable question as to whether the amount of apparatus required could be reduced materially in using a-c as suggested. Like many problems of this sort considerable thought, experimentation, and actual trial will be necessary before any definite conclusions can be drawn on the subject.

Mr. Herzog has brought up the point that a spring might be used instead of the spring or reference winding on the control motor. This is absolutely correct only in case a spring of infinite length is used and deals with finite torque.

Otherwise a greater torque is required of the torque winding as the reeled material approaches full diameter and slowest speed. This greater torque requires a larger current in the torque winding and therefore in the armature of the motor driving the reel and this in turn gives a greater pull or tension on the material as the diameter of the reeled material increases. In other words a spring could be used only where the conditions were such that a varying tension could be permitted on the material.

In closing, attention should be called to 3 errors which occurred on page 581 of the paper. First, in figure 4 the rheostat in series with the spring winding should be marked 1 instead of 2; second, in figure 4 the legend $D$ should be "regulator field contactor"; third, the first sentence of the second paragraph starting on page 581 should start, "the torque winding $T$ of the regulator. . . " instead of "the torque winding $R$ of the regulator. . . ."

## New Oil-Filled Cable Lines in Chicago

**Discussion and authors' closure of a paper by Herman Halperin and G. B. Shanklin published in the June 1937 issue, pages 739–48, and presented for oral discussion at the power transmission session of the summer convention, Milwaukee, Wis., June 22, 1937.**

**Wm. A. Del Mar** (Habirshaw Cable & Wire Corporation, Yonkers, N. Y.): In summarizing the paper by Halperin and Shanklin, the former said that there is nothing mysterious about the installation and operation of oil-filled cable; that it can be handled without difficulty by crews trained in work on cables of the solid type. This inspires me to add that there is nothing mysterious about its manufacture. On the contrary, the manufacturing processes are based on better-understood principles than in the case of solid-type cables. The mobility of the oil makes it possible to ascertain the condition of the oil and the perfection of impregnation along the entire length by simple tests made at the ends, not only when new, but at all times in its life. This is not the case with solid-type cable, the condition of which must at all times be taken more or less on faith.

The perfect electrical record of oil-filled cables has enabled manufacturers' engineers to devote their attention to improving economy, whereas in the case of solid-type cable the main effort is directed toward improving reliability. This drive toward economy has resulted in simplified accessories, thinner insulation, and cheaper lead, as described in the paper.

**Herman Halperin:** It is gratifying to have a public statement from a manufacturer of the efforts of manufacturers to improve the economy of oil-filled cable.

Although considerable effort has been and still is being directed toward improving the reliability of the solid type of cable, considerable effort has been and still is being given toward improving the economy of such cables.

The essential consideration from the standpoint of a utility engineer is over-all economy, that is, total annual charges per kilovolt-ampere of carrying capacity. In some cases special considerations, such as limitations of diameters of existing ducts or limitations of the personnel of a utility, swing a decision to one or the other type of cable, although the initial installed cost of the cable and accessories is somewhat higher than would have been the case if a type of cable were used other than the type actually selected.

## Impulse Operation of Magnetic Contactors

**Discussion and author's closure of a paper by Carroll Stansbury published in the May 1937 issue, pages 583–8, and presented for oral discussion at the general power applications session of the summer convention, Milwaukee, Wis., June 22, 1937.**

**E. Herzog** (U.S. Army Air Corps, Wright Field, Dayton, Ohio): The author describes a very ingenious solution for the short time operation of magnetic contactors. The process is clearly designed to be used in the resistance welding of nonferrous metals where now vacuum-tube control is used. The writer having used these in the past would like to have the author furnish more detailed information on several points. What is the accuracy of timing of the new process? How is a change in timing accomplished? Are there any chance variations of large amounts as the operation is repeated? How would the life of the contactor compare with the life of the tubes in the 2 types of equipment? A rough comparison of first cost and maintenance of the 2 types would be of interest.

**Carroll Stansbury:** The questions asked by Mr. Herzog are the essential ones which must be satisfactorily answered before control of the type described can be seriously considered for short-time welding of nonferrous metals.

### Accuracy

It will be clear from the paper that the major causes of inaccuracy in contactor control are eliminated by the method. Reference to figure 3 will show that anything which affects the speed of motion of the magnet armature at the instant the contacts touch will affect the closed period slightly by causing the motion to be in accordance with a different one of the family of curves. About the only thing which may cause this type of variation in practice to any serious extent is a considerable variation in line

voltage. On the other hand, a reasonably constant line voltage is an essential requirement for this type of welding to obtain constant energy input into the weld for a given welding period.

There remains the question of variation in the number of cycles passed by the contactor due to possible variation in the arc on the contacts. We have found it possible on a number of practical installations to control this factor so that such arcing as is obtained is quite uniform and that there is no perceptible variation in the welding results throughout a large number of operations. One particular installation, which is operating at $^1/_2$ cycle on current on the order of 250 amperes at 440 volts, has continued to give welds with this timing over a period of several months without perceptible variation. Only occasional phase adjustment is necessary.

### Time Adjustment

This question is covered under the above heading in the paper. The amount of capacity in circuit is varied by cutting in or out individual electrolytic capacitors in parallel.

### Chance Variations of Large Amount

Neither our laboratory nor field experience with this control indicates occurrences of this sort.

### Contactor Life

As brought out in the paper, when operating on the true impulse basis in which the magnet does not seal, the conditions normally producing magnet wear are absent and a contactor should last for several years even on frequent operation. The magnet life on contactors of the best grade used in resistance welding work where the contactors seal in operation is on the order of 20 million operations. This life should be multiplied many fold when the magnet does not seal. So far no contactor operated by the impulse method has shown appreciable wear except on the contacts. It will be evident that with the arcing held to a minimum by this method of control the contact life should also be increased many fold and our experience indicates that this is the case.

### First Cost and Maintenance

It is difficult to give any data regarding first cost of control of this type relative to control of all-electronic type which would be applicable throughout the full range of ratings which might be required. Actually, most of this controller is electronic and it is probably correct to say that the essential difference is that the 2 power tubes are replaced by contactors. Taking the material involved apart from the power tubes or the contactors as roughly about the same, the question really reduces to a comparison of first cost and maintenance of the contactor versus the power tubes. It has been pointed out above that the contactor should last indefinitely with only occasional replacement of contacts, whereas it is the writer's understanding that the power tubes either have to be replaced periodically or are of the continuously-pumped variety which doubtless involve maintenance of the pumps and associated parts.

Actually, the necessary apparatus associated with the contactor in this type of control appears to be somewhat simpler than that associated with the power tubes in those types of all-electronic control with which the writer is familiar. The present form represents a considerable simplification in comparison with the earlier forms of this control, and it is probable that further developments will bring out the possibility of still further simplification.

## System Recovery Voltage Determination by Analytical and A-C Calculating Board Methods

**Discussion and authors' closure of a paper by R. D. Evans and A. C. Monteith published in the June 1937 issue, pages 695–705, and presented for oral discussion at the power transmission session of the summer convention, Milwaukee, Wis., June 22, 1937.**

W. F. Skeats (General Electric Company, Philadelphia, Pa.): The authors have developed 2 major ideas which will undoubtedly be of value in certain fields in the determination of recovery rates. The introduction of symmetrical components is helpful particularly in the calculation of the recovery characteristic of line-to-ground faults and the use of the calculating board promises a reduction of labor especially in the determination of the slower voltage-recovery curves.

In the introductory discussion, the suggestion is made that recovery characteristics be specified by stating both co-ordinates of one point on the curve instead of merely the slope of the steepest tangent passing through the origin. This information is somewhat more specific; however, the authors themselves point out that one point on the curve may be the important one for one interrupting device and a different point for some other device, so that there may often be some question as to which point to specify. To give all the information, the complete curve should of course be shown. Comparison of curves of different shape is likely to involve uncertainties, however, and to overcome this, the suggestion was made 2 or 3 years ago that the basis of comparison be the rate of rise based only on points on the recovery curve whose magnitude is at least 80 per cent of the normal voltage peak, with special consideration given to lower points on the curve which correspond to a higher rate where it is a question of breaker application rather than evaluation of test results.

There are one or 2 points with reference to the use of symmetrical components which will bear comment.

1. The paper states that the method of connecting the phase-sequence networks for recovery rate determination is the same as for the steady-state condition, with the apparent implication, supported by the example given in the case of the double-line-to-ground fault, that the proper connection is the same as that used to determine the current flowing in the case under consideration. Except for line-to-line or line-to-ground faults, this is incorrect for, while the calculation of steady-state current correctly ignores the interval during which less than the full number of phases are faulted, this interval must be considered in determining voltage recovery phenomena. The arrangement to be used for the first phase to clear of a double-line-to-ground fault is therefore that of the impedance encountered by current passing from one terminal of the 3-phase circuit to ground with a second terminal grounded.

2. Barring asymmetrical circuit conditions apart from the fault, the difference between positive- and negative-phase-sequence impedances exists only in rotating machinery and arises from the fact that while one is associated with a flux path that is stationary with respect to the field structure and therefore does not change throughout the cycles, the other is associated with a flux path which rotates with respect to the field structure and may therefore be subject to cyclic variation. In the course of 500 microseconds the motion of the rotor has negligible effect, so that the use of the same value for positive- and negative-phase-sequence impedances is justified. It is suggested, however, that inasmuch as with the current zero occurring at the crest of the voltage wave, the flux path in the rotor is that of the quadrature axis, the quadrature-axis subtransient reactance be used in place of the negative-phase-sequence reactance. This is of importance particularly in laminated-rotor machines without amortisseur windings.

3. For very careful calculations it is occasionally desirable to take into account the fact that the capacitance is not the same for the 3 phases in the interval between clearings on the various poles of the breaker. This greatly increases the difficulty of the solution by symmetrical components and is often easily taken care of in the "single phase" solution, so that in such cases the single-phase solution becomes the simpler even neglecting the labor of changing the constants over from one system to the other.

With reference to the use of the calculating board, I should like to make the following comments.

1. From the standpoint of circuit breaker performance, the cases in which recovery rate should be investigated are in general those in which the capacitance on the one hand is small and can usually be lumped so as to make the calculation relatively simple, but on the other hand consists of a number of minor elements so that considerable labor and possibility of error are involved in determining it. Thus the use of a calculating board eliminates only a minor part of the total labor.

2. Moreover, unless the calculating board is specially designed and very carefully used, it seems likely that it would introduce stray capacitances sufficient to cause appreciable errors in such cases.

Except in cases where a recorded recovery transient is to be compared with a calculated curve for the purpose of analyzing effects introduced by the breaker, great precision is not required for circuit-breaker work, errors up to 25 per cent being tolerable. This being the case, the determination is not so much a precise calculation of complex circuits, as a matter of good judgment in making simplifying assumptions. It would seem, therefore, that per-

haps the greatest use of the calculating board, from the standpoint of circuit-breaker application, may be in the investigation of such assumptions and the formulation of rules for making them sound.

In applications of expulsion protective gaps, on the other hand, the calculating board offers an appreciable saving in effort.

**H. P. St. Clair** (American Gas & Electric Company, New York, N. Y.): In this paper Messrs. Evans and Monteith have presented an interesting and helpful contribution to the literature on voltage-recovery transients, and the proposed method of direct measurements of transients by means of the a-c calculating board may prove to be very useful. For instance, if it is necessary to determine the recovery-voltage characteristics in connection with the operation of flashover tubes at various points on the transmission network, this method would simplify the problem since determination by analytical methods would become extremely complicated.

However, it should be pointed out that regardless of the difficulty of calculating recovery transients at various points on transmission lines, the actual severity of such transients is inherently much less than the severity of recovery transients obtainable on station busses with no transmission lines connected and with only the capacitance-to-ground of the busses, transformers, or generators themselves. Therefore, in determining the severity of recovery voltage transients which must be handled by circuit breakers, we are concerned chiefly with the station type of circuit, where it is possible to encounter the higher voltage-recovery rates.

For this general type of problem, therefore, it is questioned whether the authors' proposed method will actually provide much help.

In the first place, these circuits giving the most severe recovery transients are usually of a fairly simple nature and can be calculated fairly readily after the constants are known. In such cases where we are interested primarily in the worst condition which the given circuit can offer, the most difficult part of the problem is an accurate determination of the small values of capacitance involved in the station bus and in the transformer or generator windings. The authors have referred briefly to this problem in the paper, and it is obvious that the a-c calculating board cannot be of any assistance in connection with this part of the problem. It is doubtful, therefore, whether its use in such cases would be justified.

In the second place, it is doubtful whether the equipment described by the authors would be adequate to record very severe voltage-recovery transients since such transients frequently involve a time duration of only a fractional part of those which the authors discuss. All of the typical records reproduced by the authors both from analytical determinations as well as from direct measurements are of comparatively slow transients which would not be of particular interest in the circuit-breaker problem. For example, in figure 22 the recovery transient for a line-to-ground fault on a 132 kv line is shown with approximately 130 volts per microsecond. All of the other transients shown are more or less of this order. Actually, circuit breakers have been called upon to handle recovery rates at least as high as 4,000 or 5,000 volts per microsecond, and for such transients, it is believed that the rotating type of recording device as used by the authors could not possibly be operated at sufficient speed to give the necessary time scale.

As stated above, the most difficult part of the problem in connection with extremely high rates of recovery voltage is the determination of small values of capacitances involved in more or less simple setups. For this problem it is likely that a greater contribution would be some device either for directly measuring transients in the circuit itself or of measuring the capacitance of the circuit directly. For example, the high-frequency generator or oscillator may be used for determining the natural frequency of the circuit and thereby arriving at the capacitance since the inductances involved are generally known.

The authors are to be congratulated, however, for having worked out a very interesting application of the a-c calculating board and one that may prove of great value in its field.

**J. R. North** (Commonwealth & Southern Corporation, Jackson, Mich.): Experiences which we have had with arc-interrupting devices have time and again brought to our attention the need for more information and data concerning recovery voltage. The methods of analysis described in this paper by Messrs. Evans and Monteith will be of considerable assistance to power system engineers in applying interrupting equipment.

The question of recovery voltage is important not only in the application of circuit breakers, but in all arc-interrupting devices such as fuses, lightning arresters, and protector tubes which may be located at stations or out on lines. Also, the problem is not confined to fault conditions. For example, circuit breakers used for normal switching of synchronous condensers, and line charging reactors, have at times shown considerable distress due to a high rate of rise of recovery voltage. Certain lightning arrester troubles have also been encountered which could be traced to rapid recovery voltage of the system.

Fuses usually clear faults in a relatively short time. The curves shown in figure 26 show that the voltage rise during the first 200 microseconds is much steeper for a fault having a duration of one-half cycle than for a fault of one cycle duration. This would seem to indicate that fuse and protector tube applications require particular attention from the standpoint of recovery voltage.

The reduction of a power system of any size to a simple equivalent network system such as is shown in figure 11 involves considerable work. It would be desirable to have a more detailed explanation as to just how this is accomplished, and with particular regard to obtaining the proper values of equivalent system constants to give the correct values for both normal system frequency and for the natural frequency of the system. It would also be interesting to know how this is taken care of on the a-c calculating board, which is designed for 440 cycle operation.

In the caption for figure 27, it is believed that reference should be made to figure 18 rather than figure 19.

The check between the values obtained by the authors using the analytical method and the a-c calculating board with the field tests is indeed interesting. With more test data available, it would appear that the burdensome analytical studies could be confined to special problems involving only a few elements of a system. It is, therefore, urged that measurements be made of recovery voltage whenever the opportunity presents itself in connection with other system tests. These data will facilitate the application of the methods outlined in the paper to general system studies.

**S. B. Crary** (General Electric Company Schenectady, N. Y.): The authors are to be congratulated for the presentation of a paper which should prove to be of real benefit in studying the effect of various factors on the recovery voltage characteristics.

In using a minature system or model, it is well to view rather critically the assumptions required in order that the model may be used to predict or explain actual system performance. Unfortunately, the most important cases of arc suppression which result in extreme or high recovery voltage are the ones which do not permit of easy representation by a miniature setup. As shown by the authors, high peak values of recovery voltage may be obtained when the current is interrupted off of normal current zero. The amount and manner in which the circuit is interrupted off normal current zero is a function both of the actual arc characteristic of the interrupting device itself and the circuit to which it is connected. For those cases when the arc characteristic is not influenced appreciably by the connected electrical circuit and the characteristics of the interruptor are known, then a device can be made which will duplicate the performance of the actual device. However, for those cases when the interruption phenomena are dependent upon the electrical circuit as well as the interruptor, it becomes exceedingly difficult to build a model which will duplicate actual performance, this case may well be most easily obtained by test of the actual circuit and interruptor.

Another source of high recovery voltage, as shown in the paper "Circuit Breaker Recovery Voltages" by R. H. Park and W. F. Skeats (AIEE TRANSACTIONS, March 1931, pages 204–239), is that due to the saliency of rotating machines, which cannot be easily reproduced in a static setup.

**E. M. Hunter** (General Electric Company, Schenectady, N. Y.): Messrs. Evans and Monteith have given a very interesting discussion on using the a-c calculating board for estimating system recovery voltages. The procedure which they describe should be very useful to those interested in making a large number of independent recovery voltage calculations on a system.

Interest in recovery voltages centers mainly around the application of oil circuit breakers and expulsion protective gaps to different electrical systems. In modern oil-circuit-breaker applications only the very fast recovery rates of the order of several

thousand volts per microsecond need to be considered. These very fast recovery rates usually result from circuits which contain only small amounts of capacitance, such as is found, for example, in transformers and bus work. It is often difficult to reproduce a miniature of this type of circuit and the authors' comments on the suitability of their a-c board for studying these fast transients would be of considerable interest.

The recovery voltages associated with the application of expulsion protective gaps usually are not in excess of several hundred volts per microsecond and accordingly, are of a much lower rate than those encountered in oil-circuit-breaker applications. Usually the mathematics governing the circuits to be analyzed are not too involved, and the recovery voltages can be calculated provided the system constants are known. The biggest obstacle in making any analysis of recovery rates today is the determination of the system constants. A big step toward the solution of the recovery rate problem came with the development of a practical 3-element cathode-ray oscillograph, such as is described in Messrs. Rudge and Wade's paper on "Expulsion Protective Gaps" presented at this convention. With this measuring instrument it is now possible to make field tests and actually determine the recovery rates. With system constants unpredictable, there is a need for more field tests. Once system constants are known, the a-c calculating board will be a useful tool for extending the study of system recovery voltages.

**L. R. Ludwig** (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): The problem of a-c circuit interruption has long been a very important one, both as far as circuit breakers of high interrupting capacity and smaller apparatus are concerned. However, even until 1928, the notions of the phenomena involved in a-c interruption were vague and incomplete. Comparatively recent papers on the subject glibly discuss the "quenching" effect of oil on an arc, and bemoan the necessity of interrupting a circuit by means of a "burning" arc at all.

In 1923, Doctor Slepian began to visualize the true physics of a-c circuit opening, as a result of research with grids and a vacuum arc. By 1925 his "deion" ideas were formulated, and in 1928 in Denver, he presented a paper entitled "Extinction of an A-C Arc" which for the first time called attention to the facts that the arc space between the separated electrodes of a breaker had to deionize before any appreciable voltage could be applied without restriking, that the time available for this deionization was a function of the circuit, and that interruption depended on the relative progress of deionization and voltage recovery.

This paper, mildly discussed at the time, has become the source-book from which our present accepted knowledge has been derived. As appreciation of Doctor Slepian's work grew, there was a rush to the laboratory to test circuit interruptions under actual system voltage recovery conditions. But what were these actual conditions? How to set the laboratory was the problem. The theory was clear enough, but determination of time to crest and recovery voltage under operating conditions was not simple.

The circuits were analyzed mathematically, but several approximations were needed. For several years there has been no completely practical and simple method for determining voltage recoveries.

Now Mr. Evans and Mr. Monteith have devised a tool for the determination of recovery voltage which is accurate, practical, and complete. Their idea of using the calculating board for this purpose is simple, but considerable ingenuity was required in carrying it out. For example, their use of repeated faults in order to get oscillographic records is a clever means of surmounting a mean obstacle.

The methods they have described are simple, check beautifully with field tests as well as calculation, and permit the study in the laboratory of field conditions which cannot be satisfactorily resolved by mathematics alone. We have been given a new yardstick for gauging circuit-interrupter requirements, and the added certainty of testing will prove beneficial to the development and application of breakers and deion protector tubes particularly.

An excellent example of the utility of the Evans-Monteith method is illustrated in their figure 3. It has often been customary in dealing with recovery voltages to speak only of the rate of rise of voltage, and its crest value. Such a description of the facts lacks generality; it is applicable only when testing a device having a recovery curve similar to $D$ in the figure. Mr. Evans and Mr. Monteith have been able to study system recovery curves so much more accurately with the calculating board method that earlier discrepancies become very apparent. We can now begin to deal with the entire recovery curve, rather than with one or 2 points on the curve which are presumed to be critical values but may not be. We cannot easily enjoy the certainty of dealing with the complete facts.

**H. G. Brinton** (General Electric Company, Pittsfield, Mass.): The Evans-Monteith paper considers the recovery voltage as the sum of 2 components, (*a*) the steady-state component and (*b*) the natural-frequency component.

The first component is sometimes called the restored voltage and is the generated voltage that is suddenly impressed when the 60-cycle inductive drop in generators, transformers, etc., is suddenly removed by the 60-cycle current stopping at zero.

The second component usually rises so rapidly that the first component can be considered as a constant or continuous voltage during the brief period in question. It is the transient voltage appearing on the capacitance in shunt with the circuit opening device when the restored voltage is suddenly impressed on the circuit. In the worst case this circuit is oscillatory and the recovery voltage rises rapidly at the natural frequency of the circuit.

In a 3-phase circuit the first component is sometimes impressed on a rather complicated network. In calculating the recovery voltage conservative assumptions are made so that the actual recovery voltage will not exceed the estimated value which is used in making the application of expulsion gaps or similar devices.

Oscillographic tests may be made on actual service setups and also on miniature laboratory setups. The 2 methods are complementary to each other rather than competitive. The field tests deal not only with recovery voltages under various conditions but also with the life and characteristics of the circuit-opening device and its effect on the system. These field tests are a necessary part of the development and improvement of the circuit-opening device.

Field tests cannot be carried on continuously and miniature laboratory setups afford a valuable means of obtaining a greater amount of data and of broadening out the test program.

A number of field tests on the operation of expulsion gaps and the resultant recovery voltages have been made recently. In general, it has been found that the calculations have been conservative and satisfactory in placing an upper limit on the expected value of recovery voltage. These tests are very valuable in supplying data on the effect of circuit conditions and of variations in the device tested.

In general the factors which tend to increase the recovery voltage are (*a*) limitation of the short-circuit current by inductance principally rather than by resistance so that the generated restored voltage is near a maximum when the current goes out at zero; (*b*) an oscillatory circuit on which the restored voltage is impressed so that the recovery voltage may rise to about twice the restored voltage; (*c*) a small value of the product of inductance and capacitance in the oscillatory circuit so that the natural frequency is high and the recovery voltage rise is steep.

**H. M. Trueblood** (Bell Telephone Laboratories, Inc., New York, N. Y.): This paper takes a valuable further step in the advance of our means of understanding phenomena which are not only important from an engineering standpoint, but also of great interest in themselves. In some of the studies* that have been carried on by the joint subcommittee on development and research of the Edison Electric Institute and the Bell Telephone System, an important feature has been the matter of overvoltages on power systems at times of ground faults, and the relation of these overvoltages to the use of devices for limiting fault currents. Such investigations make contact at several points with the subject of this paper, and the methods described by the authors should be helpful in them, particularly in the study of specific situations.

The main object of the paper is evidently to present practical working methods, applicable over an enlarged range of practical conditions, and with no more appeal to theoretical considerations than is needed to justify the expectation that the methods described will be accurate enough for engineering purposes. I do not wish to depart from this point of view in discussing the paper, particularly since the involved nature of the subject makes it impossible for theory to go far without clinging to the hand of experiment. The checks that the authors

* Engineering Reports of the Joint Subcommittee on Development and Research, volume IV, pages 105–137 (1937); Gilkeson and Jeanne, "Overvoltages on Transmission Lines," ELECTRICAL ENGINEERING (AIEE TRANSACTIONS), volume 53, September 1934, pages 1301–09.

give of results from both methods against measurements on actual systems are gratifyingly good, although they seem rather limited in extent. Additional data from further field work should serve to indicate what modifications may be necessary to insure results within engineering precision, as well as to define the limitations of the new methods as the latter now stand. In view of the rather high frequencies that seem to be important in these phenomena, one matter that may offer difficulty is the determination of the degree of refinement necessary in the equivalent networks. This would be involved in both the analytical method and the use of the calculating board. In the former, in fact, one might run up against another obstacle, arising from the fact that actual power systems are not altogether symmetrical, so that the decomposition into the usual sequence networks is not strictly justified. Unbalances among the 3 networks, unimportant from some points of view at low frequencies, acquire increased significance at higher frequencies. If this sort of difficulty should prove important, it could presumably be taken care of, up to a certain point, in the calculating board setup, at the cost of some complication. The question, of course, is purely one of how much practical difference it would make.

As I understand, the calculating board used is ordinarily operated at 440 cycles and with impedance elements differing by a conversion factor from the elements of the actual network. I think some further detail about how the board is set up and used in this new application would be of interest, since the results sought go rather beyond the usual range.

**R. D. Evans and A. C. Monteith:** The discussions indicate that the methods presented in the paper have application to a variety of problems of interest and importance to the industry. The authors are appreciative of these discussions and are encouraged to continue their general study of system recovery voltage and to develop further the methods and their applications.

When a paper describing new analytical methods is presented the discussion is usually concerned with the proper field of application. In the present case the discussion follows these lines. The paper presents 2 general methods of solution and much of the discussion is concerned with the choice. It is the authors' opinion that the simpler circuit problems should be studied by the analytical methods while the more complicated circuit problems and general investigations should be studied by the a-c calculating-board method. The 2 methods can be used to advantage in complementing each other. For the particular problem of opening the last circuit breakers on a bus, we believe that the analytical methods are adequate and not too cumbersome. For such calculation we believe the symmetrical component method of solution described in the paper provides a simplification over previous methods and at the same time gives a better visualization of the various factors entering into the problem.

Several of the discussers have raised a question as to the applicability of a-c calculating-board method for problems involving the higher rates of recovery voltage, basing their view on the limitations of recording apparatus and relative importance of stray capacitance. In this connection it may be observed that the equipment described in the paper for the a-c calculating-board method is suitable for recording much higher natural frequencies than those shown in the few examples. This range can be extended by the use of equivalent circuits of lower natural frequencies, when used with appropriate corrections for the change in the fundamental frequency. By this method difficulties in recording and the effect of stray capacitance are minimized. The limitations of the polar form of recording can of course be overcome by the use of a cathode-ray oscillograph which incidentally was originally developed for surge testing. Thus, for the study of high-speed transients, the a-c calculating-board method is more flexible than would be indicated by some of the discussions. Several discussions have dwelt on the limitation of the a-c calculating-board method in arriving at the recovery voltage for the opening of the last circuit breakers on a bus section. It should be appreciated that there is a large number of other problems in connection with circuit breakers, as well as with other pieces of apparatus on the system for which the a-c calculating-board method is applicable.

Two of the discussers have raised the question as to the frequency used with the a-c calculating-board method. While the board was designed for 440-cycles supply, practically all of the transient studies have been made with a separate 60-cycle supply although some studies have been made with other lower frequencies such as 25 cycles.

Doctor Trueblood's discussion is valuable in bringing out the multiplicity of factors entering into the recovery voltage problem and the technical difficulties involved in the circuit problem. He has ably summarized the authors' approach to the problem which has been to provide a practical method giving engineering accuracy. We are in hearty agreement with Doctor Trueblood, Mr. North, Mr. Brinton, and others, on the desirability of obtaining further system tests to establish benchmarks which are themselves valuable and which will provide a sound basis for broader analyses by the methods presented.

Mr. North's discussion is valuable in that it emphasizes the fact that there are a number of pieces of apparatus whose performance is vitally affected by recovery voltage characteristics. He has also raised the question of the method for reducing an extensive power network to a relatively simple equivalent. It is difficult to formulate a general procedure since to a considerable extent each network must be considered as a special case. In general, the complicated system may be set up on the a-c calculating board in a manner similar to that used for load studies when line capacitances are taken into account, with the additional complication of setting up the network on a 3-phase basis and making the zero-sequence circuit of proper value in a manner similar to that shown in figure 15. In the case of very large networks it may be necessary to set up at one time only a part of the system and to obtain an equivalent network for this part.

We agree with Mr. North that the reference in figure 27 should be to figure 18 instead of figure 19.

Mr. Skeats has suggested that recovery-voltage characteristics for circuits and apparatus be defined in terms of the rate of rise to certain points on the recovery voltage wave. The authors are of the opinion that a better and more complete picture of the voltage recovery problem both from the standpoint of the system and of the apparatus will be obtained by the method used in the paper which defines the recovery voltage in terms of a curve plotting magnitude and time. Having such a curve in mind it is convenient to express particular points of interest in terms of magnitude and time to crest. The phenomenon of arc interruption reviewed by Mr. Ludwig is a subject which must be thoroughly understood in order to broadly consider the recovery-voltage problem.

Mr. Skeats' point concerning the connection of the sequence networks is not clear. It is assumed that he refers to the fact that a switching operation is required for changing the connection of sequence networks when representing the opening of one pole of a breaker on a double-line-to-ground fault. This is a complication with the sequence network method of representation but it is of course not encountered with the 3-phase method which has been more generally used by the authors. The sequence network, however, does assist in separating the components of the total recovery voltage and thus gives a better visualization of the phenomena taking place.

Mr. Skeats suggests that the machine reactance used in recovery studies should be based on the quadrature subtransient reactance on the basis that the current is interrupted at the crest of the voltage wave at which time the flux path in the rotor is in the quadrature axis. However, the recovery phenomenon generally of interest is that corresponding to the clearing of some unbalanced fault on the transmission system and for such conditions the flux path in the rotor will not be wholly in the quadrature axis. Hence some combination of the reactances corresponding to both direct and quadrature axes should be used. The negative-sequence reactance is an average of these reactances and was suggested in the paper as the value to be used in recovery voltage investigations. A more important correction than the cyclic variation in reactance may be due to the harmonic distortion which occurs with unbalanced faults on salient-pole machines without dampers. This point, mentioned by Mr. Crary, has been recognized by the authors. The effects of harmonic distortion are admittedly difficult to include in setup but can be compensated for by separate correction. The use of such a procedure for this very special case is believed to constitute only a minor limitation to the general value of the method.

Mr. Crary has also raised a question of the fault representation for the interruption of an arc at other than its normal current zero. If the arc characteristics are known, a fault representation device may be devised and its effect introduced into a calculating-board study. One such arc representation device is described by the authors in connection with figure 18. The a-c calculating-board method permits interruption at any desired point. As pointed out by the authors, interruption of an arc on a system will ordinarily take place at or close to the normal current zero because of the fact that

the recovery voltages for interruption on either side of this point are higher than at the normal current zero.

In connection with Mr. Hunter's discussion, we do not understand the difficulties which he anticipates in the determination of circuit constants for systems on which flashover protector gaps are to be applied. It is our opinion that if the physical layout of the system is known the electrical constants may readily be calculated with engineering accuracy.

## Characteristic Constants of Single-Phase Induction Motors

**Discussion and author's closure of a paper by Wayne J. Morrill published in the March 1937 issue, pages 33–38, and presented for oral discussion at the power generation and electrical machinery session of the summer convention, Milwaukee, Wis., June 24, 1937.**

P. L. Alger: See discussion, page 1312.

P. H. Trickey (Diehl Manufacturing Company, Elizabethport, N. J.): I was very much interested in Mr. Morrill's paper partly because of its usefulness and partly because he has used a similar method of attack to that used in my paper on shaded-pole motors.

In checking the 2 papers against each other, I find several points of interest. In the first place in my own paper the first sentence of the paragraph on harmonic reactance should read "The above reactance $X_m$ is here defined as the magnetizing or mutual reactance." In the second place, after taking the differences of the total and magnetizing reactances, the terms were rearranged, and the term $\sin^2 \beta/2$ was inadvertantly omitted from the denominator of the constant $C_h$ which should read

$$C_h = \frac{1.232\ \alpha - \mathrm{Sin}^2\ \beta/2}{\mathrm{Sin}^2\ \beta/2}$$

Having made this correction and putting the constant 3.19 in Mr. Morrill's equation for permeance, it can be shown that the 2 equations became identical for the special case of one coil per pole with a pitch equal to the pole area of the salient-pole motor.

In developing these formulas, I feel that Mr. Morrill has very definitely contributed to the more accurate calculation of motor constants. The formulas which my associates were using when I first began to calculate motors, were the original formulas of C. A. Adams, published in 1904. However, to partly compensate for a wide divergence between calculation and test, they were using Adams' "belt leakage" even on squirrel-cage motors. After Mr. Veinott developed the formulas for skew leakage, and after I had worked up some curves for the reactance of closed-slot rotors, we attempted to drop the fallacious use of the belt leakage. We found that we were always low if we omitted it and high if we used it. So for a number of years now we have been arbitrarily using $^1/_3$ of the calculated belt leakage, and have had very satisfactory results. We have justified it, as partly compensating for some differential leakage not covered by the zigzag.

I have lately checked 4 repulsion-start induction motors, comparing the present method of zigzag plus $^1/_3$ belt to Mr. Morrill's stator and rotor harmonic leakage.

In all the cases; the present method, Mr. Morrill's method and test values were very close together, but in every case Mr. Morrill's method was closer to test than the present method.

Mr. Morrill has given us some very useful formulas which can be applied directly to repulsion-start induction motors. Would it be out of place to ask him if similar formulas are available for the rotor reactance of the squirrel-cage rotor?

2. THE LEAKAGE REACTANCE OF INDUCTION MOTORS, C. A. Adams. International Electric Congress, St. Louis 1904 *Transactions*, pages 706–24.

**Wayne J. Morrill:** I am pleased to receive the discussion from Mr. P. H. Trickey, announcing close agreement between calculation and test which had been obtained by him using the method of my paper.

Mr. Trickey asked whether similar formulas are available for the rotor reactance of squirrel-cage rotors. It was my intention to point out in the paper that the developed formula for rotor-air-gap reactance applies equally well to squirrel-cage rotors and wound rotors.

## End-Winding Inductance of a Synchronous Machine

**Discussion and author's closure of a paper by B. H. Caldwell, Jr., published in the April 1937 issue, pages 455–61 and 474–5, and presented for oral discussion at the power generation and electrical machinery session of the summer convention, Milwaukee, Wis., June 24, 1937.**

G. W. Hampe: See discussion, page 1318.

P. L. Alger (General Electric Company, Schenectady, N. Y.): The appearance of the 4 papers by Beckwith, Caldwell, Douglas, and Morrill, carrying further the analytical study of leakage reactance, and the recent appearance of an article on "Induction Motor Leakage" by Mr. L. H. Carr (Metropolitan Vickers Gazette, volume 16, May 1937, pages 426–31) indicate that there is still much to be done in making the knowledge of this important subject adequate for design purposes. Professor Douglas' suggestion of procedure for end-connection reactance calculation, and Mr. Caldwell's actual carrying out of such a process for the end leakage reactance of synchronous machines, are particularly important contributions. I believe that Mr. Caldwell's results are more exact and give a more satisfactory understanding of the variations of end leakage reactance with design proportions than any methods heretofore published. Further work in this field is still desirable, however, first to verify the practical application of his results over a wide range of machines, second to add methods of allowance for the additional reactance due to the presence of magnetic retaining rings, such as are used with high-speed machines, and third to determine the end reactance when the secondary currents flow in a distributed armature winding or a squirrel cage, instead of in a salient-pole field winding.

I also believe that Mr. Morrill's contribution in presenting a method of more accurately calculating the air-gap reactance of single-phase motors is important. The results in some ways conflict with those obtained by Mr. Carr in the paper mentioned above, Mr. Carr preferring the method of calculating the average overlap of the teeth to obtain the permeance of the combined zigzag leakage flux paths, instead of using the difference between the total air gap flux and the fundamental component for rotor and stator separately, as used by Mr. Chapman and Mr. Morrill. Also, Mr. Carr suggests that the variations in the air gap fringing coefficients for the fundamental and the tooth harmonic fluxes introduce an error when Mr. Morrill's method is used. While further work should be done to reconcile these different views, my own belief is that Mr. Morrill's method is substantially correct.

Another problem to be solved in this reactance calculation field is that of determining the leakage reactance for various types of irregular or multiple windings, such as are used in part-winding starting of motors and double-winding operation of alternators. These windings have relatively large air-gap leakage reactance components due to the large harmonics in the field form, and they also have additional slot reactance, depending upon the arrangements used, as discussed in the paper presented before the Institute in 1929, entitled "Double Windings for Turbine Alternators (P. L. Alger, E. H. Freiburghouse, and D. D. Chase, AIEE TRANSACTIONS, volume 49, January 1930, pages 226–44). I believe that the orderly system of notation and the use of connection tensors, suggested by Mr. Kron, are helpful in analyzing these problems of irregular windings, and I hope that a paper can be presented before the Institute dealing with this aspect of the subject in the near future.

J. F. H. Douglas (Marquette University, Milwaukee, Wis.): Caldwell's fourth assumption, namely that there is 100 per cent eddy-current shielding in the end laminations, is equivalent to the use of a Rayleigh insulating surface, and is a conservative assumption. Thus his values of inductance are smaller than the true values, but if they are, as indicated by the discussion, higher than previous published values they are nearer the truth.

With regard to the factor (2) which disappears between Caldwell's equations 12 and 15 I believe that this is the point he chooses to introduce the effect of both end windings, and that his equation 15 is substantially correct.

It should be pointed out next that the writer has carefully checked the various formulae as far as equation 25 and suggests

a slight modification only in equations 13 and 23. Thus the work appears to be substantially accurate and in accordance with the postulates. The method is, moreover, of considerable power, and leads to convergent series and a workable formula for inductance.

The capabilities of the method, transcend the postulates, Caldwell's third postulate is equivalent to placing a Rayleigh conducting plane tangent to the ends of the winding and increases the inductance perhaps 5–10 per cent. By moving the plane away from the poles and using a double harmonic series as is used in the theory of the square drum head this error may be reduced ["Fourier Series, Surface, Zonal, and Spherical Harmonics" (a book), Byerly].

Caldwell's fourth postulate, namely that of 100 per cent eddy-current shielding may be replaced by its opposite 0 per cent shielding and the method would still be applicable. In figure 1 is shown a wave of mag-

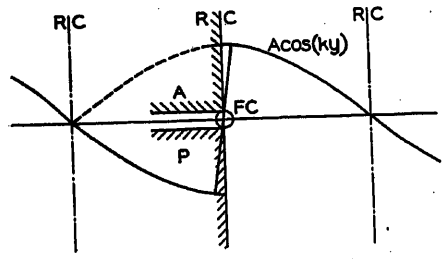

**Figure 1. Magnetomotive-force wave with no shielding**

netomotive force varying in the $y$ direction, the right-hand wave and the left-hand dotted wave are in accord with Caldwell's fourth postulate, the solid curve indicates the needed change to make the polar and armature iron an equipotential surface. $P$ represents the poles, $A$ the armature, $FC$ the fictitious conductor closing the gap, and $RC$ represent Rayleigh conducting planes. The series of harmonics is now a double series, contains terms of double frequency only in $y$ and converges more slowly than before. Thus Caldwell's method should be capable of considerable further development.

Comment should be made on the ingenious experimental technique shown in figure 10. This is believed to be a very useful contribution. In this figure it appears as if the long side of the triangular test coils returns on the outside of the end connections. It is believed that this misses considerable flux, and that the correct location of the return conductor should be on the air-gap side of the end connections and adjacent to the tips of the teeth.

One important consequence of Caldwell's analysis, and equally true even when different postulates are used, is that the field is essentially a cosine function of $x$. This means that the field in the end zone is substantially a revolving field for either positive-or negative-sequence components, and a pulsating field for zero-sequence currents.

I wish here to record my reasons for believing that Caldwell's fourth postulate of 100 per cent eddy-current shielding is needlessly conservative. This is an important point, since a particular case showed decidedly greater inductance with 0 per cent shielding. The largest difference is made by flux leaving ends of stator teeth and reaching the pole shoe. Here there is no shielding in the rotor as it moves synchronously with the flux (positive sequence assumed) and little shielding is offered by the teeth as they are too constricted for eddy currents. In the second place the flux leaving the side of stator laminations is undoubtedly cut down somewhat by eddy currents, but it is suggested that flux penetrating only 2 or 3 laminations would find an easy return path, and the shielding should not be large. There is enough evidence available from the loss caused by lapped-over butt transformer joints, and in the reactance of core-type transformers to estimate the probable shielding of eddy currents. Caldwell's assumption is nearer correct for cross-magnetizing flux than direct, nearer for negative and zero phase sequences than for positive. It is suggested that further experiments are very much needed.

In commenting on Caldwell's figure 11 the solution of a particular case indicated the plane $aa'$ to be nearer the end connection than the pole core, I conclude that Caldwell's fringing is an important factor, and as pointed out it could be calculated as part of the end-zone flux.

In place of the author's equation 13 for pitch other than 100 per cent I get the magnetomotive force as a double summation of surface harmonics of the type

$$M = \sum_{n=1}^{n=\infty} \sum_{m=1}^{m=\infty} A_{mn} \times \cos\,(mxP/D) \sin\,(nky) \quad (1)$$

where the value of $A_{mn}$ is given by

$$A_{mn} = \frac{32\,(ni)\,(p)\cos\,(1.57\,mp)}{(3.14)\,(m)\,(n^2 - m^2p^2)} \sin\,(1.57n) \quad (2)$$

This reduces to the form of Caldwell when there is 100 per cent pitch. We request Caldwell to give more details in his discussion.

In attempting to check Caldwell's equation 23 I get a slightly different result. Calling $k$ the ratio of slot width to tooth pitch,

$$K_m = K_{pm}K_{hm}'\left(\frac{3}{3.14m}\right)^2 \times \left(\frac{\sin\,(km30°/s)}{k\sin\,(m\,30°/s)}\right) \quad (3)$$

It is believed that the neglect of the last term in equation 3 introduces an error less than 10 per cent with the postulates adopted by Caldwell, but with 0 per cent shielding, and a less rapidly converging series the term may be of consequence.

**Ernst Weber** (Polytechnic Institute of Brooklyn, Brooklyn, N. Y.): The general outline for the computation of the reactance of end connections as given by J. F. H. Douglas, is extremely interesting and certainly opens a wide field for experimental as well as mathematical research. The specific application of mathematics to this particular problem exposed in the paper by B. H. Caldwell illustrates the power of the judicious combination of theory and experiment. There are, however, a number of points to be considered in a more thorough study of this leakage problem. The Fourier series employed by Caldwell presupposes an infinite grid system of square loops. In reality, taking into account the magnetic image of the end coils one would have a single infinite line of diamond-shaped coils and the Fourier-integral method should be employed to obtain the proper field distribution perpendicular to the magnetic mirror. The apparent agreement between measured and computed values might be essentially due to the simple geometric form used. This agreement fails immediately when measurements are made on completed machines as evidenced in table II of the paper, where the error in the mutual inductance is 29 per cent and the error in the self-inductance 13 per cent.

On account of the simplifications introduced by Caldwell, one cannot possibly expect his formulas to hold in actual machines. I should like to call attention to a very thorough study of this problem extending over a period of almost 15 years, which leads to formulas taking into account all the details of actual machinery. The mutual linkage, for example, between field coil and stator winding is taken into account there and not ignored. I am referring to the set of volumes "Elektrische Maschinen" by R. Richter, successor to E. Arnold, at the Technical University "Fridericiana" in Karlsruhe, Germany. Four volumes have appeared, published by J. Springer, Berlin, Germany. The first volume, dealing with the general elements of electrical machines, published in 1924 (price approximately $11.00), gives on page 281 an exposition of the general problem of end-connection leakage. Some of the salient points of Richter's presentation are: distinction of the useful flux (linked with stator winding and field coil or rotor winding in general) and true leakage bux; computation of the leakage inductances by means of Biot-Savart's law in its form modified by J. C. Maxwell; distinction between self- and mutual inductances of the stator coils taking into account the relative position for the various types of windings used in electrical machinery, and finally a general form for the specific end-connection leakage whereby factors are introduced obtained by experimental research on a large variety of coil models, executed in the laboratories of the Technical University of Karlsruhe under the supervision of R. Richter.

Volume 2, dealing with the synchronous machines and synchronous converters, published in 1930 (price approximately $12.60), gives on page 91 a general formula for the specific end-connection leakage, introducing correction factors taking into account the shape of the rotor, the combination of the coils into coil groups and the pitch of the individual coils. Curves are given for those correction factors which were determined experimentally.

Volume 4, dealing with synchronous machines, published in 1936 (price approximately $12.60), gives on page 161 the application of the general formula for the end-connection leakage to the types of windings used in asynchronous machines, and takes into special consideration squirrel-cage rotors and slip-ring rotors of various numbers of phases. Again, distinction is drawn between useful flux and individual leakage flux of the opposing windings and correc-

tion factors are given in table and graph form.

Since the formulas published in the set of volumes mentioned above have been checked carefully in the course of many years, and since the resources of the Technical University of Karlsruhe are of world-wide repute, it might be very valuable to compare the results there obtained with the procedure suggested in the papers before us.

**Leroy Coffin** (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The subject of end-winding leakage reactance is of particular importance to designers of rotating electrical machinery because it forms an elusive part of the more important reactances. It may be a considerable part of the transient and subtransient reactances, particularly in machines with short cores, and for that reason the determination of these reactances may depend largely upon how closely the end-winding leakage reactance may be estimated.

Mr. Caldwell has made a very ingenious mathematical analysis of the end leakage field and it appears that with some modification to cover particular cases that we are now nearer a solution of this problem.

A flux map of this end-winding region shows a portion of useful flux extending well out into the space occupied by the coil ends and entering the stator teeth and core. The existence of this flux may be verified by means of iron shavings placed in a glass test tube. While this component of useful flux may be small in comparison with the flux in the air gap it is not necessarily small in relation to the total flux existing in the end zone. Each end conductor is also linked with flux which does no useful work. This we term leakage flux. We attempt to calculate the amount of this leakage flux but there is no way of readily measuring it. Exploring coils may fail to link all the leakage flux and are usually cut by useful flux. We thus measure the total flux, cutting the exploring coil but have failed to divide it into its respective components.

Most machines have masses of iron in this end zone, such as core end heads or finger plates, coil shields or end bells, and pole end plates or rotor-coil support rings. These, of course, change the reactance and their presence will require correction factors which will necessarily be empirical.

Caldwell's equation 16 gives values higher than those calculated by the usual methods. Calculations were made on a number of 3-phase machines, varying from 4 to 88 poles and in no case did the mutual leakage exceed 3 per cent to 4 per cent. A great many salient-pole machines have rotor pole end plates extending well out into this end zone. It would not seem that any appreciable amount of mutual leakage flux could exist between the 2 windings with this magnetic material between them.

In order to compare the various methods of calculating this end-winding leakage a hypothetical case was considered. It was assumed that we had a core which could be wound for 4 to 20 poles. The air-gap flux density, effective ampere conductors, and the output factor were arbitrarily kept constant in order to make the results comparable. Low-voltage insulation was assumed. Figure 2 shows the calculated per unit values of end-winding leakage reactance for a full pitch winding. The calculations were made by Caldwell's method and previously published methods.[1-3] No allowance was made for mutual leakage. No multiplying factor has been applied to the values obtained by Still's method. He recommends a figure of 1.7 to 3.5, depending upon the type of machine. Figure 3 shows calculated values for the same machines wound with $^2/_3$ pitch. This shows the influence of short pitch on the various methods. This example does not mean that the variation by different methods will always be as shown here. The results depend upon the amount of insulation on the coil, the ratio of slot to tooth width, the angle of the V part of the coil, and various other factors. However, with the various methods now available, used in conjunction with tests on actual machines, the designer should be able to estimate this end-winding leakage reactance with reasonable accuracy.

3. CALCULATION OF SYNCHRONOUS MACHINE CONSTANTS, L. A. Kilgore. AIEE TRANSACTIONS, volume 50, page 1201.

**B. H. Caldwell, Jr.**: The appearance of the factor 2 in equation 15, which has been questioned by Mr. Coffin, has been carefully checked both by Mr. Douglas and the writer, and the conclusion is that with the stated assumptions (15) is correct as it appears in the paper. In proceeding from (12) to (15) a multiplier of 2 does appear to take account of both ends of the end winding.

There may be some confusion regarding the definition of $n$. Perhaps a clearer definition would be to define $n$ as the number of V-shaped end-winding conductors per phase per pole. Throughout the paper the V-shaped conductor has been used as the unit. This corresponds to the number of series connected turns of the armature winding as a whole.

There happens to be an easy way of comparing the result given by (15) with Mr. Alger's result (reference 1 of the paper). His equation 13 for the peripheral component of end-winding leakage flux, when expressed in the nomenclature of this paper, is

$$\frac{X_{EP}}{2\pi fP} = \frac{12\,\pi\,D\tan\alpha}{P}\,K_{pl} \qquad (1)$$

Equation 15 differs from (33) only in that the tan $\alpha$ is replaced by sec $\alpha$. For $\alpha = 60$ degrees the ratio of (15) to (33) is 1.155. Now Mr. Alger adds the axial component of end-winding leakage to $X_{EP}$ to obtain the final expression for the total leakage, while the mutual linkage is subtracted from (15) to obtain the final expression for the leakage inductance, hence it appears logical to expect the 2 methods to agree with fair accuracy.

Mr. Douglas calls attention in his (1) and (2) to an approximation not specifically mentioned in the paper. The approximation involved is equivalent to assuming curve 1 of figure 4 instead of curve 2 as the magnitude of the space fundamental of flux density along the $y$-axis. Curve 2 which is theoretically correct has its maximum at

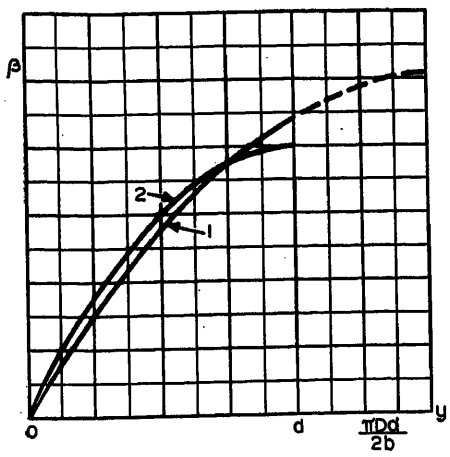

Figure 4

$y = d$, while the assumed curve 1 has its maximum beyond $y = d$. Only the region between $0<y<d$ is involved, and the simplification of the expression for the pitch factor warrants the approximation. For $^3/_4$ pitch this introduces an error of about 3.5 per cent.

The approximation pointed out by Mr. Douglas in his equation 3 is specifically noted in the paper. Space limitation prevented discussing it in detail. As he points out, it may lead to considerable error in some cases, particularly where the ratio of slot to tooth pitch is large. However, Mr. Douglas apparently overlooks the fact that, because of the angle of the end connections, the ratio of the peripheral dimension of the conductor in the end zone to the tooth pitch is much closer to unity than it is in the core length, which makes the approximation quite good for the fundamental. In cases where the series of equation 22 converges slowly equation 21 instead of 23 should be used to compute $K_m$.

Both Mr. Coffin and Mr. Douglas have pointed out the importance of fringing flux across the air gap. Measurements with exploring coils as well as flux plots indicate that they are correct. I would like to refer them to the discussion of this under "conclusions" in my paper. What I have attempted to calculate and measure is end winding *leakage* inductance. It seems obvious that practically all of the flux lines which enter either the pole directly or the rotor pole end plates will thread the pole coil, appear as fringing flux at an adjacent pole, and complete their paths by returning through the stator iron. There is, of course, some flux which passes from a tooth side to the adjacent tooth side. This is truly leakage flux and F. W. Carter in a discussion of a paper, "The Reluctance of Some Irregular Magnetic Fields," J. F. H. Douglas, AIEE TRANSACTIONS, volume 34, 1915, pages 1067–1134, has calculated this as a correction for the slot leakage flux. This seems to be a logical way to handle the other components of fringing flux. Thus this flux would contribute components to the flux of armature reaction and differential leakage as well as the slot leakage. Except for machines with a very short stacking these fringing components would probably be a very small correction. On this basis I have chosen to ignore the fringing flux in calculating the end-winding leakage inductance, and it enters the problem only in that it distorts the end-winding leakage field.

In the exploring-coil method of measuring the end-winding leakage inductance this question of fringing flux again appears. As Mr. Douglas points out, the exploring coils are not linked by all of this fringing flux. However, they were in the same positions for both the measurement of the self and the mutual flux, hence the omitted part would add to each of these values in the same way and cancel in the final result.

It is not my purpose to minimize the importance of calculating the fringing flux. Although it does not, according to the postulates of my paper, constitute a part of the end-winding leakage flux and except in rare cases the corrections of slot leakage, differential leakage, and inductance of armature reaction to account for it are probably small, it is very important in calculating losses. Most of this flux enters unlaminated sections of iron, hence it is probably responsible for a large part of the magnetic losses of machines.

For this reason, further work along the lines suggested by Mr. Douglas is very desirable. Also, as Mr. Alger points out, the method outlined should be useful in calculating the inductance of a larger class of machines. The discussion of this group of papers has revealed many useful suggestions and it is to be hoped that these suggestions will be the subject of further theoretical and experimental study by the various authors.

# Reactance of End Connections

**Discussion and author's closure of a paper by J. F. H. Douglas published in the February 1937 issue, pages 257–9, and presented for oral discussion at the power generation and electrical machinery session of the summer convention, Milwaukee, Wis., June 24, 1937.**

P. L. Alger: See discussion, page 1312.

G. W. Hampe: See discussion, page 1318.

Ernst Weber: See discussion, page 1313.

L. T. Rosenberg (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The designer is always eager to adopt refinements in methods of calculation of performance that will consistently yield more accurate values. Heretofore, end-connection reactance has been computed on the basis of certain assumptions which gave reasonably good results in most cases. When test values of reactance showed poor agreement with calculation, it was not always easy to determine the exact source of the error, although it was only natural to suspect those places where approximations had been used.

In synchronous machines having magnetic rotor pole end plates with axially overhanging pole piece to support the rotor coil ends, and in turbogenerators not equipped with nonmagnetic rotor-coil retaining rings, the proximity of the magnetic material evidently had its effect upon the end-winding reactance. Since these effects are most pronounced in the immediate vicinity of the core and pole ends, and since in machines of moderate to large ratings the stator coils usually project straight out of the slots for a distance of from 2 to 6 inches and then bend radially outward at an angle, it would seem reasonable that end-connection reactance might well be divided into 2 distinct parts; that part corresponding to the straight stickout with the proximity of iron accounted for in accordance with Doctor Douglas' paper, and the remainder corresponding to the V-shaped ends considered to be far enough away from the iron to be unaffected as treated by B. H. Caldwell in a companion paper. A rigid solution on this basis may prove to be less difficult and thus permit taking account of the conical shape of the end winding plane.

The application of the Schwarz-Christoffel transformation to the solution of magnetic fields as described in the paper will generally lend itself to the expression of permeances as a function of the physical dimensions in the form of curves, thus facilitating practical use of the results. End-connection reactance might then be computed in very much the same manner in which we now use the Carter coefficient to calculate the effective air gap of a slotted armature surface.

J. F. Calvert and E. K. Rohr (Iowa State College, Ames): We have several items which we wish to discuss in connection with Professor Douglas' paper and will introduce these approximately in the order in which he has presented them.

1. In his discussion of figure 2 of the paper, he describes how ampere turns applied across the air gap may be replaced by current-carrying conductors of proper strength. However, for his figure 1 and the lower view shown in figure 5, where imaging is proposed, we would like to ask why the air gap magnetomotive force has not been replaced by a current sheet (or Rayleigh insulating surface for magnetic flux)?

2. Referring now to the right-hand drawing in figure 2 of Professor Douglas' paper, we do not believe that this presents a strictly correct treatment of the problem. Either it must be assumed that other conductors exist such that there will be the same magnitude of magnetomotive force for the air gap over each coil, or else, if only one coil is to be assumed in the air gap, as is shown in his figure 2, the return current at the air gap for the single coil end must divide and travel along the air gap in 2 paths. This is illustrated further in figures 1 and 2 of this discussion. If only one coil is to be assumed in the machine and it spans one-fourth of the air gap periphery, figure 1*a* of the discussion shows the air gap magnetomotive force to be replaced, and figure 1*b* shows how this should be accomplished. If 4 coils, each of one-fourth pitch, are to be assumed and are so disposed that the magnetomotive force on the air gap is symmetrical, figures 2*a* and 2*b* of this discussion show how the air gap magnetomotive force should be replaced by current-carrying conductors. We assume that for the right-hand drawing of figure 2 in the paper, Professor Douglas is assuming that

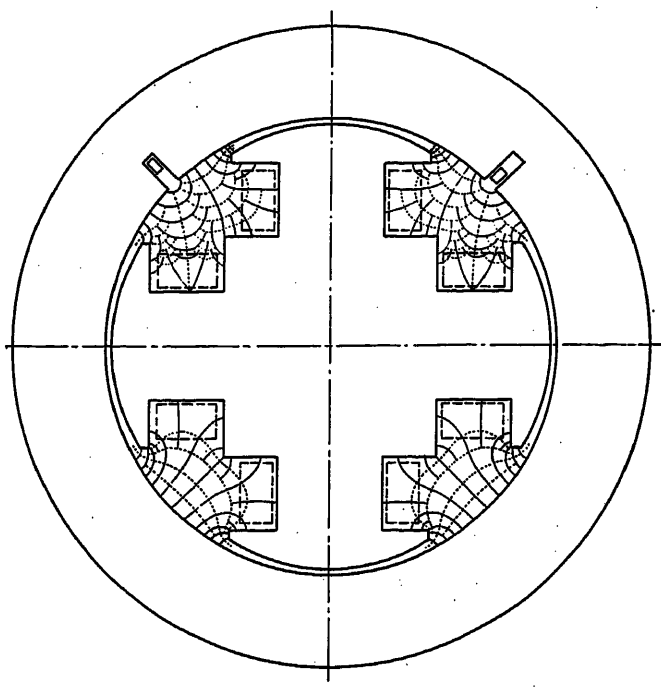

FIGURE 1a

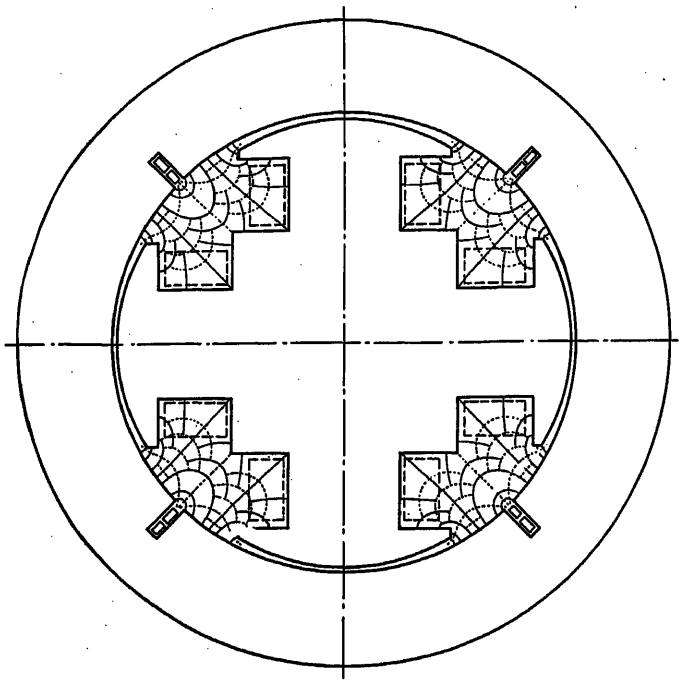

FIGURE 2a

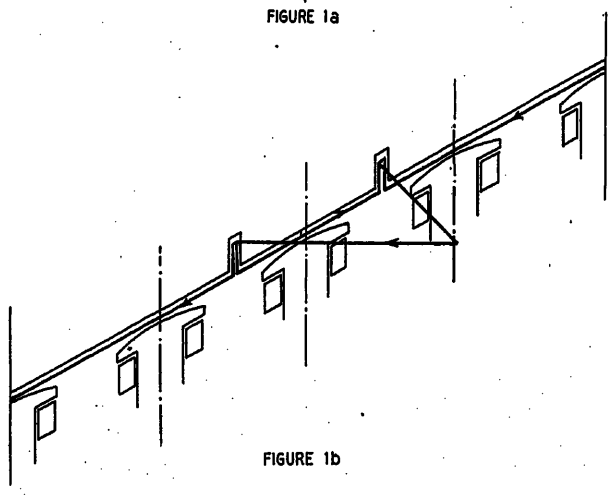

FIGURE 1b

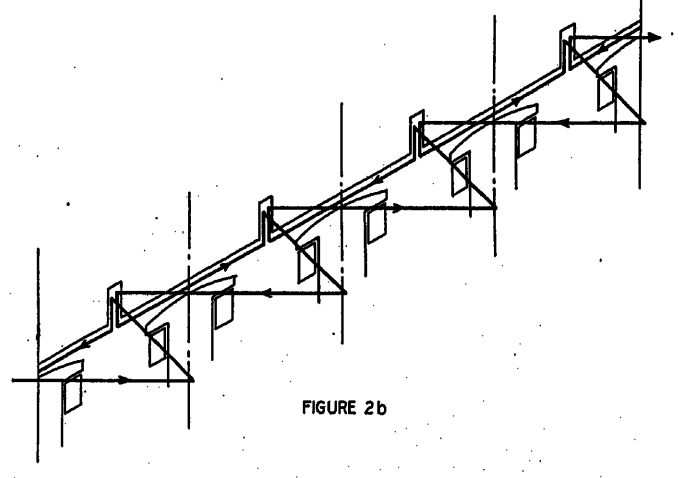

FIGURE 2b

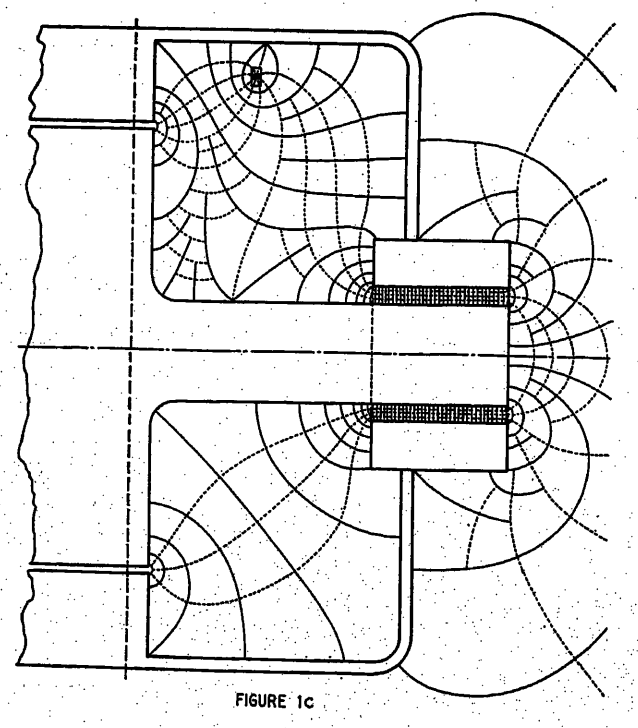

FIGURE 1c

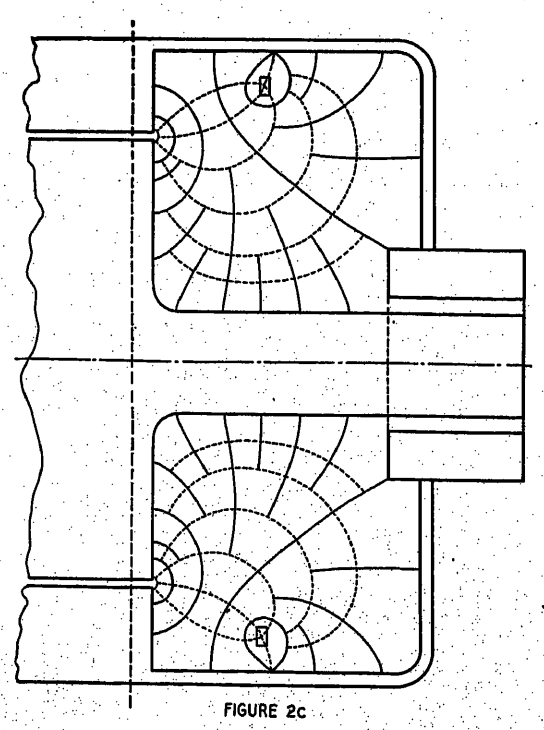

FIGURE 2c

**Figure 1a. Only one full pitch coil excited**

Solid lines show the flux. Dotted lines show the ampere turns, and also the directions and relative densities for the current when the air space in this plane is replaced by a current sheet or Rayleigh insulating surface for magnetic flux

**Figure 1c. Approximate flux and magnetomotive-force distribution on the radial plane through the pole center line with only one full pitch coil excited in a 4-pole machine**

Note the map is only 2-dimensional. Also note that the stator finger-plate and end-plate and also the overhang on the pole end-plate are neglected to give a plane surface and thereby permit imaging. This has been done to be most nearly in conformity with the paper

**Figure 2a. Same as figure 1a except with one full-pitch coil per pole excited as shown**

**Figure 2c. Same as figure 1c except for one full-pitch coil per pole**

an even number of coils are disposed around the machine in a manner similar to that indicated by figures 2*a* and 2*b* of this discussion. Figures 1*c* and 2*c* of this discussion show the end zone flux mapped on the assumption of a 2-dimensional field. It must be recognized that a 2-dimensional analysis here is only approximate, but it does give the general direction of the magnetic flux, and the orthogonal surfaces.

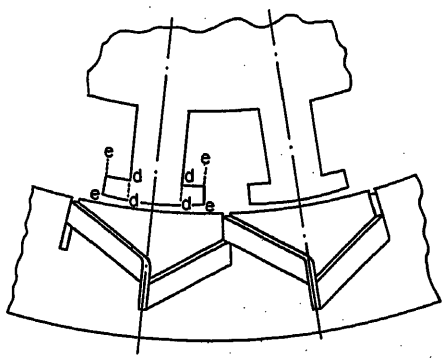

**Figure 3**

3. In his discussion of figures 5 and 6 of the paper Professor Douglas assumes a Rayleigh insulating surface to be located in a plane parallel to the edge of the field poles. It would appear that Professor Douglas intends to neglect the pole overhang or pole-shoe. However, we would like to ask first whether this Rayleigh insulating plane is to be assumed at *e-e* or at *d-d* as designated in figure 3 of this discussion, or at some intermediate location, and second on what basis a Rayleigh insulating surface in this zone between *e-e* and *d-d* can be assumed to be a plane? We feel that this assumption is an ingenious development, and if it can be adequately justified may prove to be a useful artifice, but we also feel that further justification for the assumption of a plane for this surface should be presented.

4. The pole and armature present Rayleigh conducting surfaces for magnetic flux in the end zone. However, the interpolar space may be considered merely as a widening out of the air gap in the radial direction. Therefore, in the polar zone as defined in the

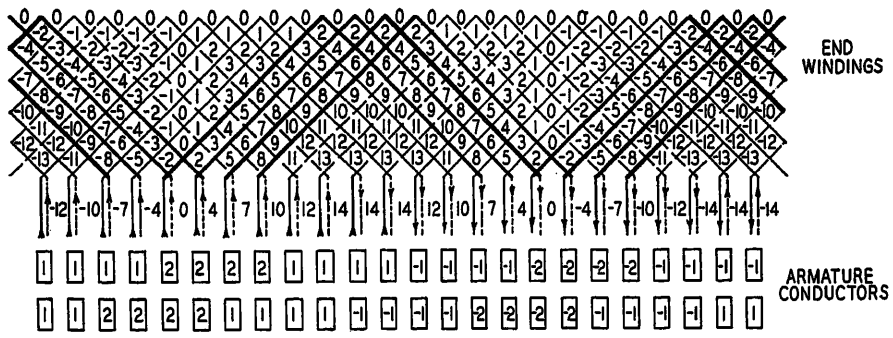

**Figure 4. End-winding and air-gap magnetomotive forces**

Three phase, 4 pole, 48 slots, coil span = 10 slot pitches

paper, the pole and armature do not form a continuous Rayleigh conducting surface, but must have a Rayleigh insulating surface between them to represent the air gap as illustrated in figure 3 of this discussion. That this must be done, is not made clear in that part of the paper in which figure 5 of the paper is discussed.

5. The use of the Rayleigh conducting surface $RC_2$ in the lower right-hand corner of figure 5 of the paper would seem to be a reasonable assumption for those machines in which the frame and end bracket overhang the coils, and do present such a conducting surface for magnetic flux over both the polar and interpolar zones. However, the assumed plane should be so located as to most nearly represent these magnetic parts. It may need to be closed in on machines with bracket-type bearings making reasonable allowance for the space between bracket arms. (See figures 1*c* and 2*c* of this discussion which are for a machine where the actual bracket arms came outward on diagonal lines from near the frame to the bearing.)

6. To be in conformity with the paper, we have confined our discussion to the case of one full-pitch armature coil per pole. We wish now to discuss the actual cases of distributed windings. Exploring coils will show that the flux lines pass through the armature end winding in directions reasonably nearly perpendicular to the conical surface between the 2 layers of the end winding. Reasons for this can be offered.

If no iron were present at all and the coil span was not a great percentage (one-fourth or less) of the armature bore, then the reluctance inside and outside the coil would not be greatly different and the flux field near the conical surface of the end winding would be almost symmetrical with respect to this conical surface. This would mean that the flux would pass nearly perpendicularly through this surface between 2 layers of coils in the end winding. The introduction of iron into the problem produces tremendous effects where it is near the coils. However, it is not near the conical surface of the end winding and will not produce great effects here just as the imaged conductors with the iron removed would not produce great effects on densities near the coil which is imaged—provided the spacings between coil surface and iron are relatively great as is the case for most of the armature end winding.

It might be desirable to make use of the magnetomotive forces through this surface at various points as mentioned before. The end zone like the air gap and interpolar zone is merely part of the air space between the rotor and stator. On the basis of these 2 remarks, it might seem desirable to extend the usual magnetomotive-force diagram for the air gap to the end zone as is illustrated in figure 4 of this discussion. This viewpoint has been discussed in more detail in the paper "Additional Losses in Synchronous Machines," AIEE TRANSACTIONS, volume 46, 1927, pages 84–97, by C. M. Laffoon and J. F. Calvert. We offer this merely as a possible treatment. We wish to point out that our figure 4 of this discussion merely gives the approximate magnetomotive force distribution and not the reluctance for paths through the winding. The effects here might be considered analytically by assuming the magnetomotive-force distribution mentioned above and considering the iron boundary conditions as they exist in the end zone. Another possible attack would be to excite the armature coils with direct current, and explore the directions of flux with a compass. The discussers are of the opinion that the experimenter would then deduce that exploring coils placed within the conical end winding would show practically the total linkage in this zone under a-c conditions. The flux distribution under these d-c conditions will be practically the same as under normal a-c conditions because sufficient eddy currents cannot flow in the armature end plates and frame to alter greatly the flux distribution under normal load. That this must be true can be reasoned as follows: The armature winding carries the full armature magnetomotive force in the end winding. If the flux is to be kept out of the end plates, frame, etc., damping currents of practically equal magnetomotive force would have to flow in these parts. When one considers the depth of current penetration in the iron which is normal at the commercial frequencies, the loss densities are many times higher than can actually exist without greatly overheating the machine. Another method of attack here is to neglect saturation and calculate by means of 2-dimensional flux maps what the flux entering the iron parts will be. Then calculate the saturation produced making due allowance for proper flux penetration in solid parts. Then by use of Rosenberg's formula consider the ampere turns present in eddy currents. These eddy currents will be found small enough to have little effect on the general shape of the end zone flux.

We hope that Professor Douglas will give a detailed discussion of how he intends to consider the various phase groups in the end

zone either with or without the use of the Rayleigh insulating plane to divide the space into polar and interpolar spaces when he proceeds to the cases of actual armature windings.

7. In addition to the use of Rayleigh insulating and conducting planes as Professor Douglas describes them, we wish to suggest that any surface in a magnetized space may be replaced by combinations of current and magnetic sheets for use in electrical machine calculations. This has been illustrated in the paper "Forces in Turbine Generator Stator Windings," by J. F. Calvert, AIEE TRANSACTIONS, March 1931, pages 178–94, and the scheme might have some value in this work of Professor Douglas' as well as in that for which it was used where the forces exerted on armature end windings were to be calculated.

**J. F. H. Douglas:** I quite agree with Mr. Alger's remark that considerable work is yet to be done. My paper is really more of a program for research, than anything else. It is gratifying to know that it seems to be a sound procedure.

Mr. Rosenberg's suggestion is interesting and of value. It is equivalent to assumption of a Rayleigh insulating plane perpendicular to the shaft at some point approximately 2–6 inches from the pole. Caldwell's method would be rigorously applicable outside this surface, my method could could be applied inside this surface. However no advantage is gained as yet. If immediate results are wanted Caldwell's formula is apparently the best to date. If greater accuracy is wished for the future why asume this plane at all? The assumption of a Rayleigh plane always decreases the answer, we would not know at present where to place it for best results, and we would still lack a usable formula for immediate use. The chief merit of this suggestion seems to me as a means of adapting theory to fit test results at some later date if it prove that Caldwell's formula is lower than test, and that my method gives reactances larger than test values.

Referring now to the careful analysis of Messrs. Calvert and Rohr, in the sequence of their numbered points.

1. Their suggestion of a current sheet appears decidedly superior to my rather crude semicircular fictitious conductor. It meets boundary conditions theoretically, and leads to an added item of permeance of 0.7 line per ampere turn for each inch of pole width (0.27 per centimeter). Their figures are particularly elegant and instructive.

2. Their point that the current sheet should divide in the ratio of 75 per cent and 25 per cent in a 4-pole machine is perhaps theoretically right for an isolated coil. However the simplest unit from which to build up inductance, is, perhaps, one coil for each pole, and for this case the distinction is unimportant.

3. I believe that the radial Rayleigh insulating planes should be intermediate between the pole-shoe tip and the edge of the pole core: (1) not much error is caused by assuming the outer end of the pole tip as insulating, (2) not much error is caused by assuming the narrow strip between this plane and the pole edge as conducting, (3) these errors compensate.

Their second point is whether a plane Rayleigh surface can be assumed with propriety at all. A Rayleigh surface always causes some error, but this error is small when in regions of highest density the lines are nearly parallel to the surface. In this case near the air gap the actual lines are parallel to this plane. Near the trace of the conductor they meet it at 40 degrees, It is believed therefore that some error is made but less than that of other methods proposed. By moving the Rayleigh plane toward the interpolar axis we eventually arrive at a point where it is obvious that the permeance is too large.

I conclude that by assuming the Rayleigh plane intermediate between the pole tip and the pole edge, but nearer the pole tip, we will get a balance between calculations and experiment.

4. In figure 5 the air gap should have been shown perhaps. However, if we assume armature ampere turns and balancing field ampere turns, we do not need any current sheet in the air gap, and have a basis for computing that part of the flux in the end zone, for 2 important cases, namely Potier reactance, and the inductance of commutation.

5. I believe these comments to be well founded, and helpful where housing iron needs to be considered.

6. The suggestions should be considered by future investigators. I believe them as more helpful in guiding tests than as an aid to calculations.

Hopes are expressed for a detailed discussion of how I propose to consider various phase groups in the end zone. A closing discussion is hardly the place for much detail and, to be frank, the writer is not going to take up the detailed solution at this time. Enough has been done since the paper was published, however, to show that Laplace's equation is easily integrable for coils that are 45-degree isosceles triangles both for self-induction, and for mutual induction between coils in the same and adjoining phase belts. The coil is the first unit, the phase belt is naturally the second, and the mutual inductance between phases and adjoining pole pitches naturally follow.

## Approximating Potier Reactance

**Discussion and author's closure of a paper by Sterling Beckwith presented at the power generation and electrical machinery session of the summer convention, Milwaukee, Wis., June 24, 1937, and published in the July 1937 issue, pages 813–18.**

**P. L. Alger:** See discussion, page 1312.

**S. B. Crary** (General Electric Company, Schenectady, N. Y.): Mr. Beckwith's paper presents interesting data in regard to Potier reactance and methods of approximating it, which check with good accuracy a large number of test results. This information is valuable in that it increases our knowledge of machine reactances.

It is well to keep in mind that Potier reactance has only a limited field of usefulness, namely the approximate determination of field excitation for normal conditions of voltage and power factor. For any unusual conditions such as high terminal voltage or leading power factor or for the determination of the load angle and stability characteristics, the use of Potier reactance determined at normal voltage may give results which are too approximate. There appears to be no real reason for using Potier reactance for design computations as in such work all the machine quantities are available and the field excitation can be calculated by more accurate methods. For those cases other than for design computations Potier reactance can usually be determined by test.

The method which Beckwith has used for determining the pole saturation, by adding the transient reactance drop to terminal voltage to obtain the pole flux, can only be used for the condition of zero power factor, which is the condition for determining Potier reactance. For other power factors, if the approach is made from the armature, it would be necessary to add to the direct-axis component of terminal voltage the direct-axis component of transient reactance voltage drop. In order to determine these direct-axis components, it is necessary to know that component of saturation-magnetomotive force which is a function of the quadrature-axis flux, as saturation in the quadrature axis affects the machine angular displacement. These complications are to a considerable extent the reason for the use of Potier reactance for excitation calculations, as it provides a method which has been found to give approximately the correct excitation by a comparatively simple calculation. However, the use of Potier reactance does not give the proper load angle of the machine and in some cases does not give the correct excitation. The greatest disadvantage for its use is that it tends to conceal the true physical picture.

**G. W. Hampe** (Commonwealth Edison Company, Chicago, Ill.): The writer is pleased to see that the constants of synchronous machines are being subjected to careful analysis, both in regard to furnishing sound concepts and in development of methods of computation and test. As one who makes computations for systems containing synchronous machines, the writer can say that such studies are needed, and that the results should be made available to all who can make effective use of them.

If it is granted, for the present, that the primary concepts have been defined and methods of computation and test have been made available, what is the resulting advantage to the operating engineer? Manufacturing companies have always willingly furnished data on their machines, both old and new. Likewise, power companies have freely given information to their interconnected associates. Unfortunately, however, these communications have been haphazard and occasionally repetitive.

The writer suggests that a standard form or set of forms be developed so that all data pertinent to the electrical properties of a given machine can be recorded on one sheet. Part of the data for such a form, such as the reactances, would usually be supplied by the manufacturer, and the balance, referring to external reactors, field rheostats, etc., would

be filled in by the operating company. The writer would like to call this matter to the attention of the AIEE committee on synchronous machinery.

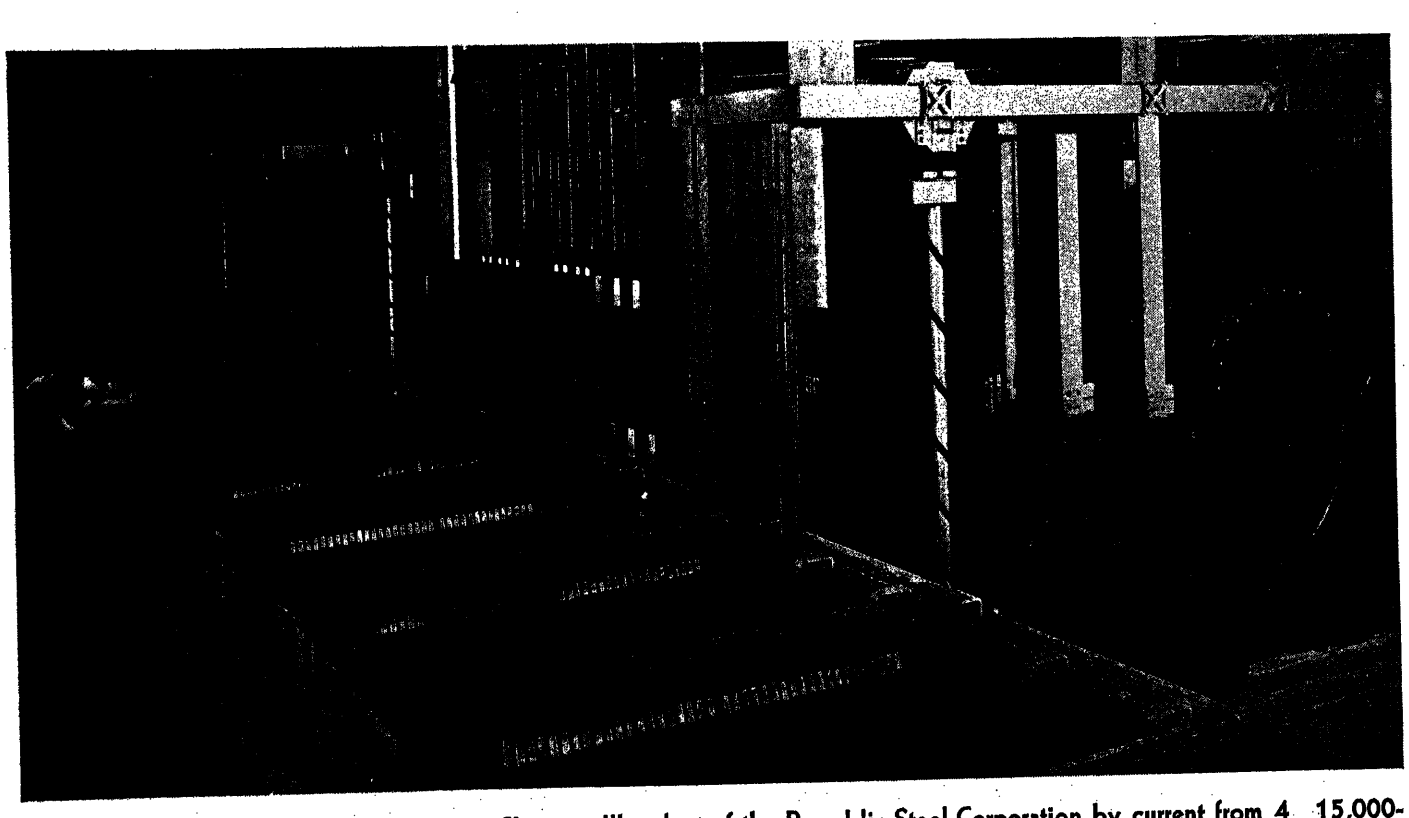
Such a form should *not* be made up with a view of obliging each manufacturer to compile all the data for every machine, large and small. When data are furnished, however, they should follow the standard definitions accepted, at that time, and the use of a standard form would systematize communications.

The papers, particularly the one by Mr. Beckwith, added to the rather scanty stock of published test data. More data are needed in regard to machine constants in general, particularly for large machines. As an example of this need, Mr. Beckwith offered an approximate formula relating Potier reactance to unsaturated transient reactance, which brings up the question of saturation. In the AIEE summer convention in 1931, Mr. S. H. Wright stated that the saturated transient reactance $x_d'$ was related to the unsaturated value by the formula:

$$x_d' \text{ (sat.)} = 0.88\, x_d' \text{ (unsat.)}$$

This formula was questioned, but to date the writer has not seen a satisfactory alternative. In some types of power system computations both the saturated and unsaturated values are needed, and usually one must be derived from the other by a formula of some sort.

The test methods known at present are not applied for several reasons. The manufacturer seldom has facilities for testing a large machine before shipment. The operating company could make the test, but it means trouble and expense, not only for the testing setup itself but because the machine may be badly needed on the system. A large part of the cost is hidden and indirect. Furthermore the operating company probably has only one machine of that class, and a refinement in data means little because of its limited applicability. The same expenditure for a test of system stability or relay performance yields data of greater value.



The manufacturer can profit by tests on individual machines, because he is concerned with a number of machines of the same class, and, furthermore, there should be occasional checks on general methods of computation and design. It would seem then that the manufacturer should co-operate more frequently with the operating company in securing test data, and it would seem that the manufacturer should share the costs.

**Sterling Beckwith:** Mr. Crary's comment that the use of Potier reactance tends to obscure the exact picture is quite correct, and should be borne in mind when using the reactance. However, a clearer picture of the magnitude and range of the reactance and its relation to other reactances should have the opposite effect. Mr. Crary limits the use of Potier reactance to the calculation of field currents, but a further use is for determining the effects of saturation on stability.

Although Potier reactance varies with current and voltage, it should be pointed out that most synchronous-machine reactances are subject to the same variation. Furthermore Potier reactance is subject to easier and more accurate test than are most reactances.

Mr. Hampe raises the question of saturation of transient reactance. The curve mentioned showing an average value of saturated reactance equal to 88 per cent of the unsaturated value does not take terminal voltage into account. Thus when the internal voltage is above normal the saturation factor may be much lower than 88 per cent. Tests with which the writer is familiar indicate that an average value is 83 per cent to 88 per cent for a dead short circuit at rated voltage, but that it may vary very greatly in different machines.

Perhaps Mr. Hampe's suggestion of a standard form for machine characteristics might be filled to some extent by references to the "Proposed Test Code for Synchronous Machines." One advantage of references to such a test code is that definitions are usually definite and unambiguous, whereas any abbreviated form might lack this advantage. A summary sheet added to the test code might make it more suitable for the purpose.

**Steel wire is electrogalvanized in the new Chicago, Ill., plant of the Republic Steel Corporation by current from 4 15,000-ampere d-c generators. The current is distributed to 27 sets of porcelain-insulated fingers which make contact with 40 strands of wire that pass continuously through the 140-foot electrolytic bath at speeds from 35 to 70 feet per minute. Thickness of the zinc coating is controlled by speed of wire travel and current density. Electrogalvanizing produces a coating that is considered superior to hot galvanizing because of its better adherence, greater uniformity, and purity, but difficulties of cleaning and deposition, solved only recently, retarded development**

## Pacific Coast Holds Successful Convention at Spokane

TWO hundred and sixty-six members and guests enjoyed the 25th Pacific Coast convention, which was held at Spokane, Wash., with headquarters in the Hotel Davenport, from Tuesday morning through Friday, August 31–September 3, 1937. On the part of those in attendance full advantage was taken of the technical sessions, student sessions, entertainment, sports, and inspection trips, which had been well arranged by the convention committee, and many were afforded the opportunity of meeting old acquaintances.

The opening session on Tuesday morning was called to order by Dean H. V. Carpenter, convention chairman, who introduced Arthur W. Burch, mayor of Spokane. The mayor welcomed to the city those attending the convention and he advised that Frank G. Sutherlin, commissioner of public utilities, would be delighted to have members inspect the electric plant up the river.

President Harrison expressed appreciation on behalf of the Institute of the welcome extended by Mayor Burch, who had been ill but came down to greet the assemblage on his second day out. He complimented the District and Section officers upon the favorable manner in which the conventions, student activities, and student prizes have been conducted on the Pacific Coast. At the conclusion of the opening of the convention R. W. Sorensen proceeded with the conduct of the selected subjects session.

### Technical Sessions

A keen interest on the part of those who attended the 6 technical sessions and 2 student sessions was maintained throughout the duration of each session. One of the 6 technical sessions, which dealt informally with the subject of electric house heating, was held on Wednesday evening with Professor F. O. McMillan presiding. Doctor C. E. Magnusson, director of the Engineering Experiment Station, University of Washington, presented a summary and recommendations of the investigation on the electric heating of homes in the Mont Lake district of Seattle. The work was originally done for the State Planning Council. The complete report of this work, with results and conclusions, is available in Bulletin No. 93, "Electric Power Markets in Washington —Part I, Electric Heating of Residences," recently published by the Engineering Experiment Station, University of Washington. Dean H. V. Carpenter of the State College of Washington, presented a paper on the same subject, which reported the results of experiments on different methods of heat storage for electrically heating the specially constructed and insulated houses at Mason City. These papers were discussed by several well-known executives and engineers of operating companies in the Pacific northwest, who found the studies to be most valuable but not in agreement with the practical problems of power distribution, as experienced in operating company work. Another session, on the subject of communication, which was held jointly with the members attending the Institute of Radio Engineers' meeting, was well attended and considerable interest was manifested in the 6 papers which were presented.

Most of the convention papers were personally presented by their respective authors, and, in cases where the authors were unable to attend, comprehensive and effective presentations were made by F. C. Lindvall, California Institute of Technology, P. B. Garrett, Westinghouse Electric & Manufacturing Company, H. H. Skilling, Stanford University, W. C. Smith, General Electric Company, and S. B. Wright, Bell Telephone Laboratories, Inc.

### Student Technical Sessions

In accordance with the practice followed for a considerable number of years, 2 student technical sessions were held as parts of the convention technical program. Eleven papers, as listed below, were presented:

**Wednesday Afternoon**

J. S. Mascovich, chairman, University of Santa Clara Branch, presiding.

Balanced Feed-Back Amplifiers, Edward L. Gintzton, University of California

A Method of Measuring Losses in Small Transformers, Bruce Morgan, California Institute of Technology

Laboratory Equipment for Construction of Experimental Electron Tubes, H. P. Blanchard, Stanford University (presented by Leonard M. Jeffers, Jr., chairman, Stanford University Branch)

Magnetic Focusing of the Electron Gun, L. Dale Harris, University of Utah (presented by William R. Wilson, chairman, University of Utah Branch)

Influence of Utensils on Heat Transfer from Electric Range Elements, William G. Short, Oregon State College

**Thursday Afternoon**

Gordon B. Allan, chairman, Montana State College Branch, presiding.

A High Impedance Detector Circuit With a Diode, John W. Stoker, Jr., Montana State College

Torque in Induction Disk Instruments, G. I. Goumeniouk, University of British Columbia

Variable Gain Amplifier and Its Application, J. F. Kalbach, University of Washington (presented by Rush Chase, University of Washington '37)

Electrostatic Air Purification, W. D. Arms, University of Idaho (presented by W. T. Connely, University of Idaho, February '37)

Measurement of the Field Strength of Radio Station KWSC, William Lean, State College of Washington

Characteristics of A-C Welding, O. C. Bixler, University of Southern California (presented by A. E. Harrald, chairman, University of Southern California Branch)

The quality of the presentations was high despite the facts that several authors were absent and their papers were presented by students and recent graduates not directly connected with the work discussed. The subject matter of all maintained a high degree of interest throughout the 2 sessions and some of the papers were discussed by students and others.

### Conference on Student Activities

A joint conference on student activities for representatives of the student Branches in Districts 8 and 9, and the University of British Columbia Branch, as well as District officers and others interested, was held at a dinner meeting on Wednesday evening, with an attendance of 38, as reported in more detail below:

**Branch Chairmen**

John Draper, University of Arizona, Tucson
Bruce Morgan, California Institute of Technology, Pasadena
Peter Duyan, University of California, Berkeley
Gordon B. Allan, Montana State College, Bozeman
Guy K. Patterson, University of Nevada, Reno
Victor S. Carson, Oregon State College, Corvallis
J. S. Mascovich, University of Santa Clara, Santa Clara, Calif.
Leonard M. Jeffers, Jr., Stanford University, Calif.
William R. Wilson, University of Utah, Salt Lake City

**Counselors**

W. B. Coulthard, University of British Columbia, Vancouver
F. C. Lindvall, California Institute of Technology, Pasadena
Abe Tilles, University of California, Berkeley
J. H. Johnson, University of Idaho, Moscow
A. L. Albert, Oregon State College, Corvallis
W. G. Angermann, University of Southern California, Los Angeles
E. F. Peterson, University of Santa Clara, Santa Clara, Calif., and chairman, committee on Student activities, District 8
H. H. Skilling, Stanford University, Stanford University, Calif.
A. LeRoy Taylor, University of Utah, Salt Lake City
O. B. Osburn, State College of Washington, Pullman
R. E. Lindblom, University of Washington, Seattle

**Others Present**

J. P. Jollyman, vice-president, District 8
A. M. Bohnert, secretary, District 8
C. E. Rogers, vice-president, District 9
S. E. Caldwell, secretary, District 9
F. Ellis Johnson, director, and chairman, committee on student Branches
E. A. Loew, member, committee on student Branches
R. W. Sorensen, director, and member, committee on student Branches
H. V. Carpenter, chairman, Pacific Coast convention committee
R. H. Hull, chairman, student activities subcommittee, Pacific Coast convention committee
H. H. Henline, national secretary, and several professors, students, and others as guests—total 38

## Analysis of Attendance at 1937 Pacific Coast Convention

| Classification | Spokane | Dist. 9* | Dist. 8 | Dist. 10 | Misc. | Totals |
|---|---|---|---|---|---|---|
| Members | 28 | 35 | 25 | 5 | 15 | 108 |
| Men Guests | 22 | 43 | 23 | 2 | 7 | 97 |
| Women Guests | 20 | 20 | 16 | 1 | 4 | 61 |
| Totals | 70 | 98 | 64 | 8 | 26 | 266 |

* Outside of Spokane Section territory.

Professor E. F. Peterson of the University of Santa Clara, chairman of the committee on student activities in District 8, presided, and presented as the first item for consideration a list of suggestions for the guidance of counselors in Districts 8 and 9 which had been prepared by a committee including all counselors in Districts 8 and 9, with Professor Peterson as chairman. After an extensive discussion of the individual suggestions, the committee was given a vote of thanks and requested to continue the work and report again at the next conference.

It was voted to recommend that the board of directors consider the possibility of re-establishing the cash prize of $100 for the best Branch paper prize.

Many of those present expressed strong hope that such a joint conference, with traveling expense allowance to official representatives, may be provided for regularly so it will not be necessary to request special action each year. There was some discussion of the best time for such conference from the standpoint of attendance by students.

Vice-presidents Jollyman and Rogers, Directors Johnson and Sorensen, chairman and member, respectively, of committee on student Branches, Professor E. A. Loew, member of that committee, and National Secretary Henline were called upon for brief remarks, and all responded, giving information and opinions regarding various phases of student activities in the Institute.

After the adjournment of the conference, the counselors of the 2 Districts met in separate groups and elected as chairmen of the District committees on student activities:

Pacific District (Number 8)—Professor H. H. Skilling, Stanford University
North West District (Number 9)—Professor A. LeRoy Taylor, University of Utah

### Entertainment

On Tuesday evening a number of members and guests enjoyed an informal reception and dancing held in the Marie Antoinette Room of the Davenport Hotel. The entertainment concluded with the banquet and presentation of sports prizes, which took place on Thursday evening and which was well attended. Splendid entertainment in the form of aesthetic dancing, singing, and music rendered by the Mann Brothers orchestra was furnished. Toastmaster J. E. E. Royer, vice-president and general manager of the Washington Water Power Company, conducted the banquet in true social fashion by admonishing those in attendance "to forget their kilowatt words" and enjoy themselves. President W. H. Harrison of the AIEE and President H. H. Beverage of the IRE greeted the guests.

### Presentation of Sports Prizes

The sports prizes were presented in person by the well-known pioneer in hydroelectric developments in the northwest, John B. Fisken. The competition for the Fisken cup resulted in a tie between C. E. Boozier, Portland, C. H. Cutter, Seattle, and R. H. Dearborn, Corvallis, which was decided by the rolling of dice. Dean Dearborn won the trophy with C. C. Boozier runner-up. W. E. Wallace, Seattle, won the guests' competition with J. F. Gogins, Spokane, runner-up. Prizes were presented for the remaining events open to both members and guests: low gross, J. C. Henkle, Portland; longest drive at hole number 3, M. P. Buswell, Seattle; approach nearest pin at holes numbers 9 and 17, J. C. Henkel and H. A. Boring, Seattle; kickers handicap, L. R. Elder, Portland; and high gross, C. B. Carpenter, Portland. Birdies were scored by J. E. E. Royer, J. W. Butler, Schenectady, J. C. Henkle, M. P. Buswell, and J. W. Ferguson, Seattle. The women's putting contest was won by Mrs. W. H. Ude, Spokane, with Mrs. Chet Reis, runner-up. First prize for approach was won by Mrs. M. M. Phegley, Glendale, Calif., and second prize was won by Mrs. H. B. Hodgins, Spokane. The winners of consecutive flights were respectively as follows: Mrs. J. H. Siegfried, Kennewick, Mrs. C. E. Rogers, Seattle, Mrs. M. M. Phegley, Mrs. S. B. Wright, South Orange, N. J., Mrs. J. C. Bird, Seattle, Mrs. A. C. Schwager, San Francisco, Calif. Mrs. R. W. Sorensen, Pasadena, and Mrs. A. H. Beckwith, Spokane. Excellent prizes consisting of leather luggage, golf clubs, a silver platter, golf balls, and favors were made possible through the courtesy and financial support of several manufacturing and operating companies in the Pacific Coast region.

### Women's Entertainment

Under the guidance of Mrs. L. R. Gamble, Seattle, chairman, women's entertainment committee, a pleasant series of events was arranged. Tuesday morning the women got together for the purpose of becoming acquainted with one another, after which the group divided; one group took a drive about the city and gardens, while the other attended the "movies" at the Fox Theater. Luncheon was held in the Elizabeth Rooms of the Hotel Davenport. On Wednesday morning shopping tours were conducted and a bridge-luncheon was held at Glen Tana. Winners of prizes were Mrs. J. F. Spease, Portland, Mrs. C. C. Boozier, Portland, Mrs. Charles North, Kamloops, B. C., Canada, and Mrs. J. H. Neher, Philadelphia, Pa. Mrs. J. C. Bird of Seattle won the auction. One of the prizes consisted of a jar of herbs obtained from the beautiful gardens at Glen Tana. Thursday the principal event consisted of a scenic drive through the residential districts and civic gardens of Spokane, which was followed by a putting tournament and tea at the Spokane Country Club and a musical hour with selections rendered on the harp and cello.

### Trips

The principal trip was held on Friday, when over 250 members and guests of the AIEE and the IRE left the Hotel Davenport by bus and private car at 8:00 a.m. to see the Grand Coulee Dam, now in process of construction. Addresses on the features of the project were given by A. F. Darland, C. D. Riddle, and Mr. Banks, and a model of the dam was seen in the West Vista House. Luncheon was served in the contractor's mess hall on the east side of the river. The return to Spokane was made via Grand Coulee, and Dry Falls where the Columbia River once outrivalled the Niagara.

During the convention, trips were taken in private cars to various points of interest in Spokane and vicinity. Among the places visited were the Up-River Hydroelectric

## Membership—

Mr. Institute Member:

AIEE meetings and other activities get under way about this time of the year in many Sections.

I hope you will plan to get the most out of your Institute connections this season by attending what conventions, Section meetings, and other affairs you can, and by taking an active part in them in some way.

You may also be able to assist a nonmember friend by taking him with you and by introducing him to other members. If he becomes interested and is eligible for membership your membership committee will help him in making his application. Just write to your Section membership chairman or to headquarters.

L. L. Webb

Assistant Chairman
National Membership Committee

Station of the water department, the Ray and Hartson Pumping Plant, the radio tower of KHQ-KGA, and the Inland Paper Company mill, as well as the beautiful residential section and gardens in the city.

The personnel of the committee and the subcommittee chairmen which made all of the foregoing events possible is as follows: H. V. Carpenter, chairman; R. D. Sloan, vice chairman; M. F. Hatch, secretary; Reinier Beeuwkes, S. E. Caldwell, J. B. Fisken, L. R. Gamble, J. C. Gaylord, C. R. Higson, N. B. Hinson, R. H. Hull, H. S. Lane, F. O. McMillan, H. L. Melvin, H. S. Osborne, George Quinan, C. E. Rogers, R. W. Sorensen, and A. Vilstrup: L. R. Gamble, meetings and papers; J. S. McNair, finance; L. A. Traub, transportation; H. W. Webbe, housing; J. R. Murphy, entertainment; J. B. Fisken, sports; H. B. Hodgins, publicity; R. H. Hull, student activities; D. H. Olney, registration; Earl Baughn, inspection trips; and Mrs. L. R. Gamble, women's entertainment.

# AIEE Board of Directors Meets at Institute Headquarters

THE regular meeting of the AIEE board of directors was held at Institute headquarters, New York, August 3, 1937.

Present: *President*—W. H. Harrison, New York, N. Y. *Past-President*—A. M. MacCutcheon, Cleveland, Ohio. *Vice-Presidents*—O. B. Blackwell, New York, N. Y.; C. Francis Harding, Lafayette, Ind.; I. Melville Stein, Philadelphia, Pa.; A. C. Stevens, Schenectady, N. Y. *Directors*—C. R. Beardsley, Brooklyn, N. Y.; F. M. Farmer, New York, N. Y.; F. Ellis Johnson, Columbia, Mo.; C. R. Jones, New York, N. Y.; W. B. Kouwenhoven, Baltimore, Md.; K. B. McEachron, Pittsfield, Mass. *National Treasurer*—W. I. Slichter, New York, N. Y. *National Secretary*—H. H. Henline, New York, N. Y.

Minutes of the meeting of the board of directors held June 24, 1937, were approved.

Report was presented and approved of recommendations adopted by the board of examiners at its meeting held July 21, 1937. Upon the recommendation of the board of examiners, the following actions were taken: 3 applicants were transferred to the grade of Fellow; 29 applicants were elected and 35 were transferred to the grade of Member; 124 applicants were elected to the grade of Associate; 20 Students were enrolled.

Disbursements in July amounting to $27,618.84 were reported by the finance committee and approved.

Approval was given to a proposed meeting of the Southern District in Miami, Fla., in November 1938.

Announcement was made of the appointment by the president of Institute committees for the new administrative year, beginning August 1, 1937. (A list of committee members was published in ELECTRICAL ENGINEERING for September, pages 1217–21.)

The board confirmed the appointment by the president of H. P. Charlesworth as chairman of the Edison Medal committee for the year beginning August 1, 1937, and of C. R. Jones, Everett S. Lee, and H. S. Osborne as members of the committee for terms of 5 years each beginning August 1, 1937, and of L. W. W. Morrow to serve for the unexpired term, ending July 31, 1939, of L. C. Nichols, deceased. From its own membership, the board elected C. R. Beardsley, A. M. MacCutcheon, and K. B. McEachron to serve on the committee for terms of 2 years each, beginning August 1, 1937.

The board confirmed the appointment by the president of F. J. Chesterman, C. F. Hirshfeld, and A. H. Kehoe as members of the Lamme Medal committee for terms of 3 years each, beginning August 1, 1937.

It was decided to discontinue the Advisory Committee to the New York Museum of Science and Industry, as there appeared to be no further need for this committee, the museum having become well established on a definite basis.

Representatives of the Institute on various bodies were appointed for the year beginning August 1, 1937, and the appointment of certain representatives was deferred until further information could be obtained regarding the activities of the organizations, the necessity for continued representation thereon, or concerning suitable individuals for appointment.

W. I. Slichter was reappointed a representative of the Institute on the Library Board of the United Engineering Trustees, Inc., for the 4-year term beginning in October 1937; and L. W. Chubb was nominated for reappointment by The Engineering Foundation board to the research procedure committee of Foundation, for the term of one year beginning in October 1937. J. B. Whitehead, past-president of the Institute, was appointed to fill the unexpired term, ending in October 1939, of E. B. Meyer, deceased, on the John Fritz Medal Board of Award.

Local honorary secretaries were reappointed for the term of 2 years, beginning August 1, 1937, as follows: Frederick M. Servos, for Brazil; A. P. M. Fleming, for England; Renzo Norsa, for Italy; P. H. Powell, for New Zealand; A. F. Enstrom, for Sweden.

The following amendments to the by-laws were adopted:

Section 32, to include the District vice-chairmen of the membership committee, amended to read as follows:

**Sec. 32. To facilitate co-operation among the Sections there shall be an executive committee in each geographical district, including in its membership the vice-president representing the District on the board of directors, as chairman, a District secretary to be appointed by the vice-president, as secretary, the vice-chairman of the national membership committee, who may be a member of the District executive committee in another capacity also, and the chairmen and secretaries of the Sections within the District; also, in order to encourage co-operation between Sections and Branches, the chairman of the District committee on student activities.**

Section 41 was amended to read as follows, in order to define the boundaries of Sections, which were recently revised in accordance with recommendations of the special committee to revise Section territories:

**Sec. 41. Unless otherwise authorized by the board of directors and approved by the Sections and finance committees, the territory of a Section shall be defined as follows: A Section shall include those counties lying wholly or partly within a circle having its center at the headquarters of the Section and a radius of 50 miles. With the additional approval of the vice-president of the District involved, other unassigned counties, to be known as auxiliary Section territory, may be assigned to a Section. If, for the purpose of establishing a new Section, or for any other reason, it becomes desirable to reassign counties in auxiliary Section territory, this may be done without the approval of the Section to which such auxiliary territory is assigned, provided the change meets with the approval of the Sections committee and the vice-president of the District. All other questions with regard to overlapping of Section territories shall, if possible, be decided by agreement by the Sections concerned, otherwise by the Sections committee. Both ordinary and auxiliary Section territories shall be defined by county line boundaries.**

Section 65 was amended by the substitution of the name "committee on basic sciences" for "committee on electrophysics."

Section 76 was amended to read as follows:

**Sec. 76. The membership committee shall consist of one vice-chairman from each geographical district and a suitable number of other members, all to be appointed by the president; also the chairmen of the membership committees of the Sections of the Institute, *ex-officio*.**

**This committee shall bring the advantages of membership to the attention of desirable candidates for admission to the Institute, through such measures as it may consider advisable to interest prospective members who have the standing and qualifications specified for the various grades of membership. Under the general direction of the chairman, the vice-chairman may enlist the co-operation of the Sections and Branches within his District in such work. The committee shall have such other duties as may be delegated to it by the board of directors.**

The following appointments by the standards committee of Institute representatives on subcommittees of the Sectional Committee for Revision of National Electrical Safety Code were approved: W. R. Bullard—Grounding; C. A. Powel—Part I; T. H. Haines—Part II; E. B. Paxton—Part III; S. B. Graham—Part V.

Upon the recommendation of the standards committee, approval was given to (1) Revised Code for Protection Against Lightning, developed by the sectional committee *C-5* under ASA procedure, and (2) Revised Test Code for Polyphase Induction Machines.

An invitation to nominate an individual for the award of the 1938 Kelvin Medal was referred to a committee consisting of the president of the Institute and the chairmen of the Edison Medal and Lamme Medal committees to make a nomination.

The report of the special committee on Institute activities, on which action was deferred at the June meeting of the board of directors, was considered. The committee reported that, in accordance with instructions, it had prepared a general session at the 1938 summer convention of the Institute, which consisted of an address by Ralph E. Flanders on "The Engineer in a Changing World," followed by questions from the floor, and, after intermission, a discussion by members of the Institute on the topic "How Can the Institute Programs be Made of Greatest Value to the Membership?" This discussion was opened by 6 prepared discussions which had been reviewed by the special committee, and which presented various points of view (published in August issue of ELECTRICAL ENGINEERING, pages

1054–58). As a result of this session, the special committee recommended, in brief, that major emphasis should continue to be given to the technical programs substantially along the present lines; that the programs of national conventions and District meetings of the Institute frequently include sessions at which subjects of general interest to all the membership are discussed, including broad technical subjects presented in such a form as to be of general interest to electrical engineers, and also discussions of social and economic subjects closely related to engineering, which subjects should be presented by authorities in the fields discussed, and, in many cases therefore, would take the form of addresses by men who are not members of the Institute; and that the inclusion or omission of such a general session in the case of each convention or meeting be decided by the committee in charge of the program of that convention or meeting. The board approved the report of the special committee on Institute activities.

Other matters were discussed, reference to which may be found in this or future issues of ELECTRICAL ENGINEERING.

## Additional Awards for 1936 Institute Papers

In addition to the national and District prize awards for papers presented before the Institute during 1936 announced in ELECTRICAL ENGINEERING for June 1937, page 756, and September 1937, page 1208, additional awards for District 8 have now been announced. These awards are:

DISTRICT 8

Prize for Branch paper awarded to James W. McRae for his paper "The Magnetic Vector Potential," presented at the summer convention, Pasadena, Calif., June 22–26, 1936.

Prize for graduate student paper awarded to Edward L. Ginzton for his paper "Balanced Feed Back Amplifiers," presented at meeting of University of California Branch, April 1937.

## New System of Photometric Units

THE International Committee on Weights and Measures at its biennial meeting in Paris, June 23–29, 1937, adopted a new system of photometric units intended to replace both the "international" and the Hefner units. The following report on this action has been made available by E. C. Crittenden (A'19, M'22) assistant director, National Bureau of Standards, Washington, D. C., who has been closely associated with the development. This action of the international committee is expressed in a resolution translated as follows:

1. Beginning January 1, 1940, the unit of luminous intensity shall be such that the brightness of the black-body radiator at the temperature of solidification of platinum will be 60 candles per square centimeter.
This unit will be called the "new candle," ("bougie nouvelle") with appropriate translation into the various languages.

2*a*. The values for photometric magnitudes of sources of light differing in color from the primary standard shall be determined by a procedure consistent with the luminosity factors, formerly called "visibility factors," adopted by the International Committee on Weights and Measures.

2*b*. To assure uniformity among the national laboratories of the different countries in passing from the new primary standard to secondary standards of the incandescent-filament type operating at higher efficiency, the procedure adopted for the present is the use of blue filters which, interposed between the photometer and one of the standards to be compared, will make the colors in the 2 parts of the photometric field the same.

The international bodies concerned had previously agreed, first, that the use of the luminosity or "visibility" factors adopted by the Illuminating Engineering Society and the AIEE was the only method of hetochromatic photometry which could be generally accepted; and, second, that the primary standard of light should be the black body at the platinum point. In order to fix the values of all the units, it remained only to agree upon a numerical value for the brightness of the primary black-body standard.

The freezing point of platinum, 2,046 degrees Kelvin, is only about 50 degrees below the color temperature of the old carbon-filament standards; the black-body standard therefore might have been considered simply as a reproducible means of representing the international candle at that color. However, if this had been done, several very troublesome questions would have been left unsettled.

While nominally only 2 units of candlepower are in use today, actually there are several units differing enough to cause annoyance in the lamp industry. The ratings of tungsten-filament lamps, first of vacuum type and later gas-filled, have been established without any specific international agreement. Consequently there are slight, but systematic, differences between different countries which use "international" candles or lumens, and still greater discrepancies exist between the international and the Hefner units as established for the 3 general types of lamps. For carbon lamps the ratio between the 2 units accepted in 1909 was 1.11; for vacuum tungsten lamps at color temperatures near 2,360 degrees Kelvin it is 1.45; for gas-filled lamps in the neighborhood of 2,600 degrees Kelvin it is 1.17.

Furthermore, if the old basic units were retained both international and Hefner ratings of tungsten lamps would have to be changed to bring them into accordance with recent agreements regarding photometric methods to be used in comparing lights of

## Sodium Lights for Railroad Crossings

General Electric Photo

THE Ohio Public Utilities Commission has approved the use of sodium lights for railroad crossing illumination. In the accompanying illustration is shown a typical installation of 2 sodium luminaires at the point where route 40 crosses the tracks of the Cleveland, Cincinnati, Chicago, and St. Louis Railroad.

## Future AIEE Meetings

**Middle Eastern District Meeting**
Akron, Ohio, Oct. 13–15, 1937

**Winter Convention**
New York, N. Y., January 24–28, 1938

**North Eastern District Meeting**
Pittsfield, Mass., Spring 1938

**Summer Convention**
Washington, D. C., June 20–24, 1938

**Pacific Coast Convention**
Portland, Ore., date to be determined

different colors. Most of the present tungsten standards were derived from the carbon-filament standards representing the international candle of 1909 by measurements with the common Lummer-Brodhun photometer, which has a fairly large field of view. For nearly all groups of observers this gives somewhat larger values for the bluer lights than are obtained with a small photometric field such as was used in determining the standard "visibility factors."

In brief, in order to get the ratings of tungsten-filament lamps on a consistent and systematic basis, some readjustment is necessary in all countries. Such a basis is now urgently needed also for the precise rating of gaseous conductor lamps and other sources of colored light. Consequently, when a new standard was to be adopted as a means of defining the basic unit, the time seemed opportune to make an adjustment which might bring all countries into agreement.

Determinations of the brightness of the black body at the platinum point in terms of the international candle had been made in several countries, and the value on this basis was about 58.9 candles per square centimeter. The National Bureau of Standards proposed that the round number 60 be taken for the brightness, making the unit at this color 1.8 per cent smaller than the old unit.

In preliminary discussions in 1935 and 1936 it was indicated that, if the countries which used the international candle abandoned it for the proposed new unit, Germany was ready also to accept the new unit in place of the Hefner. The plan therefore was put formally before the International Committee on Weights and Measures as a joint proposal of the national laboratories of France, Great Britain, and the United States, which have had the responsibility of maintaining the international candle.

At the same time the plan was submitted to the International Commission on Illumination, which asked the views of all its national committees. In order to determine the opinion of American interests, Preston S. Millar, president of the United States national committee of the ICI, formed a special subcommittee including representatives of all the national organizations specially concerned.

At a meeting held February 5, 1937, this subcommittee unanimously favored the proposal, and consequently the United States national committee gave its approval. During June, meetings were held in Paris by the special committee on units and standards of the ICI and by the advisory committee on photometry established by the International Committee on Weights and Measures. These meetings settled questions of detail and cleared the way for definite action by the international committee.

While the action of the international committee establishes the principle of the new system, the determination of precise values for standards of the various types will require considerable time. Determinations in different laboratories will be necessary, and standard lamps of various types must be exchanged between countries for comparisons so as to make sure that all the national standardizing laboratories are in satisfactory agreement. Standards on the new basis must then be provided for lamp factories and testing laboratories in each country.

Some of this necessary laboratory work is already in progress, but it is hardly likely that all the measurements and all the formalities of final agreement can be completed in less than 2 years. The effective data of January 1, 1940, was set with this fact in mind. It also has the advantage of making the photometric changes coincide with a small adjustment of electrical units which is scheduled for the same date.

## NRC Insulation Committee to Meet in New York

The fall meetng of the committee on electrical insulation of the division of engineering and industrial research of the National Research Council will be held in New York, N. Y., November 4–5, 1937, with the Consolidated Edison Company of New York, Inc., as host. W. F. Davidson (A'14, F'26) director of research and tests, of the Edison company, is chairman of the committee on arrangements.

A program including 16 papers to be presented at 3 sessions has been arranged; fewer papers than usual have been scheduled this year in order to allow more time for discussion. Morning and afternoon sessions will be held November 4, and a morning session November 5; all 3 sessions will be held in the auditorium of the Edison company at 4 Irving Place. Inspection trips to nearby points of interest are being arranged for the afternoon of November 5. A dinner meeting is scheduled for the evening of November 4 at which Doctor A. von Hippel of the Massachusetts Institute of Technology, Cambridge, will speak on the subject "What Can Atom Physics Contribute to Insulation Research?"

**New ASTM Standards.** At its recent annual meeting the American Society for Testing Materials accepted 51 new tentative standards and revisions of 46 existing tentative specifications and methods of test. Among these were the following, covering methods of testing electrical insulating materials:

1. Test for Insulation Resistance of Electrical Insulating Materials (D 257–37 T) (revision of standard). Committee D–9 on electrical insulating materials.

2. Testing Flexible Varnished Tubing Used for Electrical Insulation (D 350–37 T). Committee D–9.

**Coffin Award for New York Company.** The Consolidated Edison Company of New York, Inc., won the annual award for 1936 of the Charles A. Coffin Foundation, established by the General Electric Company. Presentation of the award was made to J. C. Parker (A'04, F'12) vice-president of the company, during the recent annual convention of the Edison Electric Institute. The award comprises the Charles A. Coffin Gold Medal, a certificate, and a check for $1,000 to be deposited in the treasury of the Consolidated Edison Employees Mutual Aid Society, Inc. Determination of the winner of the award was made by a committee of judges consisting of C. W. Kellogg (A'19, M'23) president of EEI; K. T. Compton (F'31) president of Massachusetts Institute of Technology; and L. H. Egan (A'08, M'15) president of the Union Electric Light and Power Company of St. Louis, Mo. The committee was particularly impressed with the all-around progress made by the utility during recent years, culminating in its splendid accomplishments for the year 1936. Progress was reflected in practically all fields of activity, including improvement of relations with consumers, refunding of bonds, reorganization of units, and the development of greatly improved generating and distribution facilities.

## 1939 Fairs to Have Electrified Farms

Electrified farms, complete in all details according to recent announcements, are to be among the feature displays of the Golden Gate International Exposition and the New York World's Fair in 1939. With an estimated 1,118,000 farms in the United States all served with electric power, these exhibits are expected to have wide significance in their demonstration of the possibilities of efficient and effective utilization of electric energy in house, barn, dairy, shop, and field.

As announced, the demonstration farm at the New York Fair will comprise some 32,400 square feet. To assure that the farm will be in full and effective operation when the Fair opens, it is expected that the building will be completed; that dairy cattle, poultry, and bees will be in their places; that crops will be growing and fruit trees will have been established before the Fair opens.

The exhibit at the Golden Gate Exposition will be in the Palace of Electricity, where a model farm, completely electrified for operations from dishwashing to forced crop production, will include demonstrations of protection against insect and walnut and prune dehydrators.

## ICI Conference Held in Paris

On the occasion of the Paris Exposition and the attendant International Congress on Lighting Applications, a conference of delegates of International Commission on Illumination national committees was held June 22 and 23, 1937, to recommend plans for the forthcoming plenary session. Twenty-five delegates from 11 countries were in attendance, the United States being represented by C. H. Sharp (A'02, F'12, member for life), E. C. Crittenden, (A'19, M'22), and A. L. Powell (A'13, F'26).

The conference recommended that the program of the plenary session be expanded to include papers on latest lighting developments. To facilitate this and allow a longer interval after the Paris Congress, it was recommended that the sessions be postponed until 1939. The Netherlands committee, host of these sessions, announced

that they would probably be held at the attractive Scheveningen seashore resort in the outskirts of The Hague.

In the event of postponement it was suggested that interim meetings be held on aviation and automobile lighting. In this connection it was reported that the International Standards Association had laid out an extensive program of automobile standardization, including that of lighting equipment.

It was expected that the *Proceedings* of the 1935 sessions, which have been delayed in publication, will be available early this fall. A pamphlet, in French, has been made available which gives the recommendations officially adopted by the International Commission on Illumination in the 1935 sessions in Germany. A list of the technical committees with the work assigned to each also is included. Requests for copies should be addressed to G. H. Stickney, secretary-treasurer of the United States National Committee of ICI, General Electric Company, Nela Park, Cleveland, Ohio.

# Current Items From American Engineering Council

## Government Reorganization

Government reorganization, including all of the ideas advanced for a public works department, was left in the muchly tangled mass of unfinished business by the first session of the 75th Congress, according to a recent "news letter" from AEC. It had the President's blessing, but the advantages to be gained by the elimination of duplication of work and the improvements proposed for administrative procedure were handicapped by moves to effect radical changes in fiscal and personnel administration and discouraged by strong opposition from within the government agencies themselves.

Council's staff advised with the several committees on government reorganization and maintained close contact with those members of both houses of Congress who had to do with reorganization legislation. In spite of the very friendly relationship, however, the public works recommendation of the American Engineering Council and the President's Committee did not become an issue. No specific reason has been given for its omission from the general bills which were introduced, but it is believed to have been considered too provocative.

Assuming that engineers generally agree that most public works are well designed, honestly executed and administered without conscious or deliberate waste or extravagance, Council made the following statement to the Select Committee on Government Reorganization of the United States Senate urging the establishment of a department of public works for the sake of economy in the conduct of government construction business. A public works department was also recommended as an ideal medium for the co-ordination of our engineering and construction resources during periods of economic depression and as a more effective means of mobilization for national defense.

"Engineers believe that the President should have effective managerial authority over the executive branch of the Federal Government commensurate with his responsibility under the Constitution of the United States, but they are not as concerned with strengthening the executive as they are with the larger aim of strengthening the administrative management system of the United States as a whole. They feel that the need for reorganization of the many agencies rests not only on the idea of savings, as considerable as they may be, but upon a very real need for a more economical and effective organization which could be more easily understood and controlled by the people. It is realized the reorganization of the many units of the executive branch of the Federal Government is an enormous undertaking, but engineers urge reorganization under direction of the Chief Executive on the basis of standards set up by Congress to provide up-to-date management for whatever activities may be decided upon by the people.

"Engineers have for many years favored the use of the merit system in personnel administration, and they now endorse the idea of expanding civil service to cover all nonpolicy-determining positions. They recognize the civil service system as a valuable part of government management under a nonpartisan Civil Service Commission and urge salary adjustments throughout the service so that the Government may attract and hold in a career service men and women of the highest character and ability. Such a career is possible only when government service is concentrated and most of its positions are filled through civil service. In that way, opportunities for advancement open up to employees in the whole career system instead of the limited confines of a small service. Under such circumstances, engineers feel that direct appointments by the President should be reduced to a very small number of only the highest positions, and all other civilian positions should be filled by the heads of departments, without fixed term, through civil service with adequate tests to determine fitness.

"Engineers, who have made enormous contributions to the social advancement and economic welfare of their country and to civilization, feel that they are qualified by training and experience to advise their Government regarding engineering and public works activities. On that assumption, they recommend the creation of a public works department to which the President should be authorized to transfer such major engineering and construction work for government agencies as may be practicable. Engineers believe that a public works department should be authorized to co-ordinate the design, construction, operation and maintenance of all large-scale public works which are not incidental to the normal work of other departments, to act as an agent of other departments on engineering public works to administer federal grants to national, state, and local agencies for construction purposes, and to gather information with regard to public works needs and standards throughout the nation. They believe that a relatively small staff could and should direct such work in the hands of engineers in private business throughout the United States, without confusion and waste or the loss of valuable time.

"Such reorganization should promote efficient government in all of its branches, because it is now extremely difficult even for persons charged with executive duties and legislative responsibilities to properly comprehend many of the problems that arise among scores of scattered agencies. As related functions falling in the same field or having the same general purpose could be brought into organic connection and their operations made capable of consideration, as a whole, it should be easier for the Chief Executive to formulate programs for submission to Congress; and the Congress should be able to give more intelligent consideration to legislation and reach less hurried decisions regarding appropriations. The service agencies could perform their work with more certainty, and the public could more readily comprehend the work of the government, more directly exercise that general control which should obtain under a popular government, and more easily transact business with the government's agencies."

Excerpts were included from resolutions by the American Society of Civil Engineers and the American Engineering Council's assembly to the effect that both organizations would support "the enactment of suitable legislation designed to create a federal department of public works, as proposed by the President of the United States, with definite provision for excluding the Army engineers and their river and harbor work from this department." It was also stated that existing working organizations need not be disturbed by the reorganization process, and that all questions involving the redistribution of duties should be subject to decisions by proper authorities in the light of subsequent experience and investigation.

## Scientific Research Legislation

Engineers may find much to interest them in the provisions of bill H. R. 7939 instigated by Congressman Randolph of West Virginia, which is "to provide for the promotion of general welfare in relation to the economic efforts flowing from scientific and technological developments" in the United States. It is based on the premise that we must continue to create new "capital outlets," that the chief source of such outlets is the development of new industries, and that scientific research is the foundation of the greater portion of our modern industries.

The bill properly differentiates between social science and natural science and advances a practical philosophy designed to unite the sciences in the application of scientific discoveries and inventions to human needs. One of the principal objectives is the stimulation of pure science as a foundation for applied science which is recognized as the greatest factor in the development of the resources of the nation.

Engineers who have studied the effects of the impacts of technological developments upon civilization may not find much that is new to them in this legislation except that the usefulness of science, pure and applied, to our social and economic well being, as a nation, is appreciated by members of Congress. Even though they may not agree with Congressman Randolph's ideas, engineers have an opportunity to applaud his efforts to effect a national recognition of the true value of technology and to contribute criticisms as well as constructive suggestions to the advancement of that cause.

# Letters to the Editor

CONTRIBUTIONS to these columns are invited from Institute members and subscribers. They should be concise and may deal with technical papers, articles published in previous issues, or other subjects of some general interest and professional importance. ELECTRICAL ENGINEERING will endeavor to publish as many letters as possible, but of necessity reserves the right to publish them in whole or in part, or reject them entirely.

ALL letters submitted for consideration should be the original typewritten copy, double spaced. Any illustrations submitted should be in duplicate, one copy, to be an inked drawing but without lettering, and other to be lettered. Captions should be furnished for all illustrations.

STATEMENTS in these letters are expressly understood to be made by the writers; publication here in no wise constitutes endorsement or recognition by the American Institute of Electrical Engineers.

## Suggestions for AIEE Programs

*To the Editor:*

At the recent meeting of the Section delegates where Institute publication policies were discussed, the sentiment was almost unanimously expressed that ELECTRICAL ENGINEERING should include a considerable percentage of articles dealing with economic and social aspects of engineering problems, and with readable articles of a general nature. The publication committee will presumably make plans for publishing such general articles, and I infer that the membership at large would similarly like the technical program committee to arrange sessions dealing with general problems.

In thus broadening the Institute field, it is important not to duplicate the programs of other organizations, nor to depart from the factual basis of all good engineering work. It also seems to me desirable to make this departure from our accustomed ways gradually, and especially not to allow controversial subjects of purely political or social nature to displace engineering discussions.

With this in mind, I should like to suggest 3 specific types of articles or discussions for the Institute to add to its programs, or to use more frequently.

First, I think it very desirable to include articles dealing with economics or social problems, so long as these are written from an engineering viewpoint, or on the basis of facts, in such a way that the ideas presented will fit into the framework of engineering knowledge. To me, it appears that the laws of economics are quite analogous to the laws of physics. We have, for example, Hamilton's "principle of least action" which says that in nature motions always occur in such a way as to make the total action of the system a minimum. In economics it appears that society always endeavors to carry out its processes in such a way as to expend the least total effort. We seek to measure effort of every sort, past, present, and future in terms of a common unit, the dollar.

Thus, it should be possible to explain the laws of prices, the development of new industrial processes, and the displacement of old ones, on the basis of a principle of economy of effort as inexorable as the law of gravitation. Looked at in this way, we may think of the laws of economics as engineering principles we are already quite familiar with. And, the task of the engineer may be outlined as that of obtaining a more correct measure of the effort involved in each element of a process, in terms of immediate dollars, and the expression of the laws of variation of effort with changes in the process. As long as only a few individuals or materials are concerned, the problem is simple. However, bringing in the large numbers of individuals, the diverse sources of material, and the long periods of time that must all be considered under modern conditions, makes the problem much more difficult. What the engineer must do is to visualize the laws of economy of effort in simple terms and then widen his vision to include the increasingly large units of society that are involved in modern industry.

I believe there is need for many articles and discussions of economic and social problems prepared along the lines of such an engineering philosophy, and these should form a very desirable addition to the Institute's program. On the other hand, I strongly oppose having the Institute become a forum for the discussion of economic and social subjects in the language and with the methods already used by experts in these fields. We should not attempt to tell the economists or the experts in any other field how to do their job nor criticize them for the way in which they are doing it. We should simply tell men who are trained in engineering how they can apply their engineering knowledge to deal with the economic and social problems they meet in their engineering work.

Second, I think it desirable for the Institute to have articles and discussions of a general expository or descriptive nature, dealing with large-scale engineering projects or application engineering. Engineers need to know what is going on in other fields, to understand its purpose and its importance, and to know where they can find details if they need them. In every field of application engineering, methods and points of view change so rapidly, that nearly every purely technical article is out of date within 5 years. There is, therefore, a large field for periodic articles reviewing the fundamental principles of each branch of engineering and giving references to up-to-date sources of detailed information. Such articles and discussions might well take up as much as one-third of our Institute programs, in my opinion.

Finally, I should like to suggest that the Institute also accept articles and hold discussions on methods by which engineers can play a more important rôle in the world at large. I believe that the Institute can help engineers both by education and by inspiration to gain greater recognition, but such recognition must be the result of their individual actions rather than any prestige conferred upon them by the Institute. Programs should be designed to encourage individual actions by engineers in their own communities, and on no account planned to make the Institute take part as a whole in controversial questions of politics or government. The basis of all engineering progress is fact. Facts must be understood and presented by individuals. They cannot be properly voted upon nor advocated by mass action.

Specifically, I think that in this social field the best way to proceed is for papers to be presented telling just how particular engineers have acted to marshal facts and bring them to the attention of the proper authorities, and have so educated the public as to promote right decisions on affairs of public importance. For example, the method by which the engineers of Cincinnati have organized to interest the public in addresses on engineering subjects should be described before the Institute, thus inspiring engineers elsewhere similarly to bring their facts out in the open. Also, the procedure should be discussed by which any individual engineer may by his interest in the problems of the community in which he lives and the judicial point of view given by his engineering training, bring together community organizations of widely different views and weld them into a force for united public action. Articles in this field which described things of public importance actually done by engineers, or with an engineering—that is, a fact-finding—basis should be of great value and inspiration to the Institute membership.

Summarizing, I believe the Institute ought to enlarge its program to include, first, articles and discussions dealing with economics and social problems described in engineering terms; second, expository or descriptive articles of a general nature showing the state of the engineering art in different fields; and, third, articles describing actual achievements by engineers in the social and governmental field.

Very truly yours,

P. L. ALGER (A'17, F'30)

Engineering General Department, General Electric Company, Schenectady, N. Y.

## Branch Activities Are First-Page News

*To the Editor:*

The first page of the July 1937 issue ELECTRICAL ENGINEERING contains a parting message from retiring President MacCutcheon. It is entitled "Branch Activity." When he became president there was no Institute work of which he knew less, and when he retired, there was "no phase in which I am more interested or which I feel is better conducted." He gives 4 columns of observations, anecdotes, and concrete suggestions.

The report of the board of directors in the same issue records the number of branches as 119 with a total of attendance of 46,000.

The number of Enrolled Students is 4,500 and the number of applications of students for membership is 2,250.

ELECTRICAL ENGINEERING is publishing articles which give a fine presentation of the engineer in his nontechnical relations. In August, Dean Bush presents his "The Engineer and His Relation to Government." Doctor Flanders, eminent engineering economist, and past-president of the American Society of Mechanical Engineers, deals with "The Engineer in a Changing World." Past-President MacCutcheon visions the engineer of tomorrow. Mr. Blaker, an engineering student, speaks his mind on "The Engineer's Responsibility to Society." Mr. Wilkinson describes an experiment in the recognition of engineers in which the careers and qualities of notable recent graduates are recorded. And, in the September issue, President Doherty of Carnegie Institute of Technology, noted industrial engineer and educator, deals with "Engineering Education and Democracy," and indicates the qualities which the student should develop who aims to be a creative engineer.

All this affords to the engineering student a wealth of information, suggestion, and guidance.

This material might well afford the subject matter for presentation and discussion at student Branch meetings. It presents various phases of the larger engineering career which the future opens to the engineering student of today.

Very truly yours,

C. F. SCOTT (A'92, F'25, HM'29, past-president, member for life)

Professor of Electrical Engineering Emeritus, Yale University, New Haven, Conn.

## Graphical Solution of Similar Impedances in Multiple

*To the Editor:*

Figure 2 illustrates a simple method of determining the equivalent impedance of 2 similar impedances in multiple, such as the pair illustrated in figure 1. It must be remembered that the ratio of reactance to resistance in each branch is the same. The construction is as follows: Choose any desired reference or base line as $AB$. Erect perpendiculars to this base line at any desired distance apart and of lengths, to any convenient common scale, equal to the impedances, as $Z_1 = 8$ and $Z_2 = 5$. With diagonals join the opposite ends of the perpendiculars as shown by the dotted lines. Then, the equivalent impedance of the multiple combination is, to the common scale, the length of the perpendicular from the intersection of the diagonals to the base line, as shown by $Z_{12}$.

Figure 1 (left)

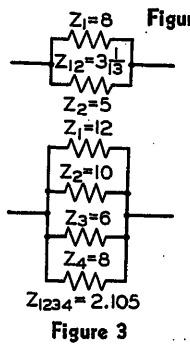

Figure 3

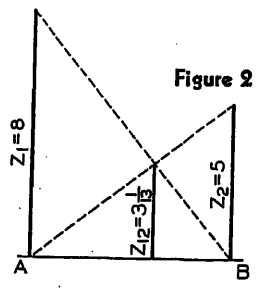
Figure 2



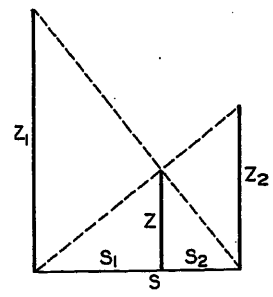


Figure 6

For more than 2 similar impedances in multiple, as in figure 3, they may be grouped in pairs and the resultant of the pairs combined as in figure 4; or take the resultant of the first 2, work it with the third, then the resultant of this combination is worked with the fourth; etc. This is illustrated in figure 5. A comparison of figures 4 and 5 will show that the resultant $Z_{1234}$ is the same in either case.

The equivalent resistance of a group of multiple resistances or the equivalent reactance of a group of multiple reactances may be determined graphically in this way, they being special cases of similar impedances in multiple.

*Proof:* From similar triangles in figure 6:

$S_1/Z = S/Z_2$, therefore $S_1 = ZS/Z_2$ and
$S_2Z = S/Z_1$, therefore $S_2 = ZS/Z_1$

Therefore $S_1 + S_2 = ZS(1/Z_1 + 1/Z_2)$; but $S_1 + S_2 = S$;

therefore $S = ZS(1/Z_1 + 1/Z_2)$, or

$1 = Z(1/Z_1 + 1/Z_2)$ or $1/Z = 1/Z_1 + 1/Z_2$ or

$$Z = \frac{Z_1 Z_2}{Z_1 + Z_2}$$

It will be noted that the expression is the well-known one for similar impedances in multiple. Also it is evident that the expressions are independent of the distance, $S$, between perpendiculars.

Very truly yours,

E. C. GOODALE (A'27)

Inspector, Puget Sound Power and Light Company, Olympia, Wash.

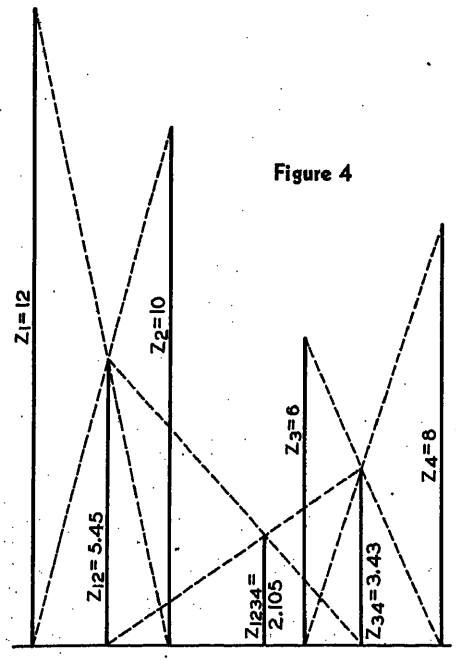

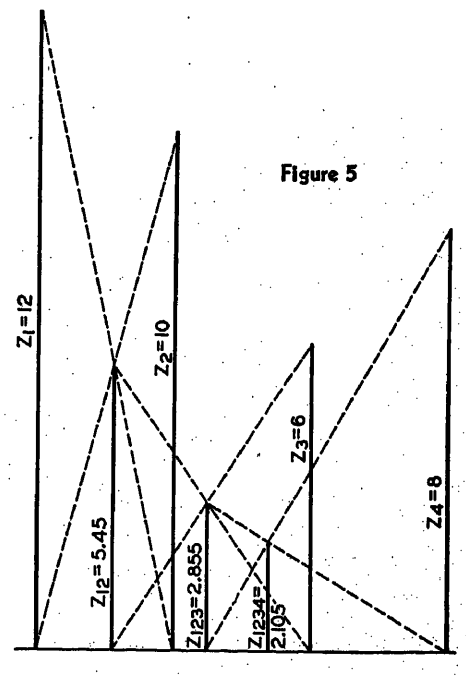

Figure 5

## On the Characteristics of Human Nature

*To the Editor:*

Should it be required to state a term which, more uniquely than any other, supposedly characterizes western civilization the adjective "scientific" will not long fail to appear. It is commonly held that this term is peculiarly applicable in that other, or preceding, social systems lack the same. Some inspection of the matter at a critical level discovers, however, a slight confusion.

Presumably the uninitiated might gather that society is employing scientific method in day-by-day effort toward improvement. Search among popular or discriminating opinion discloses little such deliberated action as admitted, as contemplated, or as reasonably possible.

The exceptional suitability of scientific method and engineering persons to cope with the present untidy state of human affairs is widely admitted. After considering the method of action of engineers, it becomes plain there is no class of mortals less likely to be permitted undisguised use of its characteristic technique.

This is all as it should be in a world where men speak of "better things" with wistful optimism and concurrently are capable mainly of invidious self-regard and of acting largely through evidenced demonstrations of force and chicane.

But, regardless of such being the reality of the matter, there still remains an urge on technically biased persons to act for an improved social order. Admit the engineers to be as willing as the need is great; as yet there is little detailed information in the literature to aid the rank and file in its action on a creaking human polity.

No small part of the engineer's approach and method has been his insistence on the dimensions and behaviors of the material he must handle. If, therefore, he must now act on men in a society rather than supervise them in industrial pursuits, he might reasonably seek a chart of performance of this substance with which he is to deal. A quantity so varied and immense as the human animal can never be precisely covered. Any attempt must necessarily be fragmentary, even tedious. Nevertheless, the importance of having some basis for action, superficial and "practical" though it be in contrast to rigorous and theoretical, warrants almost any attempt at record.

With these limitations in mind, and with some misgivings as to the form of the data, the following notes are presented.

## Some Characteristics of Human Nature

*We hug deformities if they bear our name*—Glanville

*A. Human nature possesses but little constructive imagination.*

REASONS

Its philosophy is one of belief in pragmatic effectiveness, in results, in the value of experience, in cynical practicality. E.g., its expression "Nothing succeeds like success."

CONSEQUENCES

1. Learns slowly, if at all, and largely through action on its pocketbook. Therefore repetitions and detaily; easily flustered by any unexpected response of man or machine.

2. Unable to "see" much of anything through eyes or experiences of others.

3. Able to concede experiences, knowledges or skills to others only if gained in its "presence."

4. Unable to see any personal repercussions of its instinctive social and economic indifferentism.

5. Lacks that capacity for intellectual indignation which was called to the attention of the ancient Greeks, and which is essential to the preservation of a democracy. (This in contrast to an urgent interest in sensationalism.)

6. Capable of academic consideration of but few topics. Therefore (*a*) must be able to "take sides" on matters to become interested—must become personally identified. And this possible interest is

I. In direct ratio to personal or financial concern with the matter.

II. Without much regard to the social or economic principles involved in an "isolated" event.

III. Exploitable through sales efforts appealing to the more paltry emotions.

7. Distrustful, both of itself and of others. But it is extremely vocal in its own defense.

8. Amenable to power rather than to intellectual discipline. Therefore (*a*) responsive to the compulsions of organization rather than to the demands for responsibility in co-operative independence; (*b*) impressed by bigness—physical or financial.

9. Subjective rather than objective. Therefore (*a*) pays little attention to what others say. (*b*) gives much consideration to the words put into other's mouths. (*c*) intrigued by labels, e.g., "smartness," "exclusive import," "Republican," "New Deal."

10. Seeks distinction, while demanding to be just like everyone else.

11. Cherishes a naive belief that mass emotional satisfaction is possible in a social order based on competitive gain.

*B. Human nature is a gregarious one.*

REASONS

1. Lacks self-reliance.

2. Necessary that it act on people—competitively—if it is to sense "accomplishment."

CONSEQUENCES

1. Worst form of insult to it or by it is a considered removal of physical presence.

2. Naturally urban (as regards population density).

3. Prone to bother people by invasions of space, time, or thoughts.

4. The "pleasing effrontery" of sales techniques is acceptable to it.

*C. Human nature is emotional rather than rational.*

REASONS

1. It has "gotten by" in the mass, fairly acceptably up to now.

2. Mental inertia, coupled to unfamiliarity with and distrust of reasoning processes.

CONSEQUENCES

1. It avoids thinking processes by every means at its disposal. Therefore, it is prone to rely on its instincts when under stress.

2. It is arrogant.

(*a*). Particularly in the sense that it must pursue personal vindication through any amount of conversational bramble patches.

(*b*). Seemingly it cannot consider itself as other than unique, thus can accept nothing less than—

I. Instant, unquestioning obedience.

II. Complete, enthusiastic agreement with its prejudices, under the name, that is, of "judgments."

3. It is unctuous. Therefore:

(*a*). Prone to rely on symbolic action.

(*b*). Smug.

(*c*). Apt to make virtues of necessities, that is, to rationalize its compelled behaviors.

4. It is basically disagreeable.

*Reasons.* 1. Mass emotional satisfaction based on competitive gain is a self-contradictory concept.

*Results.* (*a*) Impatient, irritable, spiteful, malicious; (*b*) instinctively uses the *argumentum ad hominem;* (*c*) attempts extreme emphasis by becoming personally abusive; (*d*) stubborn, contrary, selfish, acrimonious, rancorous; (*e*) excitable and "nervous" particularly in presence of recognized personalized challenges to its "rights."

5. Hypersensitive to any possibility of critical implication in words or actions of others. Therefore, (*a*) possessed of a bustling, impressive activity; (*b*) rushes spontaneously to its own verbal defense; that is, it is "touchy" so is prone to argue by begging the question; (*c*) easily becomes indignant over its assignments of professed rectitude to others; (*d*) bristles easily.

6. Unable to carry on true argumentation.

7. Though "sporty" lacks many elements of true sportsmanship; hence (*a*) is unsuited to interdependent social and economic existence.

8. Its standards are largely pecuniary as distinguished from economic, intellectual, scientific, etc.

9. Its philosophical bias can be put as: *Ejus cogito igitur id est,* as opposed to Descartes' statement *Cogito ergo sum.*

REFERENCES

NOTE. The list of works given below serves somewhat the purpose of a bibliography. No claim whatsoever can be made as to completeness in the assembly. The literature on this subject grows each day. What appears here will but offer the interested reader a slightly enlarged field of inquiry.

Should he wish practical reference for day-by-day use in small compass, let him possess himself of an old-fashioned rhetoric book., There he will come upon those methods making most appeal to the common run of mankind in argumentation—vicious circle and *post hoc* reasoning, begging the question, the *argumentum ad hominem,* etc. Superficial and fallacious though they be, their general applicability will be apparent. Then, let him add a copy of Rostand's "Cyrano de Bergerac" to recognize the relish for *quel geste* and its fruits.

The other works, as available, will assume their places in the perspective.

## AIEE Publications

*To the Editor:*

I have read with much interest Michel G. Malti's letter in the September issue of ELECTRICAL ENGINEERING, as it expresses not only a thought I have had for some years, but also a thought I have heard expressed by many other engineers. I would go further than Mr. Malti and estimate that the number of engineers in class *b* would far exceed those in both classes *a* and *c*.

I confess quite freely that the biggest proportion of the articles appearing in ELECTRICAL ENGINEERING are so technical in nature that I am unable to follow them and, in fact, would have no interest in following them except in a few cases where, for some reason or other, I have a personal interest in the subject under discussion. I realize that due to the amount of specialization in the engineering field it would not be possible to have many highly technical papers applicable to the various fields of specialization, but I nevertheless feel that in a magazine which is for the whole membership the articles should, if possible, be of interest to a majority of members.

It is realized that as editor of a magazine for so diverse a group of people you have a most difficult job but, nevertheless, it may be of interest and perhaps of some help to you to learn what a number of your readers think, and I know from personal contacts that I am speaking for a number rather than for myself alone when I endorse Mr. Malti's program.

Very truly yours,

M. M. BRANDON (A'34, M'36)

Associate Electrical Engineer, Underwriters' Laboratories, Inc., New York, N. Y.

## Heat Transfer Efficiency of Range Units

*To the Editor:*

The interesting article by W. James Walsh published in the August issue of ELECTRICAL ENGINEERING has just come to my attention. It is certainly an excellent article.

In the interest of bringing out the true values of the diverse designs of electrical range units, I would like to make the following comments and suggestions which may possibly help to guide future and more thorough studies of this subject with the idea of setting up modes of test and examination to bring out comparatively all the qualifications of every type of unit.

My first comment, of course, is that the tests on which this paper was based are tests only on the stated units in their brand new condition and are, of course, laboratory tests rather than cooking tests extending over a period of time such as will demonstrate what I term the quality of "stability of efficiency" and "cooking and heating efficacy over an extended time period."

We all know, of course, that the true value of a heating unit or an electrical range is not fully demonstrated by what might be termed an instantaneous test when the equipment is brand new. Such equipment does not stay brand new.

It is subject to all kinds of use and abuse in practical household work and the buyer is naturally interested in the performance of the devices throughout the period of normal life expectancies.

Would it not be an excellent thing to have these tests repeated after each of the units has been in normal practical and identical cooking use approximating as nearly as possible household use in a family of average size?

Of course, there is always some little difference in ohmic resistance of units when new and the cooking tests on the new units ought to be made at identical rated wattage regardless of the voltage required on the new units.

Better still would be to have selected new units of each make which would have identical ohmic resistance or, in other words, which would possess identical normal rated wattage when new and then let the units be operated as above stated and tested subsequently at periods of 3, 6, 9, and 12 months practical use at the voltage which originally gave the normal rated wattage when new. This test should include boiling speed tests and other practical cooking tests at the identical original voltage.

Then after having made such tests, the efficiency tests should be repeated at the same voltage.

Then a third set of tests should be made under which condition the voltage applied to each unit might be increased so as to reestablish the original rated wattages on each unit and the efficiency test repeated.

In this way it would take account of the "stability of efficiency" and of "operating efficacy" after various periods of elapsed time during which the units had all been in identical and practical cooking use.

This would really show up what the market wants to know, which is not merely what a brand new article will do on a laboratory test in the way of a technical expression of electrothermal efficiency, but it would demonstrate the stability of the various qualities of the various units and would also demonstrate efficacy of which the efficiency is only one component.

I realize that the making of such tests under conditions that would be fairly identical as between units and also fairly comparative to practical use would involve some painstaking care and experience, but it would certainly be more nearly the proof of the pudding short of actual market experience on the part of the public.

I hope that these suggestions may be of some value in assisting efforts along this line.

Very truly yours,

E. L. WIEGAND

President, Edwin L. Wiegand Company, Pittsburgh, Pa.

*To the Editor:*

Mr. Walsh's paper in the August issue of ELECTRICAL ENGINEERING should go a long way in awakening the range designers to the fact that the modern electric range is an outgrowth of the old-time wood and coal range rather than the result of good engineering design. His efficiencies of heat transfer are suprisingly high, probably higher than one would find in the average kitchen. He used square-cornered utensils, whereas most range users use all types of round-cornered and odd-diametered utensils. His efficiencies would have been considerably lower had he used a random assortment of utensils such as one finds in the average kitchen.

In the not-far-distant future a complete range will include the utensils which are to be used with it. These utensils will be of such diameter as to cover the unit completely, and will have black bottoms and square corners (similar to those shown by Mr. Walsh), although square-cornered utensils are difficult to clean. A minimum of surface units will be built into the range however; most of them will be the well-type of unit, such as is now included in modern ranges as an "economy" unit. It is also likely that surface utensils and their covers will be insulated against heat radiation from their sides and tops. There is the possibility that some day immersion units will be adapted to boiling and stewing operations, thus raising the efficiency of heat transfer to the highest possible value.

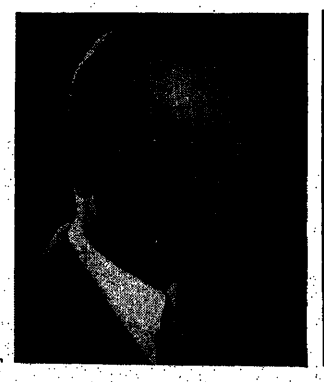
Mr. Walsh is to be highly commended for bringing to the attention of electrical engineers quantitative data on a problem which has too long been subject to much speculation without factual basis.

Very truly yours,

WALTER J. SEELEY (A'19, M'28)

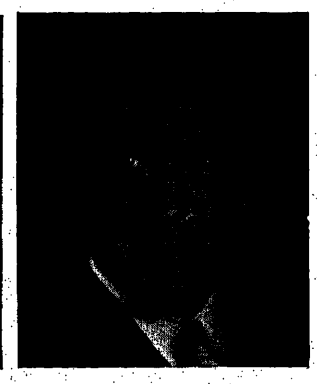
Professor and Head of Department of Electrical Engineering, Duke University, Durham, N. C.

# Personal Items



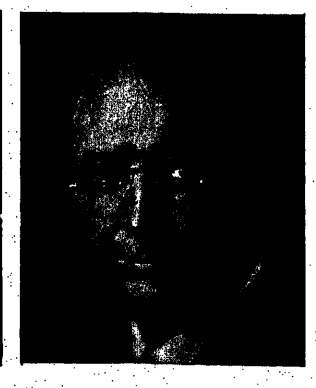
C. R. JONES (A'16, M'30, director) eastern transportation manager, Westinghouse Electric & Manufacturing Company, New York, N. Y., has been elected chairman of the Institute's committee on finance for the year 1937–38. He was born at Norristown, Pa., May 11, 1886. In 1907, he was graduated from the University of Pennsylvania with the degree of bachelor of science in electrical engineering. Since 1907 he has been continuously with the Westinghouse Electric & Manufacturing Company. For the first 2 years, until 1909, he was on the engineering apprentice course of the company at East Pittsburgh, specializing in railway work. For the next 2 years, until 1911, he was in the engineering and railway department of the company, also at East Pittsburgh, being transferred in the latter year to the New York office where he was assistant to the manager of the railway division until 1916. From 1916 to 1925 he was sales engineer in the New York office of the Westinghouse company, representing the company on large contracts involving both engineering and commercial phases. This included work in connection with the electrification of steam railroads and power supply and car equipment for the local rapid transit company. From 1925 to 1930, he was section manager of the transportation division of the New York office, continuing the same work, but in a supervisory capacity. In the latter year he became assistant northeastern transportation manager, and in 1931 transportation manager of what is now the eastern district. Mr. Jones is at present a director of the Institute and has served as a member of the national membership committee, 1928–31, and has engaged for a number of years in the activities of the New York City District (number 3). He has been active for several years in connection with the Institute's winter conventions. He is a member of the New York Electrical Society, New York Engineers' Club, and other organizations.

L. W. W. MORROW (A'13, F'25, past director) general manager of the fiber products division of the Corning (N. Y.) Glass Works, has been appointed chairman of the Institute's committee on constitution and by-laws for the year 1937–38. Mr. Morrow is a native (1888) of Hammond, W. Va., and was graduated from Marshall College in 1907 and Cornell University in 1911. During the scholastic year following his graduation in 1911 he served as an instructor at Cornell University, and in 1913 was appointed assistant professor of electrical engineering at the University of Oklahoma. During the year 1917–18 he served as professor of electrical engineering and director of the school of electrical engineering, before becoming assistant director of the U.S. Signal Corps school at Yale University. He served concurrently as an assistant professor of electrical engineering on the faculty of Yale University, and, following the World War, was retained in that position. In 1922 Mr. Morrow accepted a position as associate editor of *Electrical World;* in 1929 he became editor of that publication, but resigned in 1936 to become manager of the fiber products division of the Corning Glass Works. He has been active in the committee work and other affairs of the Institute, is at present a member of the technical program committee and the committees on co-ordination of Institute activities and publication. He is vice-president of the Thomas Alva Edison Foundation and the Institute's representative on the Engineers' Council for Professional Development. Mr. Morrow is a member of The American Society of Mechanical Engineers, American Electrochemical Society, and Sigma Xi.



J. W. BARKER (M'26, F'30) dean of engineering, Columbia University, New York, N. Y., has been appointed chairman of the Institute's committee on education for the year 1937–38. Dean Barker was born June 17, 1891, at Lawrence, Mass., and was graduated from Massachusetts Institute of Technology with the degree of bachelor of science in electrical engineering in 1916, and master of science in electrical engineering in 1925. During the World War he served in the Coast Artillery Corps of the United States Army as artillery engineer and adjutant, and also as officer in charge of civil affairs of the American forces in Germany following the war. In 1925 he was appointed associate professor of electrical engineering at Lehigh University; 1929 he became professor and head of the department of electrical engineering, but in the following year was appointed professor and dean of the faculty of engineering at Columbia University, where he has remained since. Dean Barker has been a member of the Institute's committee on education since 1930, has served on the committee on production and application of light since 1929, and was chairman of that committee from 1933 to 1935. He was a member of the technical program committee from 1932 until 1937, and is at present a member of the publication committee and an Institute representative on the Iwadare Foundation. He is a member of the American Association for the Advancement of Science, American Society of Civil Engineers, The American Society of Mechanical Engineers, American Institute of Mining and Metallurgical Engineers, Society for the Promotion of Engineering Education, and has been active in the affairs of the division of engineering and research of the National Research Council.

W. D. A. PEASLEE (A'10, F'27) consulting engineer, Indianapolis, Ind., has joined the staff of W. S. Dickey Clay Manufacturing Company, Kansas City, Mo., as chief engineer. Mr. Peaslee was born at Grass Valley, Calif. He received the degree of bachelor of arts in electrical engineering from Leland Stanford, Jr., University in 1910, and that of electrical engineer in 1916 from Oregon Agricultural College, where he was an instructor. Following service as a captain in the U.S. Army during 1917–19, he became electrical engineer and later general manager of the Jeffery Dewitt Insulator Company, Huntington, W. Va. From 1922 to 1924 he was chief engineer of Belden Manufacturing Company, Chicago, and during 1924–25 was president and general manager of Terlee Electric and Manufacturing Company, Chicago. In 1925 he became assistant to president and general manager of Daven Radio Corporation, Newark, N. J., and 2 years later accepted the position of assistant to president, Underwriters Laboratories, Chicago, Ill., which he held for 8 years. He is the author of articles on a variety of subjects, and a member of The American Society of Mechanical Engineers, American Association for the Advancement of Science, Société Française des Electriciens, and others.



O. J. ROTTY (A'25, M'31) superintendent of substations, Union Electric Company of Missouri, St. Louis, has been appointed chairman of the Institute's committee on automatic stations for the year 1937–38. Mr. Rotty was born October 14, 1898, at St. Louis and received the degree of bachelor of science in engineering at the University of Missouri in 1921. Immediately following his graduation he entered the employ of the Union Electric Light and Power Company, which later became the Union Electric Company of Missouri. His first position with that company was concerned with the physical inventory of the utility properties, but in 1923 he was appointed general substation engineer, in which capacity he worked on the

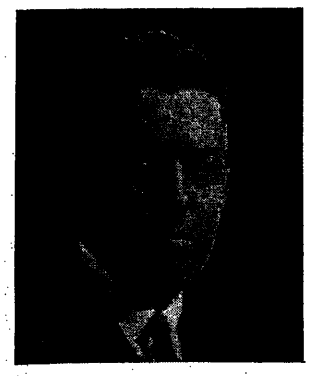
construction, testing, and operation of automatic substations. From 1926 until 1930 Mr. Rotty was substation engineer in charge of design, construction, testing, and inspection of automatic stations, and since 1930 he has been superintendent of substations. He has been a member of the committee on automatic stations since 1930, and has been an interested participant in the affairs of the Institute's St. Louis Section, having been Section secretary during 1929–30 and member or chairman of Section committees.

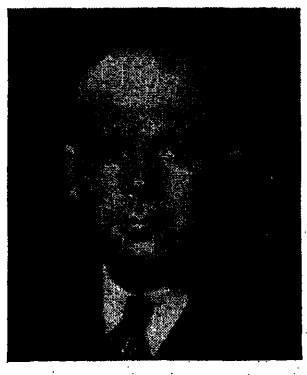
R. D. EVANS (A'21, M'26) central station engineer, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., has been appointed chairman of the Institute's committee on power transmission and distribution for the year 1937–38. Mr. Evans was born October 14, 1892, at Spring Water, Wis., and received the degree of bachelor of science in electrical engineering at the University of Oklahoma in 1914, following which he entered the employ of the Westinghouse Electric & Manufacturing Company as a general engineer. He has been affiliated with that company continuously, and has done much original work in studies of power generation and transmission, a-c railway engineering, electric furnaces, and inductive co-ordination. Mr. Evans has served the Institute as a member of the power transmission and distribution committee since 1924, and was a member of the committee on communication from 1924 until 1934; he was active also in the committee work of the former National Electric Light Association. He has presented several papers, principally on transmission-line calculations, power system stability, and network theory, before the Institute, and is co-author of a textbook on the theory of symmetrical components. In 1929 he was awarded the Triennial Montefiore Prize jointly with C. F. Wagner (A'20, M'27) for contributions to the theory of power system stability.

W. L. EVERITT (A'25, F'36) professor of electrical engineering at The Ohio State University, Columbus, has been appointed chairman of the Institute's committee on communication for the year 1937–38. Doctor Everitt was born April 14, 1900, at Baltimore, Md., and received the degrees of electrical engineer (1922), master of science (1926), and doctor of philosophy (1933), at Cornell University, the University of Michigan, and The Ohio State University, respectively. Following his graduation in 1922 he became affiliated with the North Electric Manufacturing Company, Galion, Ohio, as engineer in charge of the design and installation of relay-operated private automatic telephone exchanges. In 1924 he was appointed to the electrical-engineering faculty of the University of Michigan, was placed in charge of the courses in communication, and remained at that institution until 1926 when he was appointed assistant professor of electrical engineering at The Ohio State University; in 1929 he became associate professor; and in 1934, professor. Besides his regular teaching duties, Doctor Everitt has served as consulting engineer for several companies. He has been active in the local affairs of the Columbus Section of the Institute, having been Section chairman during 1931–32, and has served as a member of the committee on communication since 1932. He is author of a widely used textbook on communication engineering.



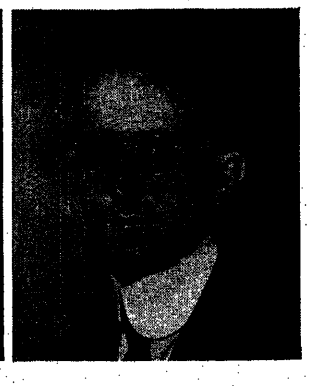
O. A. KNOPP (A'09, M'34) chief of the bureau of tests and inspection, Pacific Gas and Electric Company, San Francisco, Calif., has received the AIEE Pacific District prize for initial paper for his paper "Some Applications of Instrument Transformers." Mr. Knopp was born August 24, 1877, in Berlin, Germany, and received his technical education in that country. His first position in the electrical industry was as a testing engineer in the Bergmann Electrical Works, Berlin, in 1900. After several brief affiliations with companies in both Germany and the United States, he became superintendent of the standardizing laboratory and meter department of the Pacific Gas and Electric Company in 1908. In 1915 Mr. Knopp was made superintendent of the laboratory department; and in 1920, chief of the bureau of tests and inspection. He is a member of the American Society for Testing Materials, and was a long-standing member of the former National Electric Light Association. He served as a member of the Institute's committee on instruments and measurements from 1930 to 1934, and holds many patents on improvements in instruments and transformers.

R. R. WHIPPLE (A'30, M'36) assistant professor of electrical engineering at the University of Iowa, Iowa City, has accepted the position of designing illuminating engineer with The Trippe Manufacturing Company, Chicago, Ill. Mr. Whipple is a graduate of the University of Michigan, and had been a member of the faculty of the electrical engineering department at the University of Iowa since 1928. He has written several papers on illumination subjects, and is a member of the Illuminating Engineering Society.



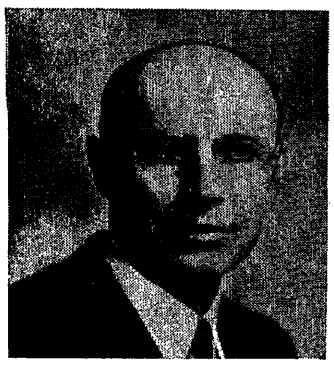
F. V. MAGALHAES (A'07, F'19) executive assistant to the president, Consolidated Edison Company of New York, Inc., New York, N. Y., has been appointed chairman of the Institute's board of examiners for the year 1937–38. A biographical outline of Mr. Magalhaes's technical career and his activities in the Institute appeared in ELECTRICAL ENGINEERING for August 1937, page 1064.

VANNEVAR BUSH (A'15, F'24, director, Lamme Medalist '35) vice-president of Massachusetts Institute of Technology, Cambridge, has been appointed chairman of the Institute's committee on co-ordination of Institute activities for the year 1937–38. A biographical sketch of Doctor Bush appeared in the March 1937 issue of ELECTRICAL ENGINEERING, pages 394–5.



J. W. MCRAE (A'37) member of technical staff, Bell Telephone Laboratories, Deal, N. J., has received the AIEE Pacific District prize for Branch paper for his paper "The Magnetic Vector Potential," which was published in ELECTRICAL ENGINEERING for May 1936, pages 534–42, and presented

O. J. ROTTY



W. L. EVERITT

R. D. EVANS

at the 1936 AIEE summer convention, Pasadena, Calif., June 23, 1936. Doctor McRae was born October 25, 1910, at Vancouver, B. C., Canada, and received the degree of bachelor of applied science at the University of British Columbia in 1933, following which he entered California Institute of Technology as a graduate student and received the degrees of master of science (1934) and doctor of philosophy (1936). He has been a member of the technical staff of the Bell Telephone Laboratories since January 1937. He is a member of Sigma Xi.

J. A. KOONTZ, (A'11, M'20) hydroelectric and transmission engineer, Pacific Gas and Electric Company, San Francisco, Calif., co-author of the paper "Cable Vibration—Methods of Measurement" with J. S. Carroll (A'24, M'37) has received the AIEE Pacific District prize for best paper. Mr. Koontz was born August 27, 1883, at Aztec, N. M., attended Throop Polytechnic Academy, received the degree of bachelor of arts at Stanford University in 1908 and the degree of electrical engineer at the same

J. A. KOONTZ

institution in 1912. Upon graduation in 1909 he was employed by the General Electric Company for one year before he returned to Stanford as a graduate student and instructor, and after he received his engineering degree in 1912 he became associated with the Great Western Power Company, San Francisco, where he eventually became electrical engineer and remained until 1930. In that year he assumed his present position with the Pacific Gas and Electric Company. He has served as a member of 2 of the Institute's committees: power transmission and distribution, 1920–23; and membership, 1931–33.

H. J. McCREARY (A'24, M'36) has resigned as chief engineer of the Leich Electric Company, Genoa, Ill., to establish an office as a consulting engineer at Chicago. A graduate of the University of Nebraska, from which he received the degree of bachelor of science in electrical engineering in 1923, Mr. McCreary was employed by the Western Electric Company, Chicago, as inspection methods and development engineer from 1923 to 1925, and by the Automatic Electric Company, Chicago, as research engineer from 1925 to 1928. For one year he was laboratory engineer with the Grigsby-Grunow Company, Chicago, and for 3 years was development engineer for the Railroad Supply Company. From 1933 to 1935 he was chief engineer of the Chicago Television and Research Laboratories, and in 1936 became chief engineer of the Leich Electric Company. He has patented several inventions,-and is a member of the Western Society of Engineers.

J. S. CARROLL

J. S. CARROLL (A'24, M'37) associate professor of electrical engineering, Stanford University, Calif., co-author of the paper "Cable Vibration—Methods of Measurement" with J. A. Koontz (A'11, M'20) has received the AIEE Pacific District prize for best paper. A biographical sketch of Doctor Carroll appeared in the August 1937 issue of ELECTRICAL ENGINEERING, page 1064, in announcement of his receipt of honorable mention in the AIEE national prize awards for best paper in theory and research.

J. T. ROBERTSON (A'06, M'13) recently at Muscle Shoals, Ala., is now connected with the firm of J. T. Robertson and Associates at Birmingham. A graduate of Clemson College in the class of 1903, he was electrical inspector for the Southeastern Underwriters' Association, Atlanta, Ga., until 1911, when he became electrical engineer and inspector for the Mississippi Inspection and Advisory Rating Company at Vicksburg. Later he was made secretary as well as electrical engineer, a position which he held until 1925 when he became superintendent of the Abbeville (S. C.) Water and Electric Plant. In 1929 he became connected with A. H. Turner, Atlanta, as special agent and engineer.

E. L. GINZTON (Enrolled Student) has received the AIEE Pacific District prize for graduate student paper for his paper "Balanced Feed-Back Amplifiers." Mr. Ginzton is a native (1915) of Russia and an electrical-engineering graduate of the University of California in the class of 1936. Following his graduation he returned to that school to pursue graduate studies.

A. L. TURNER (M'29) chief engineer, Northwestern Bell Telephone Company, Omaha, Neb., has been appointed a member of the engineers and architects board authorized recently in a bill passed by the state legislature, which empowers the board to administer an act calling for licensing of engineers and architects in the state.

W. H. HULSWIT, JR. (A'34) who has been a fellow at Northwestern University at Evanston, Ill., now is employed in the development department of United States Rubber Products, Inc., at Passaic, N. J.

G. P. KNAPP (A'30) former field engineer with RCA Manufacturing Company, Inc., at Camden, N. J., is now service manager for the company at Baltimore, Md.

F. E. LEGGETT (A'32) recently chief draftsman for an improvement project at the University of Florida, Gainesville, is now at Tallahassee as draftsman in a highway planning survey division of the Florida State Road Department.

K. J. KRACH (A'37) who has been serving with the 34th Infantry, U.S. Army, at Fort George G. Mead, is now employed by the Pennsylvania Water and Power Company at Baltimore, Md., as electrical engineer.

L. M. SORENSON (A'34) who has been a draftsman for the Beloit Iron Works, Beloit, Wis., is now assistant electrical engineer in the inspection and development laboratory of the Western Electric Company at Chicago, Ill.

C. H. JOHNSON (M'35) who has been electrical engineer for the Idaho Maryland Mines Corporation, Grass Valley, Calif., has accepted the position of electrical engineer with the General Electric Company, San Francisco.

W. M. GILMAN (A'27) engineer for the Waterbury Tool Company, Waterbury, Conn., now is employed as an engineer for the consulting engineering firm of Jackson and Moreland, Boston, Mass.

W. F. UFFELMAN (A'34) has been transferred from the sales engineering department of the Clark Controller Company, Cleveland, Ohio, to the Detroit, Mich., offices of that company, as a district sales engineer.

J. H. PERSONS (A'31) employed in the industrial department of the General Electric Company, Atlanta, Ga., has been transferred to the Charleston, S. C., offices of that company.

L. F. PRIES (A'33) formerly development engineer for The Rudolph Wurlitzer Company, DeKalb, Ill., now is employed in the engineering department of the American Steel & Wire Company, DeKalb.

M. D. BRANE (A'28) formerly a teacher of applied electricity in the Haaren High School, New York, N. Y., now is employed by the Duquesne Light Company, Pittsburgh, Pa.

C. E. GAGNIER (A'34) formerly electrical foreman, Rotary Electric Steel Company, Detroit, Mich., now is development engineer for The DeVilbiss Company, Toledo, Ohio.

F. S. ROTHE (A'36) formerly a cadet engineer for the Metropolitan Edison Company, Reading, Pa., now is employed in the test department of the General Electric Company, Pittsfield, Mass.

W. S. GIFFORD (A'16) president, American Telephone and Telegraph Company, New York, N. Y., has been appointed chairman of the advisory committee on communication of New York World's Fair, 1939.

S. V. WADTHEKAR (A'34) formerly chief engineer of the Arrah (India) Electric Supply Co., Ltd., now is resident engineer and deputy manager of the Rewa (India) Electric Supply Co., Ltd.

E. G. HEMENWAY (A'20) district manager, Western Electric Company, Inc., of Cuba, Balboa, Canal Zone, has been transferred to the New York, N. Y., offices of Electrical Research Products, Inc.

A. R. NAHRGANG (A'24) has been transferred from the staff of Electrical Research Products, Inc., New York, N. Y., to the Kearny, N. J., plant of the Western Electric Company.

N. S. MOORE (A'17, M'19) recently was appointed a member of the sales organization of The Porcelain Insulator Corporation, Lima, N. Y., with offices at Riverside, Ill.

R. J. ABRAMSON (A'33) formerly electrical engineering draftsman with Joseph Weidenhoff, Chicago, Ill., now is industrial engineer with Max Miller Company, Chicago.

C. B. SMITH (A'35) test man with the General Electric Company as Schenectady, N. Y., has been transferred to Fort Wayne, Ind., as fractional-horsepower-motor engineer.

L. L. LATHROP (A'35) formerly with the Industrial Heater Company, New York, N. Y., now is employed by the New York Power and Light Company at Schenectady, N. Y.

L. A. GRETTUM (A'24) operating manager of the Eastern Oregon Light and Power Company, Baker, recently was elected vice-president of the Northwest Electric Light and Power Association.

NIKOLA TESLA (A'88, F'17, Edison Medalist '16, member for life) recently received the Order of the White Lion of the Republic of Czechoslovakia for his contributions to science and engineering.

T. O. SWEATT (A'33) has resigned from the staff of Gibbs and Hill, consulting engineers, New York, N. Y., and now is employed by the Public Service Electric and Gas Company, Newark, N. J.

R. S. TAYLOR (A'36) division engineer, Oklahoma Gas and Electric Company, Oklahoma City, has been transferred to the Muskogee offices of that company.

D. H. ANDREWS (A'35) who has been an experimenter in the Naval Research Laboratory, Anacostia, D. C., now is an assistant electrical engineer with the General Cable Corporation, Buffalo, N. Y.

J. W. LINDSEY (A'33) formerly electrician with the U.S. Bureau of Reclamation at Boulder City, Nev., now is electrician with the Bethlehem Shipbuilding Corporation, Ltd., San Francisco, Calif.

L. J. RICHARDS (A'34) formerly cost accountant with the East Bay Municipal Utility District, Oakland, Calif., now is employed by the Southern Pacific Railway at San Jose as signalman.

R. W. DRUSHELL (A'25, M'36) distribution engineer, The Ohio Public Service Company, Alliance, has been transferred to the Elyria, Ohio, offices of that company.

KENNETH LANNERT (A'35) formerly employed by the Sunnen Products Company, St. Louis, Mo., now is associated with the Carter Carburetor Corporation, St. Louis.

J. K. WHISTLER (A'35) recently was employed as a junior engineer for Black, Sivalls, and Bryson, Oklahoma City, Okla.

C. V. BARNHILL (A'36) formerly an engineer with the Rural Electrification Administration at Wichita, Kans., now is with The Research Service, Washington, D. C.

T. H. MAWSON (A'29) formerly with the Monsanto Chemical Company at Anniston, Ala., now is with the Commonwealth and Southern Corporation at Birmingham.

R. A. SCHOLL (A'34) formerly junior engineer with the Public Service Company of Indiana, Connersville, has been made power sales engineer at Indianapolis.

BOYD STEVENS (A'33) switchman for the Illinois Bell Telephone Company at Urbana, has been made transmission testing foreman at Danville.

E. S. HENNING (A'36) now is junior electrical engineer with the bureau of engineering of the Navy Department, Washington, D. C.

# Obituary

CLARENCE LINUS CORY (A'92, M'03, F'13, member for life) professor emeritus of electrical engineering, and formerly dean of the college of mechanics, University of California, Berkeley, died in Berkeley, August 2, 1937. Born September 4, 1872, at Lafayette, Ind., and graduated in mechanical engineering by Purdue University in 1889, Professor Cory entered Cornell University for graduate work under the late Harris J. Ryan, and was awarded the degree of master of mechanical engineering by Cornell in 1891. After teaching electrical engineering at Highland Park College in Des Moines, Iowa, for a short time, he became a member of the faculty of the University of California, serving as assistant professor of electrical engineering from 1892 to 1898, as associate professor from 1898 to 1901, and as professor of electrical engineering and dean of the college of mechanics from 1901 until his retirement from active teaching duties in 1930. In addition to his long service in the field of electrical engineering education, Professor Cory early won a prominent standing on the Pacific Coast as a consulting engineer in connection with many of the early hydroelectric and other power developments in the state of California. He also was identified with several of the early long-distance high-voltage transmission-line projects. Professor Cory was the second chairman of the Institute's San Francisco Section, serving a double term from 1905 to 1907. Later (1914–19) he was an active member of the Institute's committee on economics of electric service.

HARVEY LESTER HARRIS (A'18, M'30) president of the Automatic Electric Company, Chicago, Ill., died August 10, 1937. Mr. Harris was born at Presque Isle, Me., on August 21, 1879, and was continuously in the telephone constructing, operating, and allied manufacturing business, starting as night operator for a telephone company in Ohio in 1894. In 1907 he joined the Dean Electric Company, Elyria, Ohio, as switchboard engineer, after being employed in various capacities by several telephone companies. He remained with this company and its successors until 1917, by which time he was sales engineer for the Stromberg Carlson Telephone Manufacturing Company, Rochester, N. Y. In that year Mr. Harris became general manager of the Kansas City Telephone Company and later vice-president and general manager of the Consolidated Telephone Company, Kansas City, Mo., part of the interests of Theodore Gary and Company. Since 1924 he had been executive in general charge of Theodore Gary and Company's manufacturing interests, which include Automatic Electric Company, American Electric Company, Inc., and other companies in England, Belgium, Canada, Australia, and Japan as well as in the United States, serving as director or officer. Mr. Harris was the holder of several patents in telephony. He was a member of the board of governors of the National Electrical Manufacturers Association, and a member of the Western Society of Engineers.

FRANK DANIEL BURR (A'07, M'20) consulting power engineer, Los Angeles, Calif., was killed in an automobile accident in that city on June 30, 1937. He was born at Frederica, Del., on February 28, 1872, and received the degree of bachelor of science in electrical engineering from the University of Nebraska in 1902. For a year he was employed as electrician in coal mines at Red Lodge, Mont., and then from 1903 to 1907 was employed by the Missouri River

Power Company. For the next 2 years Mr. Burr was with the Colorado Power Company, then during 1909–10 engaged in irrigation engineering work with the Arnold Company for the Denver Reservoir and Irrigation Company and the Southern Colorado Irrigation Company. In 1910 he became power salesman for the Denver Gas and Electric Light Company at Denver, Colo., and 2 years later was made power engineer. He was made commercial representative in 1920, a position which he held until 1927, when he became power sales engineer for the Southwestern Public Service Company at Amarillo, Texas. Two years later he joined the Southern California Edison Company at Ventura as power specialist. For the past several years he had conducted a consulting practice as power engineer.

SAMUEL ERNEST MCMILLAN HENDERSON (A'09, M'12, F'14, past vice-president) central station engineer, Canadian General Electric Company, Ltd., Toronto, Ont., died September 2, 1937. Born at London, Ont., September 28, 1879, Mr. Henderson received his technical education at Toronto University, graduating in 1900 with the degree of bachelor of science in electrical engineering. Upon graduation he entered the drafting department in the switchboard division of the General Electric Company at Schenectady, N. Y., and shortly was promoted to the switchboard engineering department. In 1906 he took charge of the estimating division, and 3 years later was given full responsibility for the design and manufacture of 110,000/13,200-volt switchboards for the Hydro-Electric Power Commission of Ontario. In 1910 he joined the Canadian General Electric Company at Peterboro as engineer in charge of estimating, design, and manufacture of switchboards and other apparatus, and later was transferred to Toronto as central station engineer. Mr. Henderson was a member of the AIEE committee on protective devices from 1920 to 1926, and of the membership committee 1923–25 and 1933–34, and was vice-president representing District No. 10 during 1923–25. He was a member and president of the Engineers' Club of Toronto, and had been a member of several other organizations.

ABRAM HUSSEY (A'06, M'18) retired electrical engineer, Chester, N. J., died August 19, 1937. He had been superintendent of distribution for the Brooklyn Edison Company, Brooklyn, N. Y., for 21 years prior to his retirement in 1934. Born May 9, 1868, at Lathrop, Mo., Mr. Hussey entered electrical work as a wireman for the Western Electric Company at Chicago, Ill., in 1892. Two years later he went to Rutland, Vt., as chief electrician of the Marble City Electric Company, later the Rutland City Electric Company. In 1898 he entered the service of the Cataract Power and Conduit Company at Buffalo, N. Y., and the following year was made general foreman; during his service of 8 years with the company the plant grew from a connected load of 2,000 horsepower to 70,000 horsepower. From 1906 to 1913 he was employed by the New York Central Railroad; first until 1909, with charge of all transmission facilities in the electrified zone, and then in charge of construction and maintenance of all transmission facilities during extension of electrification to more than 150 miles of track. In 1913 he accepted the position of superintendent of distribution with the Edison Electric Illuminating Company of Brooklyn (now the Brooklyn Edison Company), where he had charge of engineering, construction, and operation of the transmission and distribution facilities.

LUTHER WILSON COPELAND (A'35) assistant manager, lubrication engineering department, Wadhams Oil Company, Milwaukee, Wis., died August 26, 1937. Mr. Copeland was born at Huntington, Ark., on August 21, 1901, and received the degree of bachelor of science in electrical engineering from Georgia Institute of Technology in 1926. For a few months following graduation he was employed by the Fort Smith Light and Traction Company at Fort Smith, Ark., then for 4 years was employed by the Sinclair Refining Company at Detroit, Mich., and Atlanta, Ga., in various capacities. In 1930 he joined the Vacuum Oil Company, which later was merged with the Wadhams Oil Company, as assistant sales manager of the industrial oil department, which position he held at the time of his death. Mr. Copeland was an active member of the Milwaukee Section of the Institute, and at the last annual meeting of the Section was elected a director for the term beginning August 1. He was chairman of the entertainment committee for the 1937 summer convention held at Milwaukee in June.

EDGAR DAVIS EDMONSTON (A'02, M'07, member for life) general superintendent of the Consolidated Gas Electric Light and Power Company of Baltimore, Baltimore, Md., died August 29, 1937. He was born at Washington, D. C., October 23, 1876, and was graduated from Lehigh University in 1898 with the degree of electrical engineer. He then obtained employment with the United States Electric Lighting Company, Washington, for a year, resigning to join the Westinghouse Electric & Manufacturing Company at East Pittsburgh, Pa. In 1900, Mr. Edmonston became electrical engineer for the Lackawanna Steel Company, which was building a large electrically equipped plant at Buffalo, N. Y., and directed the electrical engineering and construction work until he resigned in 1904. In 1905 he accepted the position of chief engineer of the American Construction Company at New Orleans, La., building a complete commercial power and lighting system in that city. Since 1908 he had been with the Consolidated Electric Light and Power Company of Baltimore, which he joined as superintendent of construction, and of which he had been general superintendent since 1911.

MAURICE COSTER (A'95, M'96, F'12, member for life) retired vice-president of the Westinghouse Electric International Company died at his residence in Magog, Que., Can., on August 31, 1937. Mr. Coster was born in the Netherlands on August 4, 1856, and was graduated from Stevens Institute of Technology, Hoboken, N. J., in 1877 with the degree of mechanical engineer. For a time he was in British Guiana, S. A., as a consulting mechancial engineer, and in 1888 he became associated with the Westinghouse Electric & Manufacturing Company as an engineer, later being transferred to the commercial department. He was sent to Paris, France, as manager of the Societe Anonyme Westinghouse, and returned to the United States in 1905. In 1919, with the formation of the Westinghouse Electric International Company, Mr. Coster became vice-president, and was appointed senior vice-president in 1922, a position which he held until his retirement in 1930. He served on the Institute's board of examiners during 1914–15. Mr. Coster was one of the original 8 founders of the American Manufacturers Export Association, one of the first 50 members of the National Foreign Trade Council, and one of the 24 incorporators of India House.

ARTHUR TOWNSEND (A'05, M'31) chief inspector, Saskatchewan Power Commission, Regina, Sask., Canada, died on August 18, 1937. Mr. Townsend was born January 7, 1875, at Southampton, England, and attended Goldsmith Technical Institute in London. Between 1891 and 1901 he was employed by various companies in England, and then he entered the electrical testing department of the British Thomson Houston Company at London. He was transferred to the technical staff at Rugby in 1903, and left the company 3 years later to move to Canada, where he installed, owned, and operated the town plant at Milestone, Sask., until 1927. In 1928 he designed and built radio station CHWC at Pilot Butte, and since 1929 had been chief inspector for the Saskatchewan Power Commission.

PAUL A. CALLIS (A'34) estimating engineer, Louisville Gas & Electric Company, Louisville, Ky., died May 11, 1937. He was born at Rosedale, Ind., December 14, 1900, and had been employed by the company since he was graduated from Purdue University in 1923 with the degree of bachelor of science in electrical engineering. He began as an estimator in the electric distribution and construction department, and since 1930 had been in charge of estimating in a supervisory capacity. During this time he aided in the development of a "unit cost" system of estimating, and in compiling drawings used as standard construction by the company.

MAURICE BARRERE (A'24) consulting engineer, Schneider and Company, Paris, France, died early in August 1937. He was born at Lourdes, France, July 28, 1891, and received his technical education at Ecole Centrale de Paris and Ecole Superieure d' Electricite. Since 1919 he had been an instructor in electrical engineering at Ecole Centrale de Paris, and in 1921 had become connected with Schneider and Company. He was a chevalier of the Legion of Honor, and had received the Croix de Guerre and the Military Cross of England.

# Membership

## Recommended for Transfer

The Board of Examiners, at its meeting on September 16, 1937, recommended the following members for transfer to the grade of membership indicated. Any objection to these transfers should be filed at once with the national secretary.

**To Grade of Fellow**

Hitchcock, H. W., chief engineer, Southern California Telephone Company, Los Angeles, Calif.

McEachron, K. B., research engineer, General Electric Company, Pittsfield, Mass.

2 to Grade of Fellow

**To Grade of Member**

Allen, C. S., design engineer, General Electric Company, Fort Wayne, Ind.

Banes, C. Raymond, electrical research engineer, Long Island Lighting Company, New York, N. Y.

Bryant, W. L., electrical engineer, Imperial Irrigation District, Imperial, Calif.

Cornelius, H. A., designing engineer, Public Service Company of Northern Illinois, Chicago.

Davis, C. L., patent department, Radio Corporation of America, Washington, D. C.

Ehrensperger, C., engineer, Brown Boveri Company, Inc., Baden, Switzerland.

Fowler, C. V., toll transmission engineer, The Pacific Telephone and Telegraph Company, San Francisco, Calif.

Gear, R. B., field engineer, Commonwealth Edison Company, Chicago, Ill.

Goodrich, J. L., electrical engineer, in care of Thomas H. Allen, Memphis, Tenn.

Hallar, K. E. V., assistant operating and maintenance engineer, Husqvarna Vapenfabriks, Huskvarna, Sweden.

Hanson, D. H., section engineer, General Electric Company, Fort Wayne, Ind.

Huntsberger, J. D., battery service engineer, Philco Radio and Television Corporation, Philadelphia, Pa.

Kilbourne, C. E., designing engineer, General Electric Company, Schenectady, N. Y.

Kilgore, L. A., design engineer, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

Knoderer, C. L., technical employee, American Telephone and Telegraph Company, New York, N. Y.

Larason, G. E., extension engineer, Oklahoma Gas and Electric Company, Oklahoma City.

Mason, R. C., research engineer, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

Payne, C. C., control engineer, central electricity board, Mid-East England area, Leeds, England.

Rawls, J. A., transmission engineer, Virginia Electric and Power Company, Richmond.

Swingle, R. H., patent attorney, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

Wetherill, L., electrical engineer, General Electric Company, Pittsfield, Mass.

21 to Grade of Member

## Applications for Membership

Applications have been received at headquarters from the following candidates for election to membership in the Institute. If the applicant has applied for direct admission to a grade higher than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the national secretary before October 31, 1937 or December 31, 1937, if the applicant resides outside of the United States or Canada.

Andrews, P. R., Tennessee Valley Authority, Wilson Dam, Ala.

Archibald, C. G., Westinghouse Elec. & Mfg. Co., New York, N. Y.

Barker, C. J. (Member), Consolidated Edison Company of New York, Inc., New York, N. Y.

Barr, J. R. (Member), General Electric Company, Pittsfield, Mass.

Becker, H. E., Westinghouse Electric & Manufacturing Company, San Francisco, Calif.

Bisson, A. J. (Member), Consolidated Edison Company of New York, Inc., New York, N. Y.

Boldt, W. F., Century Electric Company, St. Louis, Mo.

Bolton, F. D., Canadian General Electric Co., Vancouver, B. C., Canada.

Bottonari, S. A., Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

Brown, C. B., McCollum Laboratories, Houston, Texas.

Cattolica, J. L., Pacific Gas and Electric Company, San Francisco, Calif.

Chamberlin, J. H., Acme Electric and Manufacturing Company, Cleveland, Ohio.

Clement, P. E., Tennessee Valley Authority, Joe Wheeler Dam, Ala.

Cosentine, L. G. (Member), Wisconsin Gas and Electric Company, Fort Atkinson, Wis.

Criley, W. (Member), Rochester Telephone Corp., Rochester, N. Y.

Daugherty, C. A. (Member), Post Office Box 582, Coral Gables, Fla.

Delo, H. E., Western Electric Company, Kearny, N. J.

Edwards, P. F., Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa.

Elam, R. D., Tennessee Valley Authority, Wilson Dam, Ala.

Farmer, E. B., Electrolux Inc., New York, N. Y.

Fremo, E. C., San Diego Consolidated Gas and Electric Company, San Diego, Calif.

Garris, C. R., General Electric Company, Pittsfield, Mass.

Grethel, B. W., Public Utilities, City of San Francisco, San Francisco, Calif.

Guice, F. J. (Member), Memphis Power and Light Company, Memphis, Tenn.

Harkins, M. A., University of Tennessee, Knoxville.

Haupt, L. M., Jr., A. & M. College, College Station, Texas.

Heath, E. A., Kansas Gas & Electric Co., Wichita, Kansas.

Kelley, W. A. (Member), E. D. Jones & Sons Co., Pittsfield, Mass.

Lyons, S. E., Wilson Dam, Ala.

Mangold, A. O., Northwestern Electric Co., Portland, Oregon.

Mattison, M., Harza Engineering Company, Columbus, Nebraska.

McCarthy, E. T., Alta Electric and Mechanical Company, San Francisco, Calif.

Meinhardt, P. W., Union Electric Company of Missouri, St. Louis.

Olson, O. F., New York and Queens Electric Light and Power Company, Flushing, N. Y.

Painter, J. C., 425 Mason Street, San Francisco, Calif.

Park, C. A., Jr., Tennessee Valley Authority, Wilson Dam, Ala.

Reifsnyder, G. C., Bell Telephone Company of Pennsylvania, Allentown.

Renzi, S. E., United Shipyard Inc., Staten Island, N. Y.

Rodhouse, T. E., General Electric Company, Pittsfield, Mass.

Rodnite, F. A., Public Service Electric and Gas Company, Newark, N. J.

Ruppert, R. B., 629 Franklin Avenue, Columbus, Ohio.

Seitz, F. W., 100–112 Seeboth St., Milwaukee, Wis.

Sims, J. B., Carbide & Carbon Chemicals Corp., South Charleston, W. Va.

Smart, D. L., Detroit Edison Company, Detroit, Mich.

Smith, C. D., Ohio Edison Co., Akron, Ohio.

Strandberg, H. V. (Member), City of Seattle, Light Dept., Seattle, Wash.

Tilyou, I. B. (Member), Cooper Wire Engineering Association, Washington, D. C.

Wade, J. R., Wilson Dam, Ala.

Walker, C. D., Bell Telephone Laboratories, New York, N. Y.

Wasserman, C., Consolidated Gas Electric Light and Power Company, Baltimore, Md.

Whitaker, H. B., Underwriters' Laboratories, Inc., Chicago, Ill.

White, W. C., Northeastern University, Boston, Mass.

Wilcox, H. M. (Member), Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

Williams, E. A., Jr., General Electric Company, Philadelphia, Pa.

Williamson, C. A., General Electric Co., Wichita, Kans.

Wohlgemuth, M. J. (Fellow) Westinghouse Electric & Manufacturing Company, Detroit, Michigan.

56 Domestic

**Foreign**

Bobal, L. (Member), Bata Shoe Company, Inc., Zlin, Czechoslovakia.

Chandler, C. E., Manning & Co. Ltd., Bridgetown, Barbados, B. W. I.

Coomar, H. N., Allgemeine Electricitata-Gesellshaft, Berlin, Germany.

Fenwick, W. (Member), Victoria Falls and Transvaal Power Company, Ltd., Germiston, Transvaal, South Africa.

Sarda, B. D. (Member), Hoshiarpur Electric Supply Company, Punjab, India.

Srinivasan, R., Tinnevelly Tuticorin Electric Supply Company, Brahmin Colony, Tuticorin, India.

6 Foreign

## Addresses Wanted

A list of members whose mail has been returned by the postal authorities is given below, with the addresses as they now appear on the Institute record. Any member knowing of corrections to these addresses will kindly communicate them at once to the office of the secretary at 33 West 39th St., New York, N. Y.

Charlton, H. C., 4827 Wilson Avenue, Montreal, Que., Canada.

Evans, Maldwyn F., Canadian Comstock Company, Ltd., Toronto, Ont., Canada.

Fassett, Frank C., 100 Seward Ave., Detroit, Mich.

Gregory, G. A., 1217 Jefferson Street, Olympia, Wash.

Hall, John R., 1464 S. 74th St., West Allis, Wis.

Handy, Lee, 525 W. 113th Ave., Vancouver, B. C., Can.

Hardy, John E., 1741 Pennsylvania Avenue, Denver, Colo.

Herr, Melvin D., South 228 Lincoln St., Spokane, Wash.

Jones, K. B., Trumbull Electric Manufacturing Company, Inc., Ludlow, Ky.

Kirk, W. C., 216 E. 22nd St., Owensboro, Ky.

Koziol, Roman Joseph, 174 Farmington Ave., Hartford, Conn.

Macomber, George S., Federal Power Commission, Washington, D. C.

Matthews, Robert W., 42 St. Stephen St., Boston, Mass.

Roberts, Fred A., 2010 West Michigan Street, Indianapolis, Ind.

Sikofsky, George L., 1206 East New York Avenue Brooklyn, N. Y.

15 Addresses Wanted

# Engineering Literature

## New Books in the Societies Library

Among the new books received at the Engineering Societies Library, New York, recently are the following which have been selected because of their possible interest to the electrical engineer. Unless otherwise specified, books listed have been presented gratis by the publishers. The Institute assumes no responsibility for statements made in the following outlines, information for which is taken from the preface of the book in question.

La FATIGUE des MÉTAUX. By R. Cazaud and L. Persoz. Paris, Dunod, 1937. 190 p., illus., 10x7 in., paper, 75 frs.; bound, 95 frs. Analyzes the principal studies of the fatigue of metals and discusses theories, methods of testing, fatigue limits, the factors that affect fatigue, and the resistance of welded and riveted joints.

BEIHEFTE zum GESUNDHEITS-INGENIEUR, Reihe 1, Heft 86. Die heiztechnischen Neuanlagen des Städtischen Krankenhauses Bad Cannstatt, by H. Wolfer. Munich and Berlin, R. Oldenbourg, 1937. 24 p., illus., 13x9 in., paper, 4.80 rm. Describes the power plant of a large German hospital and reports the results of an operating test.

Der ULTRASCHALL. By L. Bergmann. Berlin, VDI-Verlag, 1937. 230 p., illus., 8x6 in., cloth, 18.50 rm. An account of the present state of supersonics, with emphasis upon the scientific and technical uses of supersonic waves.

YEAR BOOK on COAL MINE MECHANIZATION. Washington, D. C., American Mining Congress, 1936. 362 p., illus., 9x6 in., lea., $2.00. Contains extracts from the reports of various district committees and papers presented at the 1936 convention.

DIESEL ENGINES. By P. E. Biggar. Toronto and New York, Macmillan Co., 1936, 165 p., illus., 9x6 in., cloth, $3.25. Condensed information in the Diesel field covering many particular points and the probable future development of the Diesel type.

MACHINE DESIGN. By P. H. Hyland and J. B. Kommers. 2 ed. New York and London, McGraw-Hill Book Co., 1937. 598 p., illus., 9x6 in., cloth, $4.50. A comprehensive elementary textbook on machine design, arranged to be studied simultaneously with mechanics of materials courses.

TEXTBOOK of THERMODYNAMICS. By P. S. Epstein. New York, John Wiley & Sons, 1937. 406 p., illus., 10x6 in., cloth, $5.00. Thermodynamics is treated from the physicist's point of view, and mainly as apart from statistical mechanics.

(The) SCIENCE of VALUATION and DEPRECIATION. By E. B. Kurtz. New York, Ronald Press Co., 1937. 221 p., illus., 9x6 in., cloth, $4.50. Offers scientific solutions, based on life experience tables, to basic problems in valuation and depreciation estimating and accounting.

# Industrial Notes

**Arc Welding Forges Ahead.**—True to the predictions that were made for it a decade ago, the electric arc welding process has been making tremendous strides in extending its fields of usefulness. The growth in volume in the past five years is shown by the NEMA reports of electric welding wire consumption, from 18.8 millions of pounds in 1932 to 111 millions of pounds in 1936. It is thought in some quarters that there will be recorded a further 50 per cent increase when the total for 1937 is known. That this progress is not all due to the general revival of industrial activity is shown by the steady increase in volume of consumption in the early thirties, before any real revival had started. A more graphic proof is the increasing amount of electrodes being used for each ingot ton of steel poured. In 1932 the figure was 1.4 lbs. of electrode for each ingot ton; in 1936 this figure had reached 2.4 pounds, an increase of 71 per cent.

**Electric Appliance Sales Mount.**—Retail sales of electric household washers in the first seven months of 1937 amounted to $80,531,874. Machines shipped in this period totalled over one million and their average retail price was $73.39. Ironer shipments for the same period totalled 109,270, compared to 102,988 for the same months of 1936. Vacuum cleaner sales aggregated 1,083,170 during the period, a total which was not reached until October last year. According to the Air Conditioning Manufacturers' Association, sales of air conditioning equipment of its members to the end of July amounted to $68,306,175, which was 37 per cent higher than the volume for all of last year.

**Cutler-Hammer Appointments.**—A new district office in New Orleans, was opened recently by Cutler-Hammer Inc., with Joseph Gardberg in charge. W. E. Ragsdale has been appointed manager of the Dallas office.

**Allegheny Steel Appointment.**—Charles H. McKnight has been appointed special sales representative by the Allegheny Steel Co., of Brackenridge, Pa. Since 1912 he was in the employ of the General Electric Co. During the past few years he devoted his time to special cost reduction activities.

**American Steel & Wire Promotion.**—John May has been elected vice-president in charge of sales of the American Steel & Wire Co., a subsidiary of the U. S. Steel Corp., according to a recent announcement by C. F. Blackmer, president of the wire company. Mr. May has been connected with the company since 1909.

**G-E Employees' Service Records.**—More than 40 per cent of the employees of the General Electric Company have worked with the company for 10 or more years, according to a recent survey. Those employed more than 5 years number 42,875 and those with 10 or more years of service 32,019. 53 employees have been with the company 45 or more years; more than 200 for 40 years or more; more than 1000 for 35 or more years; 11,705 have worked 20 or more years and 19,773 have been employed 15 or more years.

**Westinghouse Appointments.**—R. R. Davis, formerly apparatus advertising manager of the Westinghouse Electric & Mfg. Co., has been appointed assistant to the general advertising manager, according to a recent announcement by S. D. Mahan, general advertising manager. J. M. McKibbin, Jr., associated with the company since 1922, has been appointed apparatus advertising and sales promotion manager. Walter Thompson, formerly Eastern sales manager of the radiotron division, R.C.A. Mfg. Co., is now director of utility sales for the Westinghouse merchandising division at Mansfield, Ohio. Angus G. Scott, formerly superintendent of power distribution for Cleveland Railways, has been appointed manager of line material activities at East Pittsburgh.

# Trade Literature

**Steam Turbine Units.**—Bulletin, 28 pp. Describes in considerable detail reaction type turbo-generator units of 1500- to 5000-kw capacity. Allis-Chalmers Mfg. Co., Milwaukee, Wis.

**Capacitors.**—Bulletin 143, 4 pp. Describes a new line of capacitors for power factor correction on electric distribution systems. Cornell-Dubilier Electric Corp., South Plainfield, N. J.

**Neutral Clamp and Thimble.**—Bulletin 629-H, 2 pp. Describes and gives catalog information on a clamp for grounding the neutral conductor on primary and secondary systems of distribution lines, and on a thimble for dead-ending conductors. Ohio Brass Co., Mansfield, O.

**Time Switches.**—Catalog. Describes Sauter synchronous and electrically-wound time switches. Types for all time switch applications are listed. R. W. Cramer & Co., Inc., 67 Irving Place, New York.

**A-C Generators.**—Bulletin 1158-A, 8 pp. Describes a-c bracket bearing type generators, built in standard ratings from 30 to 1000 kva, suitable for coupled service to high speed steam or internal combustion engines. Allis-Chalmers Mfg. Co., Milwaukee, Wis.

**Suspension Insulator Tests.**—Bulletin 623-H, 8 pp. Describes tests of dynamic characteristics of cap-pin insulators; explains what factors influence insulator life, and shows how test data are used in correlating insulator design with field performance. Ohio Brass Co., Mansfield, O.

**Vibration Elimination.**—Bulletin, 16 pp., "Eliminating Vibration Losses." Describes the application of various methods and materials, such as cork, rubber, etc., for eliminating vibration in the operation of many types of heavy machinery. Korfund Co., Inc., Long Island City, N. Y.

**Transformers.**—Bulletin GEA 2206C, 4 pp. Describes rural-line distribution transformers in ratings of 1 and 3 kva, which meet the need for inexpensive units designed for application to lines of 13,200 Y volts and below, where a solidly grounded common neutral is used for both high-voltage and low-voltage circuits. General Electric Co., Schenectady, N. Y.

**New Constant Level Oiler.**—Bulletin. Describes a new line of inexpensive constant level oilers for automatically maintaining an accurate level of oil in ring and ball bearings of motors, line shafts, pumps, and other machinery having oil wells. Trico Fuse Mfg. Co., Milwaukee, Wis.

**Arc Welder.**—Folder, "The Characteristics of a Modern Arc Welder." Includes volt-ampere curve analysis for general welding, heavy welding and light-gauge welding; describes single-current control, self-excitation and other features in the design and construction of the Hansen Smootharc welding generators. Harnischfeger Corp., 4400 W. National Ave., Milwaukee, Wis.

**Mercury Switches.**—Catalog 603, 12 pp. Describes the complete line of Kon-nec-tor mercury switches. Full-size illustrations of the twelve common types of mercury-to-mercury and mercury-to-metal switches are included, as well as a table giving the capacity and electrical specifications of each type. A section is devoted to desirable applications of mercury switches. General Electric Vapor Lamp Co., Hoboken, N. J.

**Watthour Meters.**—A series of bound, loose-leaf bulletins. Bulletin No. GEA-615E, 4 pp., General Information and Index to Contents. No. GEA-2668, 16 pp., Single-Phase, Type I-20. No. GEA-2669, 12 pp., Two-Element, Types V-2 and V-3. No. GEA-1046A, 8 pp., Polyphase, Types D-14 and D-15. No. GEA-1093B, 8 pp., Switchboard A-C Meters, Types IS-8, DS-19, DS-20, DS-21 and DS-23. No. GEA-2670, D-C Meters, 8 pp. No. GEA-1350A, 4 pp., Portable Standards. No. GEA-2671, 12 pp., Accessories and Supplies, describes protective cases, autotransformers, jewels, tool kits, etc. General Electric Co., Schenectady, N. Y.

**Modified Schering Bridge.**—Catalog E-54 (2), 8 pp. Describes a modified form of Schering bridge for determining the characteristics of samples of both liquid and solid dielectrics. High voltage is applied only to the test samples and to the standard air capacitor. A method of compensation for residual capacitance is used which enables results to be calculated from simple equations. In the case of low power factors, the result is read directly. Capacitances ranging from 40 mmf to 0.020 mf and power factors from 0.0001 to 0.70 can be accurately determined. The bridge is intended for use on 60-cycle circuits and the standard air capacitor and sample holders listed are rated at 10 kv. Leeds & Northrup Co., 4962 Stenton Ave., Philadelphia, Pa.

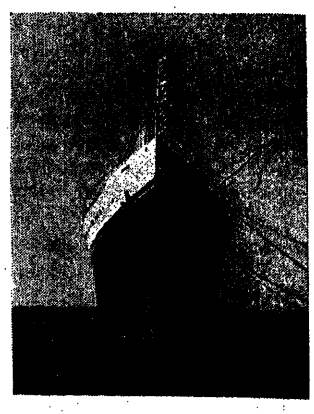
**American Institute of Electrical Engineers**

(Founded 1884)

W. H. Harrison, President

H. H. Henline, National Secretary
G. Ross Henninger, Editor
Floyd A. Lewis, Associate Editor
C. A. Graef, Advertising Manager

Publication Committee—I. Melville Stein, *chairman* J. W. Barker O. W. Eshbach H. H. Henline L. W. W. Morrow A. G. Oehler H. S. Osborne H. S. Phelps D. M. Simmons M. W. Smith W. H. Timble



Entered as second class matter at the Post Office, Easton, Pa., April 20, 1932, under the Act of Congress March 3, 1879. Accepted for mailing at special postage rates provided for in Section 1103, Act of October 3, 1917, authorized on August 3, 1918. ¶ Publication Office: 20th & Northampton Streets, Easton, Pa. Editorial and Advertising Offices at the headquarters of the Institute, 33 West 39th Street, New York

## The Cover

**The completely electrified liner, S.S. "President Coolidge," powered by 2 13,250-horsepower 133-rpm synchronous motors each supplied from an individual turbogenerator set**

Westinghouse Photo

# High Lights

**D-C Transformers.** Various methods have been proposed for transforming voltage on d-c systems without using a motor-generator set. Although little practical use has been made of the device, the d-c transformer using grid-controlled mercury-arc rectifiers for commutating the direct current is one of the more promising of the systems thus far devised. The general theory of d-c transformers is discussed in a paper in this issue, and 2 new types of d-c transformers using grid-controlled mercury-arc rectifiers are described (*pages 1372–8*).

**Grand Coulee Dam.** Irrigating more than a million acres of land is one of the functions of the dam being built as part of the Columbia Basin project in the State of Washington. Pumps motor-driven by power generated at the dam will draw water from the river for distribution through hundreds of miles of canals; millions of kilowatt-hours of firm power will be produced annually. Construction of the dam is being accompanied by new accomplishments and records (*pages 1339–45*).

**ECPD Annual Meeting.** At the fifth annual meeting of Engineers' Council for Professional Development, additional engineering curricula were accredited, making a total of 442 curricula now so recognized in 127 educational institutions. Reports of committees and election of officers constituted the other principal items of business (*pages 1416–19*).

**Correction.** In the article "Engineering Income and Earnings, 1929–34," published in ELECTRICAL ENGINEERING for September 1937, the second sentence in the second paragraph under the heading "Earned Annual Income," page 1092, should read "Some 479 reported incomes less than $800 per year, while 295 earned more than $19,000 a year."

**New Committee Chairmen.** As usual, the newly appointed chairmen of AIEE committees are being introduced to the Institute membership through the "Personal Items" section. Items on the first group of chairmen were published in the October issue; items on the remainder are included in this issue (*pages 1424–6*).

**Short Circuits.** Water-wheel generators that are without damper windings and connected to a capacitive load such as an open transmission line can produce abnormally high voltages during unsymmetrical short circuits because of resonance or near resonance of the capacitance of the load and the reactance of the machine (*pages 1385–95*).

**Load Loci.** The method of circular loci may be applied to the solution of a circuit containing 2 transformers operating in parallel. The variation of current in either transformer or the ratio of the 2 currents is said to be obtainable as a function of the load impedance or the ratio of transformation without much involved computation (*pages 1379–84*).

**Important developments** in publication policy and procedure just approved by the board of directors, affecting both ELECTRICAL ENGINEERING and the TRANSACTIONS, are outlined on *page 1409* by Chairman I. Melville Stein of the AIEE publication committee.

**Noise in Small Motors.** Careless or inaccurate manufacturing methods sometimes are responsible for flaws such as uneven air gaps, loose bearings, or loose rotor bars, which contribute to noisy operation of small electric motors. Some of this noise can be minimized by proper design procedure (*pages 1359–67*).

**Akron District Meeting.** A strong and well received industrial flavor characterized the busy program of the recent Middle Eastern District Meeting. Of the 464 persons included on the registration list, approximately a third were students. A comprehensive report of activities will be found in this issue, beginning on *page 1410*.

**Engineers' Income.** Data derived from reports of 52,589 engineers tend to show that engineers engaged in technical work reach their maximum earning capacity later than those in nonengineering endeavors, but that this disadvantage is offset after a certain age (*pages 1353–8*).

**Insulation Research.** Principal advances in insulation research made during the past year were summarized in the report of the chairman of the committee on electrical insulation of National Research Council, presented during the 10th annual meeting of that body (*pages 1346–52*).

**NRC Subcommittee Meets.** At the recent annual meeting of the American Chemical Society held at Rochester, N. Y., the chemistry subcommittee of the National Research Council insulation committee held a symposium on insulation materials (*page 1420*).

**Winter Convention.** A "general" session has been scheduled tentatively on the program of the Institute's 1938 winter convention to be held January 24–28 in New York, N. Y. Preliminary plans for the convention are now under way (*page 1415*).

**Nominations for Offices.** For the guidance of the national nominating committee, suggestions for nominations for election to AIEE offices in 1938 are invited from the Institute membership (*page 1415*).

**Letters to the Editor.** Engineering education and democracy, and synchronous motor effects on induction machines are the subjects discussed in the "Letters" columns of this issue (*pages 1422–3*).

**New AIEE Section.** A new Institute Section recently was organized at Wichita, Kans. This increases the total number of AIEE Sections to 63 (*page 1414*).

**Transformer Reactance.** A mathematical formula for computing the reactance of the interleaved component of transformers has been derived (*pages 1368–71*).

# The Columbia Basin Project

By ALVIN F. DARLAND
MEMBER AIEE

**Grand Coulee Dam, now under construction on the Columbia River in the State of Washington, will create a 150-mile lake from which irrigation water for more than a million acres of land will be pumped by part of the power to be generated at the dam. This article describes the purposes of the project, which will not be completed in its entirety for half a century, and the present status of construction of the dam.**

NEAR THE CENTRAL PART of the State of Washington is a pear-shaped body of semiarid land, approximately 85 miles long and 60 miles wide, containing $1^1/_4$ million acres of highly fertile soil, having a long growing season and a moderate climate, but without sufficient rainfall to support agricultural activities. This land, now largely covered with a determined growth of sagebrush and tumbleweed, was settled a generation ago by dry-land farmers who attempted to grow grain. Only a few relatively small areas have succeeded in maintaining anything approaching a successful farming venture. In those areas the key to success is water, available by pumping from a limited subterranean supply or an adjoining lake, or by enough rainfall to enable the harvest of an occasional crop.

Fifty miles to the north of the northern end of the irrigable area, and bordering its full length on the west, the Columbia River flows through a granite and basalt gorge from 300 to 1,500 feet below the level of the parched lands adjoining. The Columbia is the second largest river in the United States in the quantity of runoff, and the largest on the American continent in potential water power. Strangely enough, the Columbia at one time, diverted by a glacier choking its ancient gorge, was forced to carve from basalt rock a new channel some 50 miles long, from 2 to 5 miles wide, and from 600 to 1,000 feet deep, now known as the Grand Coulee. At the lower end of the Grand Coulee the diverted Columbia spread over the lands where the subsequent farming efforts failed because of the lack of water, and these lands today are known as the Columbia Basin. The river returned to its original channel after the glacial barrier melted, leaving the floor of the Grand Coulee 600 feet high and dry above its own restored level, and quitting at the same time its great lake-like channels in the Columbia Basin.

## Preparation of Plans

Two plans proposed for the irrigation of the Columbia Basin were: first, gravity flow from the Clark Fork of the river by way of a long aqueduct; and second, damming the

Essential substance of an address presented at Coulee Dam, Wash., on September 3, 1937, on the occasion of an all-day inspection trip during the AIEE Pacific Coast convention.

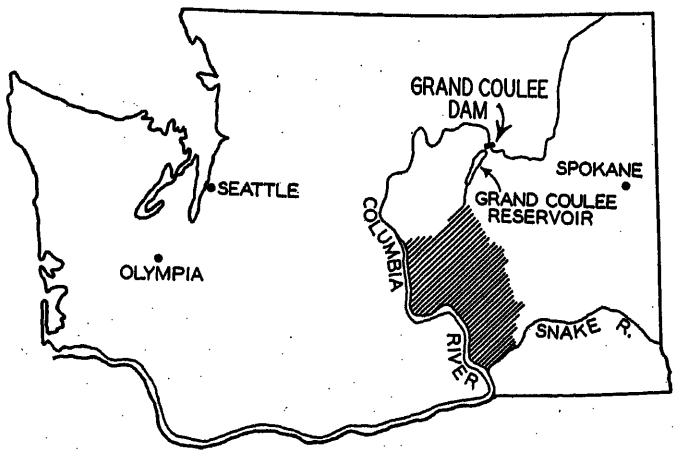
ALVIN F. DARLAND is a native of Tacoma, Wash., and received the degree of bachelor of science in electrical engineering from the University of Washington in 1914. In 1923 he became superintendent of electrical construction and design in the public utilities department of the City of Tacoma, and was in responsible charge of the design and construction of 2 hydroelectric plants built by the city. Since 1935 he has been field engineer with the United States Bureau of Reclamation at Coulee Dam, Wash.

river near the head of the Grand Coulee to form a lake back of the dam, and pumping water from this lake into the Grand Coulee, whence it could flow by gravity to the land.

The United States Engineers, acting under authority of Congress, in 1932 submitted a report of a thorough study of these plans as one phase of the report on a comprehensive plan for the economic development of the river for power, irrigation, and navigation, from its crossing of the international boundary between Canada and the United States to its mouth at the Pacific Ocean, a river distance of 750 miles, through which there is a difference in elevation of the river of 1,300 feet. This report recommended the building of the Grand Coulee Dam as the key structure to the development of the power of the Columbia River, and the irrigation of the Columbia Basin by pumping from the lake formed by the dam. The ultimate building of 10 hydroelectric projects on the river having an aggregate capacity of 10,000,000 prime horsepower was recommended. Of these, the Rock Island Dam and power plant already have been built by private capital, while the Grand Coulee and Bonneville dams, the headwater and tidewater projects, are now under construction by the United States Government.

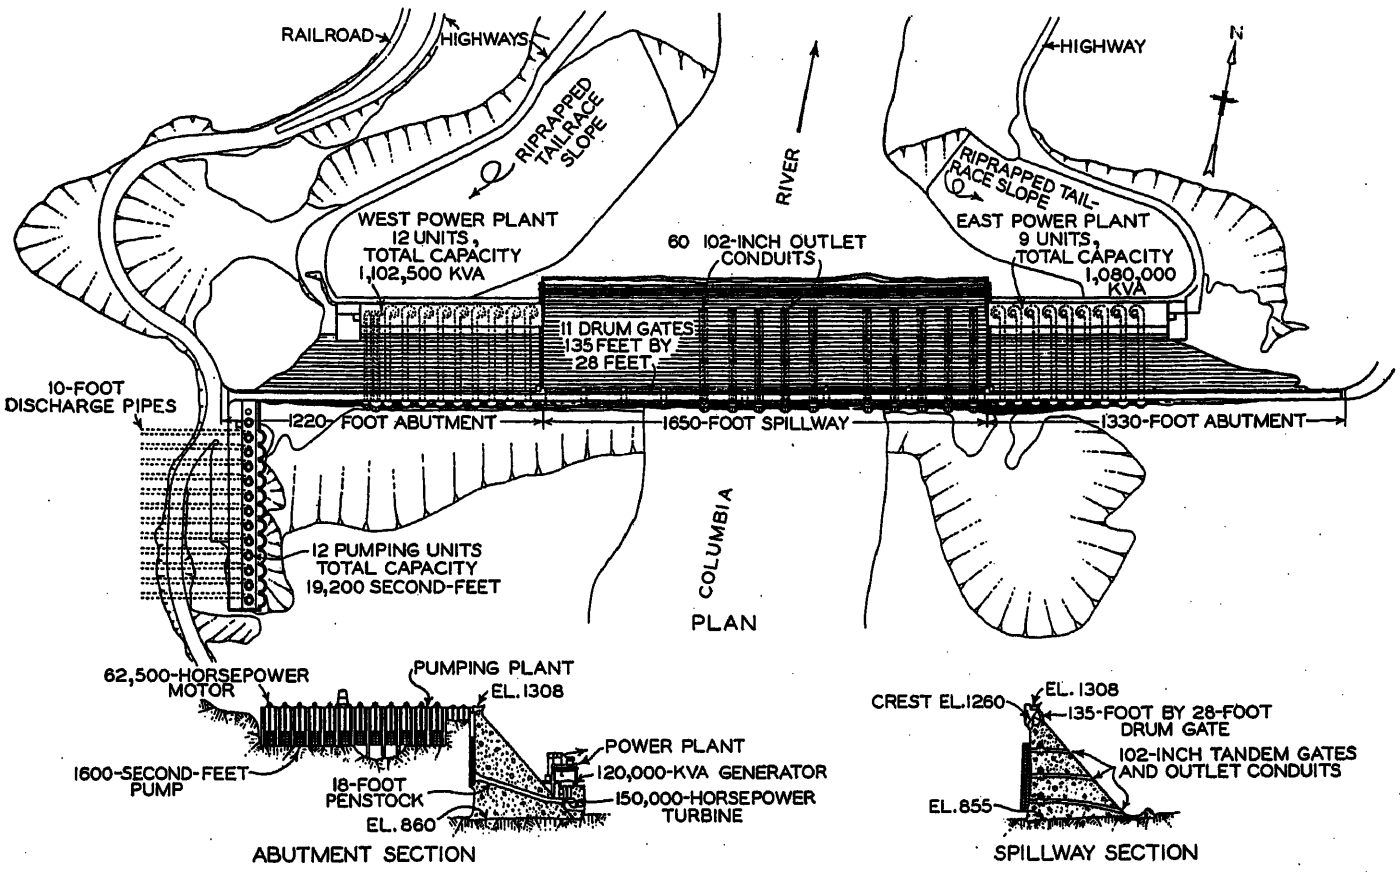
Outstanding attributes of the dam at Grand Coulee were cited as the doubling of the low-water flow of the river, an increase of from 50 to 100 per cent in the output of downstream power developments at low water because of the great storage afforded by the dam, and a reduction (from 635 feet to 295 feet) in the pumping lift necessary to divert water through the Grand Coulee to the Columbia Basin lands. The building of the dam was authorized by President Franklin D. Roosevelt in the fall of 1933 as a public works project, and work was started shortly thereafter under the direction of the United States Bureau of Reclamation; plans for the project previously had been prepared by the Bureau, following investigations and studies extending over a period of years.

## Plan of Development



Fundamentally, the plan of development of the Columbia Basin project consists of: a dam across the Columbia River at the head of the Grand Coulee; 2 power plants adjacent to the dam utilizing the hydraulic head created thereby; a pumping plant to lift water from the lake created by the dam to a reservoir approximately 23 miles long, to be developed in the Grand Coulee by the construction of 2 dams, each about 90 feet high and crossing relatively narrow sections of the floor of the coulee; and a distribution system to convey the water from the reservoir to the 1,200,000 acres of land in the Columbia Basin that are to be irrigated.

The dam and power plant are estimated to cost $179,000,000 and to have an annual output capacity of 8,100,000,000 kilowatt-hours of firm power and 5,000,000,000 kilowatt-hours of secondary power. The sale of this power is expected to repay to the United States Government the cost of the dam and power plant, and half the cost of the irrigation system. Irrigation, including the pumping plant, will cost $198,000,000 and will be repaid, half by the revenue surplus from the sale of power, and half by the settlers of the land. The total annual cost to the farmer for the contemplated irrigation is now estimated to be about $5 per acre.



### Dam and Power Plant

Grand Coulee Dam is being constructed upon the granite floor and abutments of the river gorge within a mile downstream from the point where the river was forced to make its glacial detour through the Grand Coulee. The structure, a straight gravity-type dam, will rise 550 feet above the lowest bedrock, will be approximately 4,300 feet long and 500 feet thick at the base, and will raise the river 335 feet, creating a lake 150 miles long reaching the Canadian border and providing 5,000,000 acre-feet of useful storage in the upper 80 feet of the reservoir. The average flow of the river is 109,000 second-feet at the dam site, but during an exceptionally high flow in 1894 is estimated to have reached 725,000 second-feet. A spillway 1,650 feet long with a capacity of 1,000,000 second-feet, and designed to dissipate without damage to the structure 30,000,000 horsepower of hydraulic energy, will be provided in the channel section of the dam. For the construction of the dam and power houses, $11\frac{1}{4}$ million cubic yards of concrete will be required.

A power plant having 18 120,000-kva main generating units and 3 7,500-kva station-service units is contemplated for the ultimate development, 9 main generating units to be in a power house to be constructed adjacent to the dam at its easterly downstream face, and the rest to be in a similar power house at the west end of the dam. The initial installation will consist of 3 main generating units and 2 station-service units. Additional units will be installed as irrigation and power-market requirements justify them. It is anticipated that power generating capacity of the project over and above that required for pumping of irrigation water will be absorbed within a 15-

**Outline map of the State of Washington, showing the location of Grand Coulee Dam; the cross-hatched portion is the approximate area to be irrigated**

**Grand Coulee Dam and appurtenant works**

year period after completion of the dam and initial power development, but the development of the irrigation phase of the project is expected to continue for a much longer period.

IRRIGATION SYSTEM

The pumping plant, which will lift the irrigation water from the lake to the reservoir in the Grand Coulee, will be constructed on a granite bedrock shelf upstream from the west end of the dam. The plant will have a rated capacity of 16,000 second-feet of water, and an installed capacity of 19,200 second-feet in 12 pumping units. Each pump will be rated at 1,600 second-feet and will be driven by a 62,-500-horsepower motor, 2 such pumping units to be operated by the output of one main generating unit at the west power plant. The irrigation water diversion will amount to slightly more than a seventh of the average flow of the river, and will require the power output of 5 main generating units totaling 600,000 kva for pumping. The flood stage of the river is during the irrigation season, a fact of importance to this project.

Water from the pumping plant will be conducted through penstocks to a canal, which will connect with the irrigation reservoir in the Grand Coulee. Two relatively small dams will be constructed to close the 2 ends of the upper 23 miles of the Grand Coulee, so that water may be stored to a depth of about 70 feet and in a useful amount of 339,000 acre-feet above the elevation of the outlet to the distribution system.

A main canal from the southerly end of the irrigation reservoir at a point 11 miles farther south, will branch into a main east canal and a main west canal, the former to be 156 miles long and the latter 101 miles long. These 2 canals practically will encompass the irrigable lands of the basin. A system of lateral and distribution canals will finally convey water to 40-acre units of the project. During the irrigation season, it is estimated that an average of 40 inches of water can be supplied to the land, whereas the mean annual precipitation for the area is but 8.2 inches, and the rainfall during the irrigation season is only 3.6 inches.

## Construction

During somewhat more than $3\frac{1}{2}$ years since the fall of 1933, work accomplished on the project represents a cost equal to approximately half the expenditure necessary to construct the dam (not including power development). The base of the dam has been built out from the west abutment to the original west bank of the river, and within this portion of the dam have been left multiple channels through which the river now flows while the building of the dam from the east abutment proceeds out across the old channel of the river to join that portion of the structure on the west side of the stream. This work has necessitated the building of 2 systems of cofferdams, the excavation of earth overburden amounting to 20,000,000 cubic yards, foundation rock excavation of 1,000,000 cubic yards, and

the placing of more than 3,900,000 cubic yards of concrete to October 1937. Incidental to the principal work of the project has been the building of the towns, both on the project and adjacent thereto, for the housing, care, and entertainment of more than 6,000 workmen, who with their families have brought approximately 15,000 people

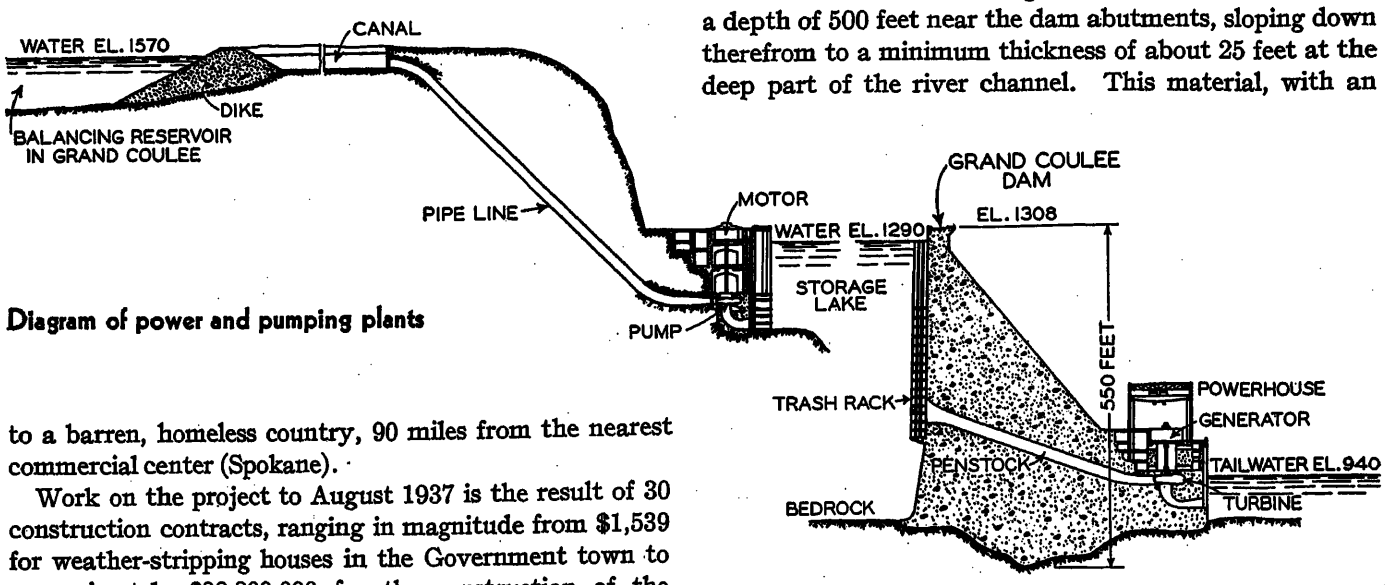


**Diagram of power and pumping plants**

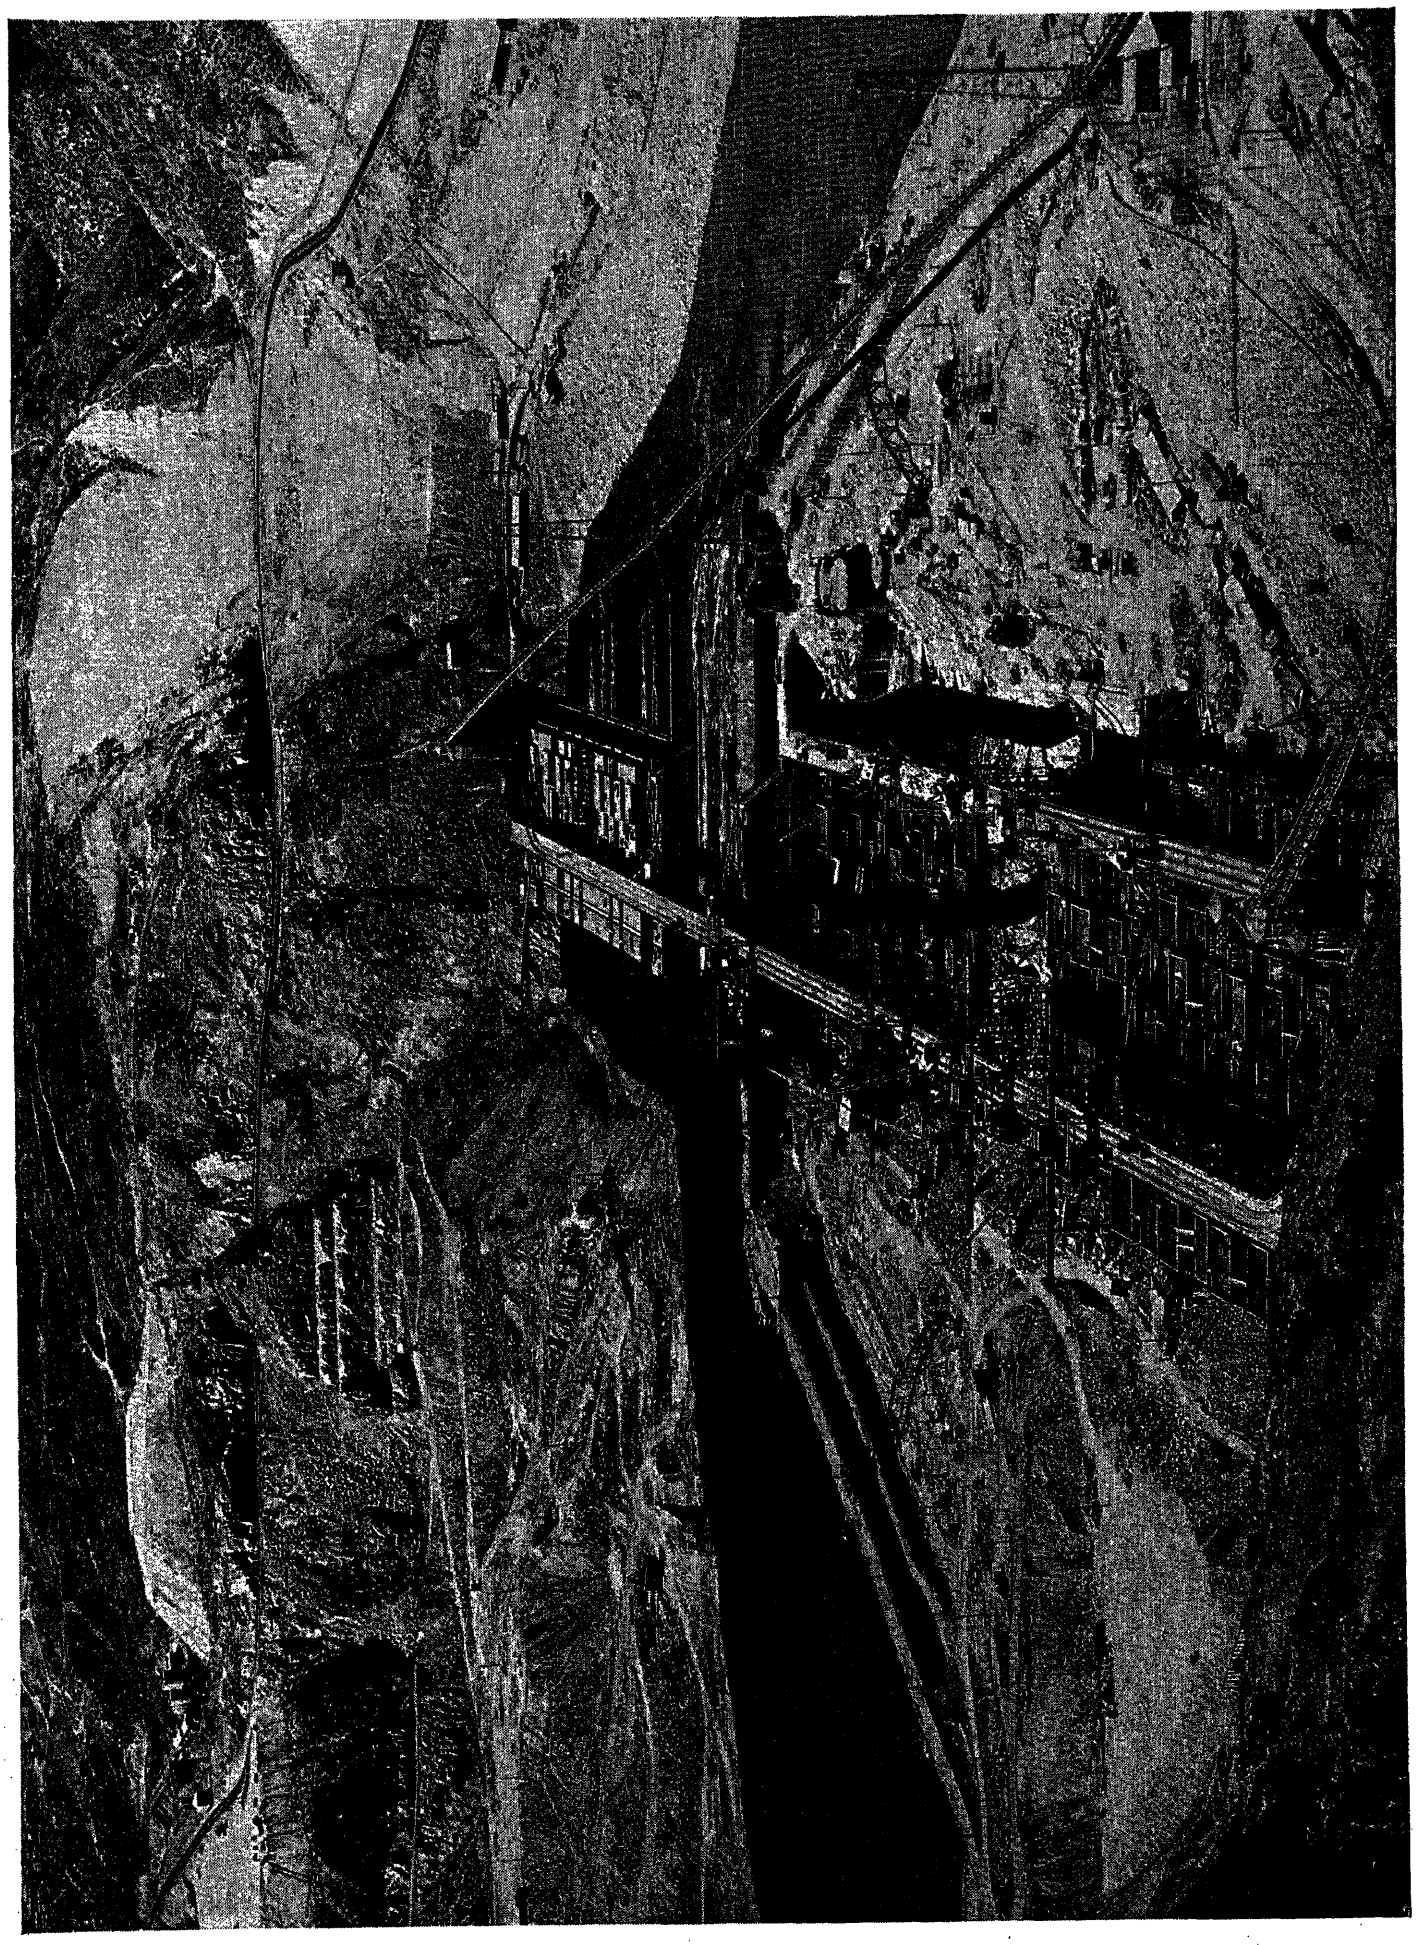
to a barren, homeless country, 90 miles from the nearest commercial center (Spokane).

Work on the project to August 1937 is the result of 30 construction contracts, ranging in magnitude from $1,539 for weather-stripping houses in the Government town to approximately $38,800,000 for the construction of the base of the dam and foundations for the 2 power houses. This latter, the principal contract of the project and the only one not yet completed, is held by the Mason-Walsh-Atkinson-Kier Company, a company organized by 3 previously independent contracting firms for the purpose of providing financing and equipment adequate to conduct operations on the large scale necessary at Grand Coulee Dam. In addition to the construction contracts, many others have been made for construction materials, the Government furnishing materials and equipment that become a permanent part of the dam and power plants.

The Mason-Walsh-Atkinson-Kier Company is within a few months of the completion of work included under its contract, which comprises briefly the building of the electrically heated Mason City, the contractor's town; most of the excavation required for the dam and power houses; the diversion of the river; and the manufacture and placing of about 4,500,000 cubic yards of concrete, which represents about 40 per cent of the concrete required for the completed dam.



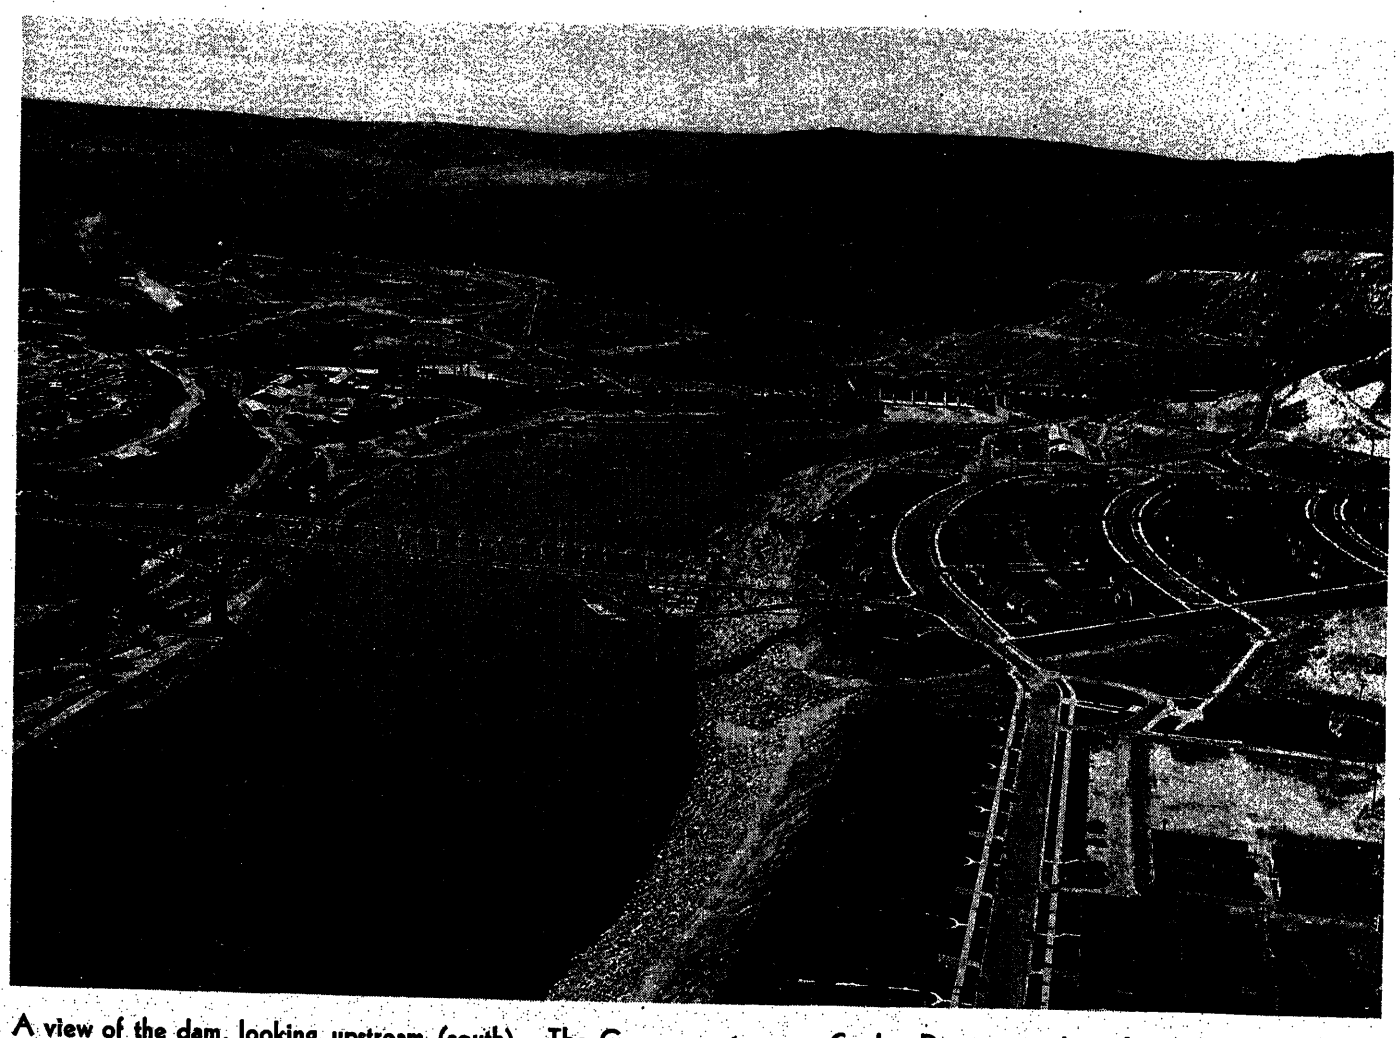
Mason City at present has a population of 300 families and 1,200 single men in semipermanent houses and dormitories, and a population of 400 men in tents. The homes and dormitories, general store, recreation hall, hotel, theater, messhalls, and company office buildings are all electrically heated, comprising a connected electrical load of 8,500 kw, all of which is active during the cold-weather months. When this condition occurs, however, weather conditions are so severe that the electrical load from construction activities is greatly reduced, and an almost uniform power demand results. Peak power demand of the project has been 14,000 kw. Power is supplied by the Washington Water Power Company at a 110-kv switching station in Coulee City, 30 miles from the project, and is transmitted therefrom by the contractor to the site of the work over a single-circuit 110-kv line.

### Excavation for the Foundation

The silt bed on the granite floor of the river gorge, placed during the existence of the glacial lake at the time of the diversion of the river through the Grand Coulee, reached a depth of 500 feet near the dam abutments, sloping down therefrom to a minimum thickness of about 25 feet at the deep part of the river channel. This material, with an occasional glacial deposit of sand and gravel, was removed by a battery of electrically operated power shovels, dumping into trucks and tractor-drawn buggies which ranged in capacity from 12 to 30 cubic yards; these in turn dumped onto a system of belt conveyers, likewise electrically operated, reaching to a canyon a mile away from the dam site and having a daily capacity of 48,000 cubic yards of excavated material. Operation of these belts required 5,000 horsepower of electric energy.

Bedrock excavation necessary to remove weathered rock and shape the granite floor and abutments in a manner suitable for foundation purposes has required excavation of about 1,000,000 cubic yards of rock over an area of 38 acres. Blasting of bedrock was permitted only with light charges of dynamite in relatively shallow, closely spaced holes, in order to minimize disturbance to sound bedrock uncovered by the removal of weathered rock. The excavated rock was hauled by trucks since the belt conveyers were unsuited to this type of material, and

**(Right). A view of the dam, looking west. High- and low-level construction trestles each have a battery of 5 traveling cranes. The suspension bridge carries a belt conveyer that delivers sand and gravel to a concrete-mixing plant at the west end, and a pipe line that delivers cement to a mixing plant at the east end. A 50,000-barrel cement storage and blending plant may be seen at the upper left, where 60 carloads of cement are unloaded daily and blown by air through pipe lines to the mixing plants. The completed dam will reach the elevation of the highway in the background**



much of it used in riprapping the tailrace and river slopes downstream from the dam. The granite floor of the dam is generally quite level, except for 3 secondary gorges across its floor that reach depths of 100 feet below the general level. The quality of the final foundation rock ranges from good to excellent granite, superior in all cases to the best concrete that can be produced. A curtain of cement grout to seal the contraction and structural joints in the bedrock will be injected in an approximately vertical plane parallel to the axis of the dam and under its upstream portion throughout the full length of the structure to depths as great as 300 feet, and with a thickness at right angles to the axis of about 100 feet.

### Diversion of the River During Excavation

The excavation on both the east and west sides of the river was carried to bedrock elevations as much as 200 feet below the water surface of the river. Two cofferdams were built to enable this excavation. The first of these, constructed during the winter of 1934–35 on the west bank of the river, was a bow-shaped structure, about a half mile long, with a central section parallel to the river channel, and the wings cutting into the silt banks of the stream. This structure employed in its building 17,000 tons of interlocking steel piling, and attained a height of 100 feet, sufficient to safeguard operations for a river rise of 55 feet above the low-water flow of the stream. The second cofferdam was constructed during the fall of 1935 on the east side of the river, and was of a shape similar to the west cofferdam, but employed timber rather than steel piling and was built only to an elevation sufficient to withstand a river rise of 30 feet above low water. This structure was topped by the river as anticipated, and work within the east cofferdam was suspended during a period of 3 months in the summer of 1936. Both the west and east cofferdams were unusually tight and but little pumping because of leakage was necessary, a condition resulting from the adequate designs by the contractor and the generally tight nature of the silt deposits over the old lake bottom.

Following completion of bedrock excavation within the west cofferdam, construction of the dam and west power house was started in the fall of 1935. About 1,500,000 cubic yards of concrete has been placed in this portion of the structure. This section of the dam contains the temporary diversion channels through which to detour the river from its original channel, and was completed to a stage of construction necessary to enable opening of the west cofferdam to the river in November 1936. In the

A view of the dam, looking upstream (south). The Government camp, Coulee Dam, is on the right side of the river; the highway bridge leads to Mason City. The river is shown at about the stage of average flow

meantime, construction had been started on the shore arms of the upstream and downstream main river cofferdams to close the river channel and enable its unwatering for construction purposes. These 2 structures were built of timber cribs rock filled and armored with a single row of interlocking steel piling driven to refusal. The cross-river cofferdams were joined to useful portions of the original west cofferdam, which portions were joined in turn to the upstream and downstream faces of the west section of the dam in such a manner that the diversion channels were west of the junction points. This arrangement exposed the east end of the west section of the dam within the enclosure formed by the main river cofferdams. Completion of these structures and the full diversion of the river through the west section of the dam were accomplished in December 1936. Removal of overburden and foundation-rock excavation had advanced from the east abutment within the area enclosed by the east cofferdam and concreting operations had been started prior to the diversion of the river. When the diversion was accomplished, and the old river channel unwatered, these operations successively advanced across the channel to meet the west section.

### Improved Methods

The successful conduct of construction work on the huge scale demanded by the physical and economic factors at Grand Coulee Dam has naturally resulted in superlative accomplishments. Here during the excavation period, for instance, was the world's largest conveyer system; now there are in operation the largest concrete aggregate preparation plant, the largest concrete mixing plants, and the greatest assembly of concrete placing equipment ever on a single construction job. The acceleration of construction rates has been accompanied by the adoption of improved methods with more consistent and uniform results than heretofore have generally been achieved. An illustration of this is the high quality of the concrete going into the dam. The average compressive strength of 3,214 28-day test cylinders, 6 by 12 inches, taken at the mixing plants from mass concrete for the dam and dry screened to $1^1/_2$-inch maximum aggregate, was 5,545 pounds per square inch, with a very high uniformity factor. Mass concrete contains one barrel of cement per cubic yard. Concrete has been placed at a rate of 15,500 cubic yards per day and it seems probable that this record may be extended to 18,000 cubic yards per day before work is completed under the present contract.

### Control of Slides

Unexpected difficulties have been experienced because of landslides of the lake-bed silt deposits from the granite side walls of the river gorge into the excavation area of the dam and power plants. Two major slides have occurred, one on the west side where about 1,000,000 cubic yards of material moved toward the power house and tailrace sites, and a second on the east side of the gorge, that moved into the forebay and dam excavation. The additional excavation occasioned by these slides amounted to 1,500,000 cubic yards of material and necessitated the construction in the west slide area of a drainage system and a rock barrier at the toe of the slide to a height of 120 feet above the level of bedrock, with a ballast blanket consisting of 225,000 cubic yards of gravel spread on the slopes of the slide above the barrier. A complete cure was necessary to prevent the slide moving into the tailrace and turbine discharge outlets of the power house.

The east slide was directly into the largest depression crossing the granite floor forming the foundation of the dam. Although movement of the slide subsequent to the construction of the dam could do no damage, about 500,000 cubic yards of slide material had to be removed to enable the complete excavation of the depression and the placement of concrete. Considerable additional excavation was avoided by the construction of a temporary barrier across a neck of the depression at a point just outside the upstream limit of the dam, to prevent further movement of the slide during the time required to fill this depression with concrete.

Before this land slide started, a concrete arch about 25 feet high, topped by a timber crib 15 feet high, had been constructed across the neck of the depression. As the slide became active, these structures were buried under the toe of the slide, which at this point was about 100 feet deep above bedrock. The slide was temporarily stabilized by the removal of the surcharge from its fan-shaped upper portion. A refrigeration plant of 80 tons capacity was rented and erected at a nearby site, and pipes through which brine could be circulated were driven into the slide. An earth-ice arch 100 feet long, from 20 to 25 feet thick, and from 42 to 50 feet deep was frozen directly over the concrete arch and timber crib submerged by the slide, and this composite structure of concrete, timber, and ice proved to be an adequate barrier to further movement of the slide and enabled the necessary excavation for the dam to be completed, and subsequent phases of the work to proceed without interruption. The dam was frozen in September 1936 and was abandoned in April 1937.

## Plans for Completion of the Project

Plans and specifications are now being prepared in anticipation of a contract to provide for the completion of the dam and west power plant building, funds to continue with the construction program having been appropriated by Congress. If future appropriations are adequate to continue at the construction rate established for the work now accomplished, the dam could be completed and the initial power-plant installation ready for operation by 1941. Surveys are in progress in the irrigable area to enable the planning of the system of canals and aqueducts necessary to convey Columbia River water to the lands of the Columbia Basin. There is a growing and insistent demand for irrigated land, and it now appears likely that the 50-year period for combined irrigation construction and land settlement originally contemplated for this project may be materially shortened. The lands, when irrigated, will provide from 30,000 to 40,000 new farm homes and an equal number of homes forming urban communities of the project.

# Recent Progress in Insulation Research

By J. B. WHITEHEAD
PAST PRESIDENT AIEE

**Another in a series of annual reports presented by the chairman of National Research Council's committee on electrical insulation, this article summarizes some of the principal advances in research work on gaseous, liquid, and solid dielectrics during the past year. References are included to both fundamental scientific studies and practical research under service conditions.**

RESEARCH in the field of dielectrics and insulation is broadly speaking of 2 general types. The first is that of fundamental scientific character in the fields of chemistry and physics. There is a constant flow of the results of studies of this type in the field of dielectrics, gaseous, liquid, and solid; and as related to their various properties, dielectric constant, electric conductivity, and breakdown. Intense interest attaches to the slow but steady unfolding of the picture of atomic and molecular structures, and of the phenomena associated with the movements therein of electric ions of various character. Unfortunately, however, it is not always possible, by reason of our inability to control the forces and extend the laws so discovered to large-scale conditions, to apply the results of this type of research to the construction and behavior of everyday insulation.

The second type of research is that in which effort is made to develop directly under the conditions of normal service improved materials and methods for insulation. Such efforts watch more or less distantly the progress of fundamental scientific research and are quick to grasp and try out on a practical plane any new discovery or suggestion. Thus, while they often have a cut-and-try character, and in this sometimes suffer criticism in comparison with more fundamental types of research, it nevertheless remains a fact that a large proportion of the advances that have been made in the improvement of electrical insulation have been through researches of this character.

Obviously both types of research are very much the concern of the committee on electrical insulation, of the National Research Council, and this review includes notices of the principal advances during the past year which have come to the writer's attention. It includes reference to a number of researches of the first type in which there is a definite interest as related to the problems of insulation, even though sometimes remote. On the other hand, the review makes no pretense of covering completely the large volume of important research of the first type which has appeared.

## Gases

From the standpoint of insulation, first interest for gases attaches to conductivity and breakdown. Most of the new work during the year has been on breakdown in air. Some of it is purely practical in character, other continues the study of the process leading from initial ionization to self-supporting spark or arc discharge. This problem continues to hold the interest of both physicists and engineers; of the former because of the light thrown on gaseous structure and submolecular behavior; of the latter because of the obvious bearing on the mechanism of the spark and arc and of various types of protective equipment.

The use of the spark gap in its various forms as voltmeter is reviewed by W. M. Thornton.[1] Best methods and empirical formulas are suggested for needle gaps, sphere gaps, plane electrodes, the corona voltmeter, the attracted-disk electrometer, the ellipsoid voltmeter, the capacitance divider, etc. K. Potthoff[2] continues a series of papers developing the relationship between corona loss as measured on laboratory equipment and the losses which occur in overhead lines. Comparative results on the laboratory equipment, consisting of wire and coaxial cylinders, and those observed on 3-phase open lines show fairly good agreement. E. Horst[3] reports an extensive study of the time constant of capacitors. The time constant in general decreases with increasing voltage, and a wide range of values is found for commercial capacitors. This author believes that the residual phase difference in air capacitors is due principally to leakage over the insulating supports rather than to radiation and electrode surface phenomena.

Of more fundamental character are a number of studies on the breakdown of gaps of various lengths and under different conditions. R. Strigel[4] reports (from the Siemens laboratories) studies on the spark lag in a uniform field and in the field between points. From the same laboratories is a study by Von Engel and Steenbeck[5] on the rôle of the positive ions in a gas discharge. All of these papers discuss the mechanism of the setting up of preliminary and then final complete discharge, with particular reference to the influence of the space charges due to the more rapidly moving electrons and the sequence of happenings leading up to the avalanche of electrons. A clear picture is drawn of the growth of the electronic avalanche introducing as new element the electrostatic force

Part of the annual report of the chairman of the committee on electrical insulation, division of engineering and industrial research, National Research Council, presented during the 10th annual meeting at New York, N. Y., November 4–5, 1937.

J. B. WHITEHEAD, professor of electrical engineering and, since 1919, dean of the school of engineering at The Johns Hopkins University, Baltimore, Md., has been a member of the faculty of that university since he was appointed associate professor of electrical engineering in 1904. He received his first degree in engineering from Johns Hopkins in 1893, and subsequently received those of bachelor of arts and doctor of philosophy. Doctor Whitehead was the founder of the Institute's Baltimore Section, and was its chairman for 19 years. A Life Member, he has served on many committees and on the board of directors, and was president during 1933–34. He is now a junior past president and a member of the committees on code of principles of professional conduct, Edison Medal, and Institute policy, and representative on the John Fritz Medal board of award and National Research Council, division of industrial and engineering research. He has been chairman of National Research Council's committee on electrical insulation since 1923.

1. References listed at end of paper.

on the electron caused by space charge, and the setting up of an accelerating force greater than that caused by the external field. The necessity for such additional force is shown by measurements indicating very high ionic mobilities. A. Köhler[6] studies the impulse breakdown at pressures between 100 and 760 millimeters of mercury in uniform fields. He shows that for both alternating and impulse voltages down to 4 milliseconds duration, Paschen's law is confirmed down to 100 millimeters for dry air, but not for air containing moisture. The cathode-ray oscillograms clearly indicate a break in the descending voltage curve after breakdown, which is attributed to the passage from spark to glow discharge. E. Finkelmann[7] studies the breakdown of different gases at high pressures up to 20 atmospheres; in homogeneous fields in gaps up to 2 centimeters, and in coaxial cylinders in gaps up to 4 centimeters. The gases studied are oxygen, carbon dioxide, air, and hydrogen. The departures from Paschen's law already recognized for small gaps are also found for large gaps. They begin at higher voltages, the greater the gap; and for different gap lengths at approximately the same field intensity, the value of the latter varying with the gas. The departures are attributed to space charges and consequent electron emission from the cathode. On account of the smaller increase of breakdown voltage of oxygen, as compared with that of carbon dioxide, the latter is to be preferred as an insulator in high-voltage practice. H. Böcker[8] studies the well-known lowering of breakdown voltage at high frequencies. The commonly accepted cause is that at a certain critical frequency during a reversal of the electrode voltage, positive ions accumulate as space charge. A limitation of the space charge is set by the rate of diffusion. Starting from this condition, the author computes the density of space charge necessary to account for the actual field distortion and derives a formula for the lowering of voltage at higher frequencies. This formula is closely similar to that for the lowering of static continuous voltage as computed by Rogowski and Wallraff.[5a] The decrease of breakdown voltage with frequency above the critical value so computed is in good agreement with the experimental results.

Outstanding contributions in this country to our knowledge of all forms of gaseous discharge are made by L. B. Loeb and co-workers.[9] In an admirable review of the mechanism of static spark discharge Loeb not only reports much work of himself and co-workers, but makes a comparative study of the significance of the results of others. The beginning of any type of discharge at ordinary air pressure is due to the collision of electrons with molecules and the liberation of further electrons, in accordance with Townsend's theory. The presence of electrons is necessary and there is always a sufficient number due to external causes to start matters. This is called by Loeb the primary process of ionization. The resulting current of itself does not usually lead to a spark, but as the applied field is increased the increase in current may become very rapid. An unstable condition results in which the current readjusts itself so as to become self-maintaining, that is, it changes to glow discharge, brush, spark, or arc. In order to reach this self-maintaining condition the ionization current must develop a mechanism by which new electrons are generated in sufficient number; that is, some new or secondary ionization process must arise. Loeb lists at least 5, and including very low pressure, 6 mechanisms of self-maintaining character by which spark discharge can occur. Among these are, in the gas itself, ions and atomic excitation by electron impact, ionization by positive-ion impact in the gas, photoelectric action in the gas, and at the cathode electron bombardment, positive-ion bombardment, photoelectric effects, and the so-called field currents, all leading to increased electron emission. Of special interest is the conclusion that under ordinary conditions ionization in a gas by positive-ion impact, as first suggested by Townsend, does not enter into the sparking equations. The most common secondary influences are the liberation of electrons at the cathode by positive-ion impact, and with photoelectric electron liberation at the cathode and in the gas. An influence of metastable atoms is noted in certain special cases, for example, low-pressure corona; also with sufficient initial ionization high local fields may be caused by space charge, leading directly to spark. The essential conclusion of Loeb's analysis is that there is no single definite secondary process which occurs universally in all discharge phenomena, but that depending on the particular circumstances, usually one or 2 of the secondary influences mentioned predominate to the exclusion of others. Other interesting experimental studies from the same laboratories, some of which are utilized in Loeb's analysis, are those of R. R. Wilson[10] on very short time lag in sparking, that of D. Q. Posin[11] on the Townsend coefficients, that of Cravath and Loeb[12] on the mechanism of the high velocity of the lightning discharge. In connection with the latter, one of the difficulties has been that the leader lightning stroke moves faster than any possible electronic velocity. "Calculations based on justified assumptions concerning the conditions known to exist in a lightning stroke show that if the field just ahead of the tip averages $10^5$ volts per centimeter for about one centimeter, ionization by collision by the electrons already present in the gas before the stroke would be great enough to advance the tip at the observed rate. In this way a propagation of the leader stroke at a velocity many times higher than the velocity of the electrons can be attained."

## Liquids

As is usual, work in this field is very voluminous. Liquids are more readily controlled, purified, and offer more uniform molecular structure than solids, and so offer themselves more readily for fundamental research. Entering as they do into many types of insulation, they also appeal to the research engineer.

To the engineer, the most interesting properties are dielectric strength and conductivity; to the physicist and chemist, dielectric constant is more important for the study of molecular structure. Theories of dielectric strength and breakdown take a wide range. The Schumann-Nikuradse theory of breakdown ties in the current-voltage characteristic in much the manner as now accepted for gases, and sees failure as an internal collision

ionization phenomenon. Koppelmann and Gyemant invoke an electrode layer of high stress due to space charge acting on a layer of adsorbed gas, thus creating gas pockets or filaments leading to gaseous ionization and breakdown. Pure electric breakdown is apparently due to electronic collision ionization and is recognized only in the purest liquids. Thermal breakdown on the other hand, due to the liberation of gases by heating in impure liquids, is also evident in many cases. From the variety of conditions which are suggested in the work supporting these several theories it may be easily seen that the approach to pure electric breakdown occurs only under conditions in which the liquid and electrodes are most carefully purified, conditions which cannot be approached for large scale use. Breakdown in liquids prepared under the best manufacturing conditions is commonly of thermoelectric character, with gas evolution and gas breakdown as the final stage. The following brief notices of recent work in this field for the most part support this view. W. Bahre[13] reports a careful series of observations on the breakdown strength of liquid and solid benzol. The outstanding feature is the extreme elaboration, over a period of months, of methods of purification. Under the final test conditions breakdown strength of the liquid reached the high value of 1,870 kilovolts per centimeter and solid benzol 1,000 kilovolts per centimeter. In each case the peak value of a wave was the determining factor, indicating electric breakdown. The very smallest amounts of added impurities lowered the dielectric strength and increased the influence of the effective rather than the maximum value of voltage, indicating entrance of thermoelectric influence. Careful studies of the influence of drying and degassing supported in general the Koppelmann theory. Working in the same field, R. Bredner[14] studies toluol, chloric benzol, nitrobenzol, and benzol, as regards both dielectric strength and loss. Similar care was exercised for purification and similar evidence adduced that for toluol in this state, breakdown cannot be thermal in character. It is shown to be independent of the rapidity of voltage increase and independent of the pressure. On the other hand, the values for chloric benzol and nitrobenzol were much lower and gave evidence of thermoelectric failure, although breakdown was still independent of pressure. Here then is a case in which thermoelectric failure seems to take place without special reference to gas formation, thus indicating the Nikuradse type of breakdown. A. Walther and O. Tscheljustkino[54] conclude that the characteristic dependence of electric strength on pressure in liquids occurs only when the gas is in emulsified form. Liquids in which the gas is completely dissolved have electric strength independent of pressure.

Of special interest as related to the foregoing are 2 papers by E. Conradi[15,16] on the breakdown behavior of commercial insulating oils. He finds the following behavior: (*a*) As delivered, from 25 to 50 kilovolts per centimeter; (*b*) after filtration, from 75 to 125 kilovolts per centimeter; (*c*) 3 millimeters vacuum, 100 degrees centigrade, 12 hours, from 120 to 150 kilovolts per centimeter; (*d*) special filtration and 3 millimeters vacuum, 100 degrees centigrade, 12 hours, from 160 to 200 kilovolts per centimeter; (*e*) 3 millimeters vacuum, 240 degrees centigrade, and direct distillation, from 200 to 245 kilovolts per centimeter. Rotating a commercial oil in a circular channel between high-voltage electrodes, at a certain velocity dust and fiber particles are swept out and a breakdown stress of 150 kilovolts per centimeter is reached, an increase of upward of $33^1/_3$ per cent, and the spread of test points is reduced to 7 per cent or 8 per cent. Combined with a specially constructed electric filter, this method increased the low breakdown strength of badly deteriorated oil to 150 kilovolts per centimeter. Fibers and dust particles cause breakdown; thermal breakdown pertains to intermediate ranges of purification; and the pure electric breakdown enters only under extreme purification. Further interesting data are presented by F. M. Clark[17] on the properties of noninflammable synthetic insulating oils of the chlorinated diphenyl type. An advantage in favor of the synthetic liquids and insulation treated therewith of at least 20 per cent over corresponding mineral-oil values is claimed.

## Oxidation

Studies of the oxidation process in insulating liquids have also continued. A. Gemant[18] proposes a rapid and simple approximate method for relative oxidation rates, based on the decrease of volume of the gas over the oil in a closed vessel. The claim is that for the better oils the contribution of volatile products of oxidation may be neglected. J. F. Gillies and J. B. Black[19] reach the conclusion that dielectric strength and power factor of transformer oil are not affected in the early stages of oxidation, nor until heavier asphaltine products begin to be formed. Similar conclusion by different methods is reached by J. B. Whitehead and T. B. Jones[20] as reported at the present meeting of this committee. G. M. L. Sommerman[21] reports results of tests on 9 viscous mineral oils of various types and their mixtures with 8 rosins. Interesting correlations between physical and electrical properties, stability in oxidation, with the viscosity index and chemical composition are reported. J. B. Whitehead and F. E. Mauritz,[22] working with a single insulating oil of high quality, have shown important correlations between changes in electrical properties, and those of several oxidation products. P. J. Haringhuizen and D. A. Was[23] report welcome quantitative measurements of the catalytic action of metals on oils. The samples were treated for 1,000 hours at 90 degrees centigrade in the presence of thin layers of copper, lead, and tin. Copper formed the most sludge, lead next, and tin least. In two of the oils contact with tin gave less sludge formation than in a blank specimen, thus suggesting an antioxidizing value. Studies of the acid number indicate that the action of copper is at first the most rapid, but that after a time the acid number becomes constant while that caused by lead finally rises above those of both copper and tin, approaching a constant value of 7. It is suggested that catalytic action in all these cases is limited, due to the accumulation of protective products on the metals. T. Itoh and Y. Hyraki[24] report methods for the recovery of badly deteriorated oils by evacuation and distillation. Claim is made that the

recovered oils were superior to the original oils, and that the volume recovered is better than 93 per cent.

Results by A. Lasarev and J. Raschektaev[25] conclude that the electric conductivity of oils polymerized by oxidation depends only on the mobilities of the ions and on changes in the macroscopic viscosity. The effect of increased temperature is to increase the decomposition of secondary associated complexes. It is stated that the Debye dipole theory adequately accounts for the temperature changes of the dielectric losses of those polymers and oxides examined, and other interesting suggestions are made.

### Gas Generation

The generation and absorption of gas in insulating oils subjected to electric discharge has been studied by Nederbragt,[26] whose results show a wide variation in volume of gas liberated over a range of oils. Of special interest is the reduction of the amount of gas evolved by the addition of selected aromatic compounds. No general formula is proposed, but the author concludes that the volume of gas generated depends on the nature of the most volatile components of the oil, and that in general the gas evolved may be substantially reduced by small percentages of aromatics, more volatile than the oil itself. In these experiments the gasifying agency is merely the layer of ionized gas or vapor over the oil, the field being roughly parallel to the surface of the oil. The nature of the action is not suggested, and should be a promising problem for further study.

### Conduction

Studies of conductivity at high stress in insulating liquids are as follows: In experiments on carefully distilled toluene, E. B. Baker and H. A. Boltz[27] claim to have demonstrated the presence of thermionic emission at ordinary temperatures from cathodes in contact with dielectric liquids. The current-voltage relations found obey, in the upper range of field strength, a law which is interpreted as being a modification of the Schottky law in vacuum. Differences are found amongst curves for adsorbed oxygen and hydrogen on electrodes of several metals and explanations offered on the basis of variations in the work function of the metal. They contrast their results with the commonly accepted view that residual conduction in dielectric liquids is due to ions initially present, formed by some ionizing agent or electrolytic dissociation. An interesting feature of the results is that the slope of the current-voltage curve of the liquid becomes less steep in the upper range. The theory of secondary ionization, as described by Nikuradse, calls for log $I$ increasing directly as the field whereas the Schottky law calls for a log $I$ variation as the (field)$^{1/2}$.

Closely related to the foregoing is the work of K. H. Reiss,[28] on ionization by intense ultraviolet radiation in highly refined liquids. The author concludes that the rise in the current-voltage characteristic of highly refined insulating liquids above the saturation value is not due to ionization by collision, as proposed by Nikuradse, nor to cold thermionic emission, as proposed by Baker and Boltz.[27] The chief experimental evidence against ionization by collision is in the observation of the increase of current over normal saturation and rising current regions, as between the nonirradiated and the irradiated conditions. The increase in conductivity due to the ionization by ultraviolet radiation was found to be constant up to 200 kilovolts per centimeter, that is, well above saturation. In other words, the large increase in the number of ions due to ultraviolet radiation did not cause any increase in the ionization by collision. Cold electron emission was eliminated by experiments with the electrode irradiated by ultraviolet radiation. A very small increase of current was noted at low field strengths, but for increasing voltage the increasing curve merged with the normal curve of the liquid. The increase of conductivity with stress is attributed by the author to the phenomenon discovered by Wien and Schiele of an increase of field strength in weak electrolytes, arising in dissociation at higher voltages. Particular support for this view is found in measurements on the mobilities of the ions which are found to be much lower than those of electrons involved in avalanche and secondary ionization processes. The author concludes that breakdown in insulating liquids at values below 400 kilovolts per centimeter can be caused only by the liberation of gas, thus supporting the Koppelmann view. Ionization phenomena in liquid hydrocarbons are also studied by C. Bialobjeski[29] utilizing X rays. He shows 3 kinds of ions, of which two are positive and the other negative. He makes studies of mobility and coefficients of recombination. Commenting upon Nikuradse's theory of the relation between the current-voltage characteristic of a liquid, and its approach to breakdown, Y. Toriyama and U. Shinohara[30] have measured the impulse breakdown voltage of distilled water and several aqueous solutions. In particular, they point to the case of a solution of $NH_4OH$, in which the breakdown voltage is greater than that for distilled water, although the conductivity of the solution is 7.5 times greater. They claim, therefore, no direct relation between the current-voltage characteristic and breakdown and that the latter is an electronic rather than an ionic conduction phenomenon.

## Solids

Owing to the complexity and wide range of type of conduction processes in solids, and to the difficulty of securing strict uniformity in bulk, research in the field of solids, as directed to their properties as insulators, is still of a broadly general character. Nevertheless much progress has been made, some of it recently, and in certain classes of materials general correlations are to be found between chemical composition, physical properties, and electrical constants and behavior. Thus in the case of the glasses, one of the most baffling groups, certain constituents are now recognized as related to conductivity and dielectric loss. The particular way in which moisture remains in fibrous materials is recognized and certain methods of control have been developed. There has been much study of the molecular polar properties of liquids when passing into the solid state and some grouping of materials as to the polar

variation of dielectric constant and dielectric loss. Studies of synthetic materials have been particularly successful in indicating wide changes in electrical properties associated with well recognized chemical variations. Examples of this are the thermoplastic rosin, poly-styrene, and the chlorinated diphenyl compounds. Similar studies have been made in the ceramic field, notably the steatite and rutile groups, the latter affording, when compounded with suitable binders, the possibility of a very wide range of value of dielectric constant. An excellent survey of some of these relationships has been presented during the year by W. Jackson.[31] In the experimental study of the dielectric strength of various types of solid materials, J. C. Dowell and C. M. Foust[32] present an important assembly of curves and data showing the impulse and 60-cycle breakdown voltages of various gaps, bushings, insulator strings, creepage paths in both liquid and solid materials. The data are presented in 33 sets of curves and 5 tables, and constitute a valuable reference source. An analytical study of the results of many workers on the breakdown of solids is given by S. Whitehead[33] in an effort to determine the figures for the breakdown strength inherent in the materials themselves. He attributed failure in practice (1) to the properties of the ambient medium, (2) to imperfections of macroscopic order in the solid material itself, (3) to the presence of foreign materials, moisture, etc. The present study looks away from these causes and analyzes the results of many workers for a determination of the limiting electric strength as determined by (*a*) thermal instability, (*b*) internal ionization, (*c*) ultimate electric strength. The author concludes that evidences of failure due to internal ionization are not very definite, and that the figures indicated for ultimate or pure electric strength, as studied by Rogowski and Von Hippel, are far above the values of present practice. Thermal breakdown is the most frequent and the values indicated for this by known material constants are also well above those of practice. The author states that there is no reason why, with a closer control of materials, field strengths of from 500 to 1,000 kilovolts per centimeter should not be possible on the basis of thermal instability alone.

Recent studies of conduction, absorption, and dielectric loss are as follows: A. Walther and Lydia Inge[34] have studied the conductivity of rock salt and glass at field strengths up to 2,000 kilovolts per centimeter. The conductivity increases as much as tenfold at high field strengths. From the conductivity-temperature relations, it is concluded that the increase of conductivity with field strength is largely due to an increase in ionic conductivity. Breakdown at room temperatures is shown to be thermal as well as electric. R. W. Sillars[35] attempts a model of Maxwell's complex dielectric, and Wagner's extension thereof, in a model of wax containing water drops. The theory is not supported by the results. Conclusion is reached that a minute amount of impurity in the form of fine needles can produce a serious alternating loss, while the effect of the same volume in spherical form would be negligible. W. A. Yager[36] also contributes in this field an exhaustive analysis of the distribution of relaxation times in complex dielectrics. The work is a careful examination of Wagner's proposal, which the results confirm, together with a somewhat extended explanation as to how the results of experiment can be utilized for determining the statistical distribution of relaxation times. The work tacitly assumes the Maxwell theory as the basis of dielectric absorption. G. A. Albert[37] measured dielectric losses parallel to the laminations of impregnated materials, showing values from 2 to 10 times the losses with field normal to laminations, depending upon the condition of the material. Thiessen, Winkel, and Herrmann[38] and Frei and Groetzinger[39] have studied the volumetric electric charges to be found in the rosin wax mixtures known as electrets. Evidence is presented that these are space charges which may have opposite signs, depending on the value of the stress applied during cooling. Thus not all of the behavior of the electret is due to dipolar orientation and fixation. Data as regards some of the new materials referred to in the first paragraph of this section are presented by M. Hagedorn[40] showing that polystyrol and similar substances can be prepared as foils with thickness from 0.02 millimeters up. Electrical properties vary with the material and proposal is made that these substances may be used in capacitors and cables. Standard Telephones and Cables[41] report new studies of the control of moisture in cellulose papers and fibers by esterification. Results on impregnated paper indicate acetic-acid values up to 30 per cent as about the limit to which this process can be extended without serious lowering of necessary physical properties of the paper.

A valuable paper is reported by C. Schmelzer[42] on the absolute measurement of dielectric losses at very high frequencies ($3 \times 10^7$) with the capacitor-thermometer. The loss is measured as the heat liberated in a small cylindrical capacitor (maximum length, 0.5 centimeter) in a glass cell. An accuracy within 5 per cent is claimed. W. J. Shutt and H. Rogan[43] made a critical experimental investigation of the oscillation or "force" method of determining the dielectric constant of slightly conducting liquids. With the improved method described, results are reported indicating an accuracy of $\pm 0.2$ per cent for solutions of electrolytes having conductivities less than 0.005 mhos. J. A. Weh[44] describes methods of measuring the thermal conductivity of sheet materials, with a maximum inaccuracy of $\pm 10$ per cent. W. D. Buckingham[45] describes an experimental method for determining the equivalent resistance and capacitance network for an absorptive capacitor, at different frequencies and voltages. The method consists of an a-c bridge with the absorptive capacitor in one arm and an air capacitor in the opposite arm. To this capacitor are added series or shunt resistances adjusted by experiment to give complete balance. Balance is determined by complete disappearance of current as indicated by amplifier and cathode ray oscillograph. Value of the method is claimed in the construction of phantom circuits and in the operation of long communication cables. H. A. Thomas[46] presents an extensive study of the causes of relatively small variations in the capacitance of capacitors with solids and with air as dielectric. Special methods for the accurate measurement of capaci-

tance are given, and methods proposed for controlling variations due to temperature.

## High-Voltage Cables

The causes of instability and deterioration continue to occupy chief attention. In recent years we appear to have passed through a series of fashions in our ideas of the principal causes of cable deterioration. We have noted as chief suspect in successive periods, high inherent power factor and loss, gaseous ionization due to temperature cycles, wax formation, and oxidation. At the moment we appear to be leaving the oxidation period and reverting to that of gaseous ionization, through new methods for studying free gas spaces in the cable.

Physical structure and dielectric loss of impregnated paper, as related to the amount of contained air and under changes of voltage, temperature, frequency, and pressure, are reported in an analytical and speculative study by P. Junius.[47] The conclusions are that the shape of the power factor-voltage curves at different temperatures changes very little in a dielectric containing large amounts of air. On the other hand, the shape of these curves varies noticeably in well-impregnated cable. In the latter case the change of power factor due to temperature change may be much steeper than that for a cable containing air. An overpressure of one atmosphere is sufficient to cause a flat loss curve in a cable which contains much air. Thus comparison between the loss curves of a pressure cable and an ordinary cable not under pressure, should not be used as a basis of the relative excellence of the 2 cables. Since gas in a dielectric may be either above, at, or below atmospheric pressure, power-factor variation with pressure and temperature are better criteria than the variation with voltage. J. Lawton[48] presents a good review and analytical study of all American research on wax formation, and also a clear classification of oils as regards correlation between chemical structure and gas evolution. The properties of the 2 broad divisions of petroleum oil, the aliphatics and the carbocyclics, are well described, and the differences between polymerization and condensation, and the relation of these to molecular structure under ionic bombardment pointed out. Two papers from French sources have appeared on the leakage of oil from oil-filled cables in service, one by P. Capdeville,[49] and the other by M. R. Laroche.[50] These methods depend on differences in pressure caused by the leaks. They are very sensitive to temperature and pressure changes. Measuring apparatus and connections are described, a few test results are given, and a maximum inaccuracy of 3 per cent is claimed. P. Dunsheath[51] describes manufacturing equipment for the continuous extrusion of lead cable sheaths.

Of most recent interest is the work of K. S. Wyatt[52] and associates on the mechanical uniformity of cable insulaton. A new method is described for the examination of the cross section of the cable. Oil is extracted from a short length, which is then impregnated with styrene and then heated so as to solidify the latter. It is stated that in this condition an undistorted wafer, as thin as 5 mils can be cut from the cable. As the styrene is highly translucent, the wafer so prepared, when viewed against a light, affords a remarkably clear picture of the laminated structure of the cable, accentuating sharply all regions of separation or voids between layers, conductors, and sheath. In somewhat similar manner longitudinal sections may also be prepared. Complete publication of the results of these interesting studies are not yet available, but we are fortunate in having a paper on the subject from Mr. Wyatt at the annual meeting of this committee this year.

**Downstream face of the Tennessee Valley Authority's Wheeler Dam, the $37,000,000 project named after General Joseph Wheeler and dedicated formally September 10, 1937, on the 101st anniversary of the general's birth, although actually completed early in the year. The dam is some 15 miles upstream from the "war baby" Wilson Dam at Muscle Shoals (which has been deeded to the TVA by the government) and is intended to extend Tennessee River navigation some 74 miles upstream to the Guntersville Dam which is now under construction. This view shows the power house in the immediate foreground with the 2 45,000-horsepower outdoor-type generating units just beyond. Above at the right is the frame of the movable gantry crane, while across the river the outlines of the navigation lock and the high arched bridge over it may be seen. The dam is 72 feet high and 6,502 feet long, with a reservoir area of 67,100 acres**

# Sources of Engineering Income, 1929–34

**Dealing with the annual incomes of engineers engaged in both engineering and nontechnical work, this sixth article[1] of a series reporting a survey of engineering employment conducted by the United States Bureau of Labor Statistics presents data, derived from reports of 52,589 engineers, tending to show that engineers engaged in technical work reach their maximum earning capacity later than those in nonengineering endeavors.**

IN 1929 there was greater spread in the earnings of engineers engaged in nonengineering work than in those obtained from engineering work. Thus, among engineers 40 to 47 years of age, 10 per cent of those engaged in nonengineering earned more than $12,424 and 10 per cent earned less than $2,420 per year. The respective annual incomes of similar proportions of all those engaged in engineering work were $9,615 and $2,705; and of graduates in engineering $10,088 and $2,936.

The age of maximum earning power for engineers arrives more quickly for nonengineering than for engineering work. At 48 to 55 years of age, however, those college graduates who stayed in engineering were doing as well as those who had gone into nonengineering work. This was true even at the highest income levels.

Despite the fact that in 1929 the tendency was for average annual incomes of engineers engaged in nonengineering to exceed slightly those from engineering work, the opportunities in the former field did not embrace more than 7 per cent of the total in any one age classification.

Over the period 1929–34 the relationship changed between the jobs engineers took in engineering and nonengineering work. On the whole it appears that in 1929 nonengineering work was an alternative to engineering work, but from 1929 to 1934 many nonengineering jobs were accepted as an alternative to unemployment or work relief.

The extent to which earning opportunities from nonengineering work depreciated between 1929 and 1934 differs at the various age levels. The average earnings of 2 groups in nonengineering who were 28 to 40 years in 1929 declined by almost one-third from 1929 to 1934. As between the groups that were over 48 years in 1929 the average income of the 1934 group is only one-half the average of the 1929 group. Similarly at each of the other income levels a greater fall is found in the average income of older men in nonengineering.

Those who were able to stay in engineering fared better. Furthermore the changes which occurred in the earnings from engineering work, as reported by all engineers and by graduates only, were consistently uniform.

The relative changes as between nonengineering earnings and those for engineering work of engineers, with advancing age and experience, are also found to be the same for men with comparable periods of experience.

It was among those newcomers who were trying to force their way into the profession that the greatest fall in income occurred. Thus average earnings in engineering in 1934, 2 years after graduation, were 37 per cent less than in 1929. The earnings of those who had been out of college 10 years were 31 per cent lower in 1934 than in 1929. At higher ages all groups averaged a decrease of 26 per cent.

In 1934 almost one-tenth of the engineers were unemployed or on work relief at the end of the year. The low level of earnings of this group during 1934 contributed to lowering the average earnings of all engineers. Thus of those engineers who were unemployed at the end of 1934 the average earnings for the preceding 12 months of those who were less than 28 years of age ranged from $700 to $950. Engineers of 40 to 50 years averaged $1,350. Only about 10 per cent of the unemployed, even though they were in those ages at which engineering earnings reached a peak, had made as much as $2,000 in the preceding 12 months. Ten per cent made less than $300 a year.

## Scope and Method

The earned annual-income data used in the preceding analysis were those reported for personal services of all classes of engineers, irrespective of whether or not they were engaged primarily in engineering or nonengineering work. They related, in other words, to the incomes of engineers, not to the incomes of men engaged in engineering. Consideration is here given to the annual incomes, classified by age, as related to the professional engineers' employment status.

While income was reported for the year, the type of employment was reported only as of December 31, 1929, 1932, and 1934. Consequently it has been necessary to assume that the kind of engineering or nonengineering employment engaged in at the end of the year was the source of the income for that year. This assumption makes possible valid general comparisons of the earnings of engineers in these 2 types of employment. But in that section dealing with the annual incomes of engineers who were unemployed, or who were employed on relief projects at the end of the year, it must not be assumed that they reflect the source of income. They are merely the incomes which had accrued during the year to those who were unemployed at the end of the year.

Before presenting the annual incomes from all kinds of engineering work and nonengineering work attention is di-

1. An article prepared by Andrew Fraser, Jr., of the Division of Hours, Wages, and Working Conditions, Bureau of Labor Statistics, United States Department of Labor, which article was published in the September 1937 issue of *Monthly Labor Review*. Articles reporting other phases of this survey were published in ELECTRICAL ENGINEERING as follows: "Professional Aspects of Engineering Education," August 1936, pages 863–7; "Unemployment in the Engineering Profession," February 1937, pages 216–23; "Employment in the Engineering Profession," May 1937, pages 524–31; "Security of Engineering Employment," June 1937, pages 655–61; "Engineering Income and Earnings," September 1937, pages 1089–1104. A detailed report of the survey will be published later in bulletin form by the Bureau of Labor Statistics.

rected to the following: It must be noted that the requirements of editing the questionnaires caused the selection of a relatively large proportion of the engineers engaged in nonengineering work in 1929 who had college degrees in engineering. Thus, elsewhere it has been shown that the general movement from 1929 to 1934 was out of engineering work either into unemployment or into work not in the engineering field. Consequently, a substantial number of those who were in pursuits other than engineering in 1929 would also have so reported in 1932 and 1934. Such returns from nonengineering graduates and "other" engineers were, in general, discarded. Therefore, the tabulations for nonengineering work in 1929 tend to be those of graduate engineers. On the other hand, a number of nongraduates who were practicing their profession in 1929 passed into nonengineering employment in 1932 and 1934. The schedules for such engineers were retained. Clearly the situation which prevailed in 1929 was less true in 1932 and 1934. Hence it is as well to compare the earnings for nonengineering both with the earnings of graduates and with those of all persons reporting who were engaged in engineering. These data are presented in table I.

Caution should be exercised in comparing earnings with various types of employment in 1929, 1932, and 1934. The earnings of all engineers in engineering work reflect best the changes in what was being paid for engineering services. Both sets of figures of engineering earnings do reflect changes in the rates for given kinds and qualities of work. This is not true of the earnings from nonengineering; they indicate merely what individual engineers were able to earn in miscellaneous employments called "nonengineering." Conceivably such persons might all have been managers of industrial establishments in 1929 and gasoline-station attendants in 1932. Obviously a decrease in earnings from nonengineering employment would not

[1] Includes postgraduates, nonengineering graduates, and first-degree engineering graduates who were professionally active prior to 1930.
[2] Less than one per cent.

then measure the fall in earnings of industrial managers. Actually the changes reflect the composite effect of a lowering of pay for various types of nonengineering work and a lowering of the quality of nonengineering work that was accepted as an alternative to unemployment.

Finally, among those reported at the end of the year as engaged in both engineering and nonengineering, there were some who suffered unemployment during part of the year. Inasmuch as unemployment was far more common in 1932 and 1934 than in 1929, this accounts for part of the decreases in annual incomes previously noted for both engineering and nonengineering. As regards engineering, rate change alone will be more fully analyzed later when monthly earnings from engineering employment are presented.[2]

## Incomes From Engineering and Nonengineering Work

The first significant point of comparison between the incomes in 1929 of engineers engaged in engineering and those in nonengineering work is that the earnings of the latter showed greater dispersion. Thus, among engineers 40 to 47 years of age, 10 per cent of those engaged in nonengineering earned more than $12,424 and 10 per cent earned less than $2,420 per year. The respective annual incomes for similar proportions of all those in engineering work were $9,815 and $2,705; and of graduates in engineering $10,088 and $2,936. It seems apparent from these figures and others for 1929, that on the one hand many engineers were attracted out of engineering jobs by favorable opportunities, whereas, on the other hand, an almost equally large proportion dropped out of engineering work and were forced to find alternative employment.

2. In the present article it must be borne in mind that the influence of unemployment in decreasing annual income was probably somewhat more important among those who reported nonengineering work as the source of income. It has been stated that the major direction of flow was from engineering work into nonengineering work. While some such transfers were made without an intervening period of unemployment, there must have been unemployment for many who lost an engineering job and went into nonengineering work after failure to find work of an engineering nature.

This point appears to be substantiated by a consideration of the variation in the relationship between engineering and nonengineering earnings in moving from the lowest to the highest of the 5 income levels.

Only at the lowest 10-per-cent income group or level did engineering incomes exceed those from nonengineering work at all ages for which comparison can be made. At the middle levels the engineering incomes were greater than nonengineering by only 10 per cent at 25 and 27 years of age, and by only 5 per cent at age 30. From this point the more rapid advance in average nonengineering earnings to a maximum at age 44 brought about an equalization of the incomes near to age 34 at a value of $3,700 per year. They again equalized at 54 years. That is, between 44 and 54 years, while the average returns from nonengineering had declined from $5,346 to $4,900, those from engineering had advanced from $4,562 to $4,900. The advance in the latter continued to age 60, attaining a value of $4,979 per year, as against $4,400 for nonengineering at the same age. At the upper 10- and 25-per-cent income groups or levels engineering work ceased to have an advantage over nonengineering near age 26. Thereafter the latter diverged upward from the former to reach a maximum of $12,495 at age 52 at the highest level, and of $8,106 at age 44 in the case of the next lowest level. The corresponding values of engineering earnings were $11,709 and $6,407 per annum. The steady advance in engineering earnings, together with the declines in nonengineering earnings, brought about an equalization of incomes at age 58.

A second point of significance is that in 1929 engineering work as such ultimately offered rewards as high as engineers were able to find in nonengineering. This arose primarily from the fact that the age of maximum earning power for engineers arrived more quickly for nonengineering than for engineering work. For at 48 to 55 years of age those college graduates who stayed in engineering were doing proportionately as well as those who had gone into nonengineering. This was true even at the highest income levels. The earnings of the upper 10 per cent of

## Table III. Comparison of 5 Levels of Annual Earnings, for Corresponding Years After Graduation, in 1929, 1932, and 1934

[1] Between 50 and 100 engineers reported. [2] Between 10 and 50 engineers reported. [3] Less than one per cent.

the college graduates continued to advance from $10,088 at age 44 to $13,516 at 60. The average at these ages rose from $4,876 to $5,590, whereas the average from nonengineering fell from $5,346 to $4,400 between these ages.

From the preceding analysis, therefore, it appears that in 1929 the tendency was for average annual incomes of engineers who engaged in nonengineering work to exceed slightly those from engineering work. Notwithstanding, it should be noted that the opportunities outside the engineering field did not embrace more than 7 per cent of the total reporting in any one age classification. Furthermore, since there is no knowledge of the basis of selection, it cannot be said that nonengineering earnings would have been greater or less for the engineer had he stayed in engineering work. The only justifiable assumption is that in 1929 there was a preference to remain in engineering by those in the 2 lower income groups or levels and a definite tendency to accept attractive openings in nonengineering work at the 2 higher income levels. The turning point in this movement occurred near to the middle levels of income reported.

## Changes in Income, 1929 to 1934

In an earlier article the changes from 1929 to 1934 in the incomes of all engineers were analyzed on an age basis. The decreases noted were due partly to salary reductions

[1] Less than 10 persons reported. [2] Between 10 and 50 persons reported. [3] Between 50 and 100 persons reported.

on given jobs. They were also due to the fact that incomes were reduced by extended periods of unemployment and by the necessity for accepting poorer jobs. That article described what happened between 1929 and 1934 on the average, for example, to engineers 40 to 47 years of age.

From the data presented in table I it is now possible to trace more precisely the influence of these several factors on the incomes of engineers. The first point to be noted is that the relationship changed between the jobs that engineers took in engineering and nonengineering work. In 1929 the essential elements of the story are to be found in the similarities of earnings in the 2 fields, rather than in the differences. On the whole it appears that nonengineering work was an alternative to engineering work. But from 1929 to 1934 many nonengineering jobs were accepted as an alternative to unemployment or work relief. Thus, the average earnings of those who were 40 to 47 years of age in 1929 and were in nonengineering work were $5,346. In 1934 a larger number of men from this age class were in nonengineering, and the average of this larger group was $3,040, a decline of 43 per cent. By way of contrast the average annual income of graduates in engineering work of from 40 to 47 years of age was $4,876 in 1929. A smaller number still in engineering in 1934 averaged $3,788, a decrease of only 23 per cent.

The extent to which earning opportunities from nonengineering work depreciated between 1929 and 1934 differed at the various age levels. The average earnings of 2 groups in nonengineering whose ages were 28 to 40 in 1929 declined by almost one-third from 1929 to 1934. As between the groups of those who were over 48 in 1929, the average income of the 1934 group was only half the average of the 1929 group. Similarly at each of the other income levels there was a greater fall in the average income of older men in nonengineering.

Those who were able to stay in engineering fared better. As illustrating this point, table II is presented, covering graduates of advancing age and experience, who were engaged in engineering work. A similar table based on the data in table I might be presented for all engineers. Essentially, however, the changes which occurred in the earnings from engineering work, as reported by all engineers and by graduates only, were consistently uniform.

In the period from 1929 to 1934 the average earnings of graduates in engineering who were 60 years old in 1929 declined 23 per cent. There was a smaller decrease for the middle-aged groups, and among those averaging 30 years of age in 1929 the decline amounted to 13 per cent. For the youngest groups shown in the table—those who were 25 in 1929 and 30 in 1934—the 5 years of added experience resulted in an actual increase in the average earnings of those who remained in engineering in 1934, as against the average for the larger numbers in the profession in 1929. The nature and extent of these changes in the averages of graduate earnings from engineering work were closely paralleled by those which occurred at the 2 upper income groups or levels. The increase in average earnings that was noted at 25 and 30 years did not occur for this age group at the 2 lower levels of income for the period 1929

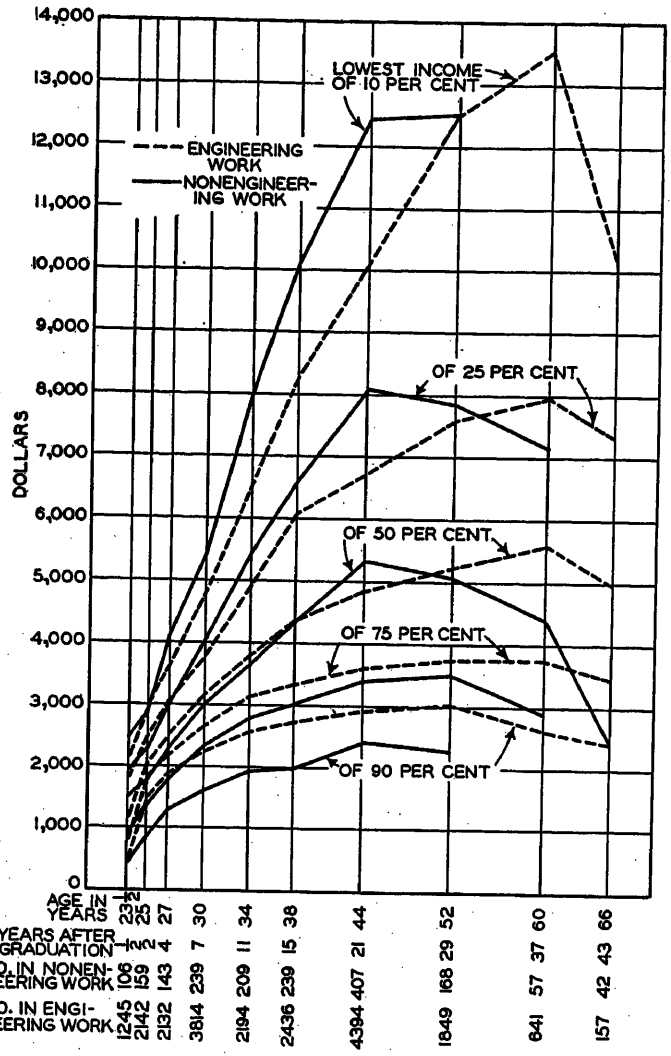

**Figure 1. Earned annual income of professional engineers in engineering and nonengineering work by age in 1929**

Primarily income reported by graduate engineers in either full- or part-time employment

to 1934. Furthermore, the declines in earnings for the lowest 10 per cent in each of the 3 older groups were greater than the average.

The relative changes as between nonengineering earnings and those for engineering work of engineers with advancing age and experience are also found to be the same for men with comparable periods of experience (table III).

As far as the comparison of nonengineering and engineering earnings is concerned, this table merely reenforces the evidence already advanced as to the severe fall of income that occurred when engineers were forced out of the profession. However, the table sets forth more clearly than table II the picture of the fall of earnings from engineering. It was among those newcomers who were trying to force their way into the profession that the greatest fall of income occurred. Thus, average earnings in engineering in 1934, 2 years after graduation, were 37 per cent less than in 1929. The earnings of those who had been out of college 10 years were 31 per cent lower in 1934 than in 1929. At higher ages all groups averaged a decrease of 26 per cent. A similar movement occurred in the level of earnings of the upper and lower 25 per cent of those in engineering, but at the level of the upper 10 per cent the declines were greater for the older engineers.

## Income of Unemployed Engineers

In 1934 almost one-tenth of the reporting engineers were unemployed or on work relief at the end of the year. The low level of earnings of this group during 1934 contributed to lowering the average earnings of all engineers.

The distribution of the earnings of this group has significance only as indicating the income which a group, unemployed in December 1934, had earned in the preceding 12 months. Some were probably men who had had a few months' work at a good rate, and a long period of unemployment. Others may have worked quite steadily at a low rate and become recently unemployed. All were unemployed at the end of the year. They could look back on average earnings for the preceding 12 months of $700 to $950 if they were less than age 28, while those of 40 to 50 had averaged $1,350. Only about 10 per cent of the unemployed, even though they were in those ages at which engineering earnings reach a peak, had made as much as $2,000 in the preceding 12 months. Ten per cent had made less than $300 a year.

**Correction.** In the previous article of this series, September issue, page 1092, sentence beginning in line 11, right-hand column should read: "Some 479 reported incomes less than $800 per year, while 295 earned more than $19,000 per year.

# Steel Structures Identified Magnetically

A PAPER "Steel Structures Identified and Flaws Located by Means of Balancing Wave Tests" was presented by Carl Kinsley (A'97, F'35, member for life), consulting engineer, New York, N. Y., at the annual meeting of the American Society for Testing Materials held in New York, N. Y., June 28–July 2, 1937. The fundamental assumption of the method is that magnetic hysteresis loops uniquely characterize any ferromagnetic material with respect to its structure and physical condition. The magnetic "finger print" is standardized and recorded by using a simple sine wave of magnetizing force which produces a cyclical magnetic flux in the material which, in turn, causes a complex induced electromotive force in a secondary testing circuit. This is quantitatively analyzed by the testing apparatus into its equivalent Fourier series of harmonic terms which are then recorded as the complete characterization of the material.

It has not been found possible to make any change in the material without having a corresponding change in one or more of the constants of its characteristic series of terms. No different combination of analysis, metallurgical structure, or physical condition has been found that would produce a duplicate of the characteristic equation of the specimen.

The correctness of the fundamental assumption was questioned in the discussion at the meeting, and the author indicated that it had been verified in every case examined throughout the whole range of laboratory investigations.

# The Cause and Elimination of Noise in Small Motors

By W. R. APPLEMAN
MEMBER AIEE

## Common Causes of Noise

MUCH OF the noise present in electrical motors is due to poor manufacture. Careless or inaccurate manufacturing methods often show up in some manner as uneven air gaps, loose bearings, brush noise, or loose rotor bars.

It is beyond the scope of this article to discuss either the various production problems or special noise insulating mountings. We shall rather confine ourselves to a discussion of the electrical design features as the selection of the proper slot combinations, winding distribution, and skew.

## Slot Combinations

The number of stator slots is usually fairly well set, or at least the selection is limited because of the number of poles and phases. We shall confine ourselves, therefore, to the proper selection of the number of rotor bars after the number of stator slots is decided upon.

An interesting example of the method used by one electrical manufacturer with an excellent reputation shows what work can be saved. About 17 different type rotors all using different numbers of bars were made up. The 3 or 4 quietest were selected and the head of the department chose the quietest one as the standard. A couple of years later one rotor was calculated which would decrease the harmonics. This rotor was quieter than the rotor selected after 17 attempts. I realized then that elimination of noise was not just the lucky finding of a good *combination* after many trials, but calculations were worthwhile. Had 3 or 4 quiet rotors been calculated and the best one selected much money and time would have been saved and better results secured. This same company received a number of complaints concerning a noisy 4-pole motor with a 17-bar rotor. As soon as the motors were used a short time by critical customers they were returned because of noisy bearings. Actually the bearing fits were still close and the noise was caused by a magnetic force.

If 2 fields exist which differ by 2 poles a rotor vibration will be set up. The unbalanced pull will be proportional to the product of the magnitude of the 2 fields. This noise will increase with the load because the magnitude of both fields increases with the load. This vibration will sound very much like a loose bearing condition. If 2 fields exist which differ by 4 poles a rotating elliptical field will be set up. A heavy or rigid yoke section will prevent this. Polarity differences of more than 4 poles will seldom cause any trouble. In fact 2 fields differing by 4 poles seldom give rise to very much noise. Our next step then is to list the harmonics present, determine whether there are some with fields with a 2-pole difference and if so, eliminate them. The harmonics caused by the slot openings have $2(P/2 \text{ plus } m)$ and $2(P/2 \text{ minus } m)$ poles. These must be figured for the following values of $m$:

$m$ = number stator slots. (These particular harmonics will show up in the winding calculations and cannot be eliminated or even altered by the winding distribution)

$m$ = number rotor slots

$m$ = difference between number of stator and rotor slots

$P$ = number of poles

In the example cited with a 24-slot stator and 17- and 26-bar rotors for 4 poles we have:

| | |
|---|---|
| 24 slots (stator) | $2(2 + 24) = 52$ poles |
| | $2(2 - 24) = -44$ poles |
| 17 slots (rotor) | $2(2 + 17) = 38$ poles |
| | $2(2 - 17) = -30$ poles |
| 7 slots (difference) | $22(2 + 7) = 18$ poles |
| | $2(2 - 7) = -10$ poles |
| 26 slots (rotor) | $2(2 + 26) = 56$ poles |
| | $2(2 - 26) = -48$ poles |
| 2 slots (difference) | $2(2 + 2) = 8$ poles |
| | $2(2 - 2) = 0$ poles |

Next the field harmonics set up by the stator winding were calculated from the formula $N = \pm (2\phi g \pm 1)$, in which

$N$ = order of the harmonic
$\phi$ = number of phases
$g$ = any positive integer

It will be noted from the formula that all odd harmonics can be present on single phase and all odd except thirds and multiples of thirds on 3 phase. The number of poles present in the harmonic field is equal to the order of the harmonic multiplied by the number of poles of the fundamental.

The number of poles of the stator field harmonics present are therefore as shown in table I.

The strength of these fields and the direction of rotation

**Table I**

| N (Harmonics) | Number Poles |
|---|---|
| 1 | 4 |
| 3 | 12 |
| 5 | 20 |

| 10 slots | 22 | 24 | 26 | 28 |
| | −18 | −16 | −14 | −12 |

## Table III

| N | Number Poles | Number Poles | Number Poles | Number Poles |
|---|---|---|---|---|
| 1 | 2 | 4 | 6 | 8 |
| 3 | 6 | 12 | 18 | 24 |
| 5 | 10 | 20 | 30 | 40 |
| 7 | 14 | 28 | 42 | 56 |
| 9 | 18 | 36 | 54 | 72 |
| 11 | 22 | 44 | 66 | 88 |
| 13 | 26 | 52 | 78 | 104 |
| 15 | 30 | 60 | 90 | 120 |
| 17 | 34 | 68 | 102 | 136 |
| 19 | 38 | 76 | 114 | 152 |
| 31 | 62 | | | |
| 33 | 66 | | | |
| 35 | 70 | | | |
| 37 | 74 | | | |

can be calculated as shown in another chapter of this paper.

Note then that the 17-slot rotor has 30 poles and the field 28 (seventh harmonic), also that the 17-slot rotor has 38 poles and the field 36 (ninth harmonic). Note again that the 7-slot difference has 10 poles and the field 12 (third harmonic), also 18 poles and the field 20 (fifth harmonic).

If, however, we use a 26-slot rotor which we did try, and adopt as standard there is a 4-pole difference and at no point a 2-pole difference. The increased quietness due to the use of a larger number of rotor bars, elimination of the 2-pole harmonic difference, and proper skew showed a marked decrease in noise, not only under load but also with no load.

Another motor with 33 rotor bars worked satisfactorily on 6 poles, but was not very quiet on 4 poles. Let us analyze the motor from the standpoint of harmonic fields with a 2-pole difference for the various numbers of fundamental poles. Also check a 34-bar rotor with the 24-slot stator. The results are shown in table II.

The number of poles of the stator field harmonics present are therefore as shown in table III.

From these tables we gather this information:

1. To avoid a difference of 2 poles between the harmonic fields it is necessary to use a rotor with an even number of rotor slots for 2- and 4-pole motors.

2. The 33-slot rotor is very good for a 6-pole motor having a difference of 6 poles between all the harmonic fields.

3. The 34-bar rotor is satisfactory for 6 poles having a minimum difference of 4 poles.

4. The 33-slot is not good for 8 poles as a 2-pole difference exists.

5. The 34-slot is satisfactory for 8 poles as it has a minimum difference of 4 poles.

Probably the most commonly used stator punching is one in approximately a 6-inch diameter with 36 slots. A very satisfactory rotor for this stator is one with 44 slots. This can be readily checked by the method just illustrated. A further check will eliminate such rotors as 39- or 41-bar for general purpose work.

It is very evident from the preceding work that it would be of great help to have 2 sets of tables for rapid checking of rotors. One of these tables consists of the number of poles present caused by stator field harmonics. Since all odd harmonics are present this will be the order of each odd harmonic multiplied by the number of poles of the fundamental. The other table is for the harmonics caused by slot openings and the difference existing due to slot openings.

More recent investigation and articles have added still more to our fund of knowledge on the selection of the number of rotor bars which will let us design our motor still quieter and eliminate some that we would still retain if we tried all those without a 2-pole difference.

Kron states: "Vibration and noise are liable to be present as follows:

1. When the slots differ by one or by the number of poles plus or minus one, transverse vibration and noise may occur.

## Table IV. Pitch Fractions

| 0.0667 | 1/15 | XIII |
| 0.0556 | 1/18 | XIV |

2. When the slots differ by half the number of poles, torsional vibration and noise may occur.

3. When the slots differ by the number of poles, torsional vibration and noise may occur and also rumbling noise unaccompanied by critical vibrations.

"The chance that the noise occurs in the working range is greater with smaller number of poles, higher speed, and with small transverse or torsional critical speeds. When these noises do occur the motor is practically useless."

The reader has probably already noticed by rule 2 torsional vibration and noise may occur in our example of the 24-slot stator and 26-bar rotor. Probably partly due to the relatively heavy yoke section this did not occur. Had we, however, avoided 26 and 28 slots because of rules 2 and 3 and avoided 30- and 32-slot because of fear of locking in points on starting we would probably have tried a 34-bar rotor. Actual experience with another firm has showed us that a 24-slot stator and a 34-bar rotor makes a quiet 4-pole motor. All combinations falling under rule 1 have a 2-pole difference, and should therefore be avoided for a double reason.

| − 2.728 | 2.728 |

It is advisable for the designer to also bear rules 2 and 3 in mind as the discussion so far would not eliminate some undesirable combinations. For a 2-pole design rule 2 would again eliminate rotors which would cause a 2-pole difference.

A general statement, subject to all the limitations of a general statement follows:

Any rotor with a number of rotor slots divisible by the number of pairs of poles of the fundamental and which differs from the number of stator slots by more than the number of poles will probably be a quiet rotor.

This does not apply to 2-pole motors as the above rule will give a motor with a difference between the number of harmonic poles equal to the number of poles of the fundamental. This rule does not cover all possibilities as it does not include rotors that would have a 4-pole difference on a 6- or 8-pole motor or a 6-pole difference on an 8-pole motor, etc. It might also be mentioned before leaving the subject that small slot openings will give rise to less violent flux disturbance than large slot openings. Rotors with closed slots should be machined accurately to keep the same thickness of steel outside the various bars. Care must also be taken in the selection of the number of rotor slots to prevent locking in at starting.

## Winding Distribution for Sinusoidal Wave Form

In our section on the selection of the number of rotor bars we showed how to calculate which harmonics could be present in the field. There are 2 ways to reduce the strength of the harmonics and consequently reduce the noise. One is to design the stator punching with heavy teeth at the center of the pole and lighter teeth toward the outside of the pole, and the other is to distribute the winding to decrease the harmonic. The former method is patented and each punching is applicable to but one given number of poles. It is well for each manufacturing company to have on hand a set of tables showing the harmonic strength for the various fractions of the pole pitch based on 100 turns. A discussion of how these may be calculated will be explained later. I am including with this thesis blue prints of the table I use. Often, the designer has little interest in knowing the strength of the various harmonics provided he has his winding distributed in the best way. The author has worked out 2 simple methods for calculating this which as far as he knows are original.

| 33 | 3.84 | − 1.929 | − 1.929 | − 3.84 | − 3.84 | − 1.929 |

### Method *A*

Let us assume a 36-slot stator to be wound 4 poles or 9 slots per pole. We want to make all the harmonics small or in other words approach a sine wave.

If the stator pole were wound with a single coil the wave form would be a rectangle. If more than one coil per pole were used the wave form would be a series of rectangles above each other, giving a resultant wave with a number of steps. Figures 1 and 2 illustrate this. As the number of slots per pole and the number of coils per pole are increased the shape of the wave will approach that of a sine wave. Since in actual practice neither is infinity nor any where near it, it is necessary that we allot the proper number of turns to each coil to make the wave as nearly a sine wave as possible. The following method of calculation is not empirical but theoretically sound. Figure 4 is the layout for a winding over 2, 4, 6, and 8 teeth for 9 slots per pole and figure 3 is its flux wave. The point of zero flux is at the center of the teeth between adjacent poles. There will be 180/9 equals 20 electrical degrees between adjacent teeth. The ordinates of the sine wave at the various teeth are as follows:

sine 20 degrees = 0.342 at teeth *B*
sine 40 degrees = 0.643 at teeth *D*
sine 60 degrees = 0.866 at teeth *F*
sine 80 degrees = 0.985 at teeth *H*

Since the wave will actually have a flat top and the maximum flux will be in teeth *B* let us call this point 100 per cent. The percentage of flux in the various teeth which is also the percentage of the total turns in all coils which surround these teeth is as follows:

tooth *B:* 0.342/0.985 = 0.347
tooth *D:* 0.643/0.985 = 0.653
tooth *F:* 0.866/0.985 = 0.879
tooth *H:* 0.985/0.985 = 1.000

Since all the flux in teeth *B* is caused by the coils in slots *A* then 0.347 of the total turns per pole lie in slots *A*. The flux in teeth *D* is caused by the coils in both slots *A* and *C*. The turns in slots *C* must therefore be 0.653 minus 0.347

## Table XI

10 Slots Per Pole

| Pitch | 9/10 0.9 | 8/10 0.8 | 7/10 0.7 | 6/10 0.6 | 4/10 0.4 | 3/10 0.3 | 2/10 0.2 | 1/10 0.1 |
|---|---|---|---|---|---|---|---|---|
| $m$ = 1 | 125.76 | 121.1 | 113.45 | 103.00 | 74.84 | 57.8 | 39.346 | 19.916 |
| 3 | 37.82 | 24.95 | 6.64 | −13.11 | −40.37 | −41.92 | −34.34 | −19.27 |
| 5 | 18.01 | 0.00 | −18.01 | −25.47 | 0.00 | 18.01 | 25.47 | 18.01 |
| 7 | 8.258 | −10.69 | −17.97 | −5.62 | 17.3 | 2.845 | −14.71 | −16.21 |
| 9 | 2.213 | −13.46 | −6.422 | 11.445 | −8.316 | −12.61 | 4.372 | 13.974 |
| 11 | −1.8105 | −11.01 | 5.254 | 9.363 | −6.804 | 10.31 | 8.577 | −11.43 |
| 13 | −4.446 | −5.757 | 9.674 | −3.027 | 9.316 | −1.532 | −7.922 | 8.728 |
| 15 | −6.002 | 0.00 | 6.002 | −8.488 | 0.00 | −6.002 | 8.488 | −6.002 |
| 17 | −6.674 | 4.403 | −1.171 | 2.314 | −7.124 | 7.399 | −6.06 | 3.4 |
| 19 | −6.62 | 6.374 | −5.972 | 5.422 | 3.939 | −3.042 | 2.071 | −1.048 |
| 21 | −5.99 | 5.767 | −5.402 | 4.905 | 3.564 | −2.752 | 1.874 | −0.948 |
| 23 | −4.933 | 3.254 | −0.866 | 1.711 | −5.266 | 5.468 | −4.479 | 2.513 |
| 25 | −3.601 | 0.00 | 3.601 | −5.093 | 0.00 | −3.601 | 5.093 | −3.601 |
| 27 | −2.141 | −2.772 | 4.658 | −1.452 | 4.486 | −0.7377 | −3.815 | 4.202 |
| 29 | −0.6868 | −4.176 | 1.993 | 3.552 | −2.58 | 3.912 | 1.357 | −4.337 |
| 31 | 0.6426 | −3.907 | −1.865 | 3.323 | −2.415 | −3.66 | 1.27 | 4.058 |
| 33 | 1.752 | −2.268 | −3.811 | −1.192 | 3.67 | 0.6036 | −3.121 | −3.438 |

equals 0.306 of the turns per pole. The turns in slots $E$ will be 0.879 minus 0.653 equals 0.226 and in slots $G$ will be 1.00 minus 0.879 equals 0.121. This method is fundamentally sound and I recommend it to anyone interested in an exact derivation. It too is quite simple involving only 3 steps namely:

1. Looking up the sine values of the angles.
2. Correcting to a percentage basis using the maximum sine value of the particular wave as 100 per cent.
3. Subtracting from each value the value listed directly above it.

There is another type of distribution which includes the use of a full-pitch coil. We know that in practice we cannot get 2 full coils in this slot so it will be interesting to see what we should have for nearly sinusoidal wave form. We shall again use 9 slots per pole with the winding distributed over 3, 5, 7, and 9 teeth as shown in figures $E$ and $F$.

sine 10 degrees = 0.174 = 18.5 per cent.
sine 30 degrees = 0.500 = 53.2 per cent.
sine 50 degrees = 0.766 = 81.5 per cent.
sine 70 degrees = 0.940 = 100.0 per cent.

Percentage of turns over 3 teeth = 18.5 per cent
Percentage of turns over 5 teeth = 53.2 per cent
Percentage of turns over 5 teeth = 53.2 per cent
−18.5 per cent = 28.3 per cent
Percentage of turns over 7 teeth = 81.5 per cent
−53.2 per cent = 34.7 per cent
Percentage of turns over 9 teeth = 100.0 per cent
−81.5 per cent = 18.5 per cent

100.0 per cent

### Method B

Another method of calculating the percentage of turns in each coil and which involves no subtraction is still simpler. The ratio of the number of teeth spanned by the particular coil to the total number of teeth per pole is first calculated. The sine of this fraction times 90 degrees is calculated for each coil and the sum of these sines considered to be 100 per cent. The various sines expressed as a percentage of the sum of the sines is the percentage of the total number of turns per pole in the individual coil. Assume again the 36-slot stator with the winding over 2, 4, 6, and 8 teeth.

sine 2/9 × 90 degrees = sine 20 degrees = 0.342/2 teeth.
sine 4/9 × 90 degrees = sine 40 degrees = 0.643/4 teeth.
sine 6/9 × 90 degrees = sine 60 degrees = 0.866/6 teeth.
sine 8/9 × 90 degrees = sine 80 degrees = 0.985/8 teeth.

Total turns per pole equals 100 per cent = 2.836

The percentage of the total turns per pole allotted to the particular coil is then in direct proportion to the ratio of the sine of that particular angle to the sum of the sines of the angles. This expressed in percentage of the total turns per pole is:

Over 2 teeth = 0.121 or 0.342/2.836
Over 4 teeth = 0.227 or 0.643/2.836
Over 6 teeth = 0.306 or 0.866/2.836
Over 8 teeth = 0.346 or 0.985/2.836

1.000 = 100 per cent
